ABOUT THE EDITOR-IN-CHIEF

V.S. Ramachandran, MD, PhD., is Director of the Center for Brain and Cognition and professor with the Psychology Department and the Neurosciences Program at the University of California, San Diego, and Adjunct Professor of Biology at the Salk Institute. Ramachandran trained as a physician and obtained an MD from Stanley Medical College and subsequently a PhD from Trinity College at the University of Cambridge, where he was elected a Senior Rouse Ball Scholar. Ramachandran's early research was on visual perception, but he is best known for his work in neurology.

He has received many honors and awards, including a fellowship from All Souls College, Oxford, an honorary doctorate from Connecticut College, a gold medal from the Australian National University, the Ariens Kappers Medal from the Royal Netherlands Academy of Sciences for landmark contributions in neuroscience, and the presidential lecture award from the American Academy of Neurology. He is also a fellow of the Neurosciences Institute in La Jolla and a fellow of the Institute for Advanced Studies in Behavioral Sciences at Stanford. He was invited by the BBC to give the Reith Lectures on 'The Emerging Mind' in 2003 and is the first physician/experimental psychologist to be given this honor since the series was begun by Bertrand Russell in 1949 – these lectures were subsequently published as *A Brief Tour of Human Consciousness: From Impostor Poodles to Purple Numbers*.

In 1995, he gave the Decade of the Brain Lecture at the 25th annual (silver jubilee) meeting of the Society for Neuroscience and more recently, the inaugural keynote lecture at the Decade of the Brain conference held by NIMH at the Library of Congress and a public lecture at the Getty Museum in Los Angeles. He also gave the first Hans Lucas Teuber lecture at MIT, the D.O. Hebb lecture at McGill, the Rudel–Moses lecture at Columbia, the Dorcas Cumming (inaugural keynote) lecture at Cold Spring Harbor, the Raymond Adams neurology grand rounds at Massachusetts General Hospital, Harvard, and the Jonas Salk memorial lecture, Salk Institute.

Ramachandran is a trustee for the San Diego Museum of Art and has lectured widely on art, visual perception, and the brain. Ramachandran has published over 120 papers in scientific journals (including three invited review articles in *Scientific American*), coauthor (with Sandra Blakeslee) of *Phantoms in the Brain* that has been translated into eight languages and formed the basis for a two-part series on Channel Four TV in the UK and a one-hour PBS special in the United States. His work is featured frequently in the major news media including BBC and PBS. *Newsweek* magazine recently named him a member of 'The Century Club,' one of the "hundred most prominent people to watch in the next century."

ABOUT THE EDITORIAL ADVISORY BOARD

David M. Buss received his BA from the University of Texas at Austin and his PhD from the University of California at Berkeley. He served in professorial positions at Harvard University, the University of Michigan, and the University of Texas, where he is currently professor of psychology. David Buss received the American Psychological Association (APA) Distinguished Scientific Award for Early Career Contribution to Psychology, the APA G. Stanley Hall Award, and the APA Distinguished Scientist Lecturer Award. The University of Texas awarded Buss the President's Associates Teaching Excellence Award. He served as President of the Human Behavior and Evolution Society (HBES). He is currently Head of the Individual Differences and Evolutionary Psychology Area of the Psychology Department at the University of Texas at Austin.

Buss's books include *The Evolution of Desire: Strategies of Human Mating* (Basic Books; translated into 11 languages); *Evolutionary Psychology: The New Science of the Mind* (Allyn & Bacon); *The Dangerous Passion: Why Jealousy is as Necessary as Love and Sex* (Free Press; translated into 13 languages); *The Murderer Next Door: Why the Mind is Designed to Kill* (Penguin; translated into 12 languages); *The Handbook of Evolutionary Psychology* (Wiley), for which he served as editor; *Why Women Have Sex* (Holt; co-authored with Cindy Meston; translated into 16 languages); and *The Evolution of Personality and Individual Differences* (Oxford University Press). Buss has more than 250 scientific publications to his credit.

Buss has extensive cross-cultural research collaborations and lectures widely within the United States and abroad. His primary research interests include the psychology of sex differences, human sexuality, mating strategies, conflict between the sexes, why people kill, warfare, terrorism, stalking, and the psychology of prestige, status, and reputation.

Richard B. Buxton received his BS (1976) and PhD (1981) degrees in physics from the Massachusetts Institute of Technology, followed by a postdoc in biomedical imaging (PET and MRI) at the Massachusetts General Hospital. He has been on the faculty of the Department of Radiology at the University of California, San Diego, since 1990. Buxton's primary research is in functional magnetic resonance imaging (fMRI), focused on understanding the connections between neural activity, blood flow, and energy metabolism in the human brain. His experimental work combines arterial spin labeling (ASL) methods with blood oxygenation–level dependent (BOLD) methods to estimate changes in brain oxygen metabolism in response to a stimulus or a drug. His more theoretical work involves mathematical modeling of the imaging methods, the BOLD effect, and oxygen transport from blood to tissue. Buxton is based at the Center for fMRI and served as the center's founding Director (2000–2007). He has written a textbook on fMRI, now in its second edition, published by Cambridge University Press (2009).

Nicholas Christenfeld received a bachelor's degree in psychology and social relations from Harvard, and a doctorate in social psychology from Columbia, and joined the faculty at the University of California – San Diego and has remained there for two decades. His research program comprises multiple, changing, only partly overlapping areas. He has addressed such topics as why some people say 'um' so often, whether babies look like their mothers or their fathers, how we choose which box of cereal to buy, why a baseball season is ten times as long as a football season, which parts of the month carry the greatest risk of untimely death, whether the support of a woman is better for one's blood pressure than that of a man, what sort of music might be useful in stress reduction, whether some initials extend and some shorten the lives of their bearers, if people who live in, or even just visit, New York City are at risk of heart attacks, and whether story spoilers do spoil stories. Currently, Christenfeld is also exploring the role of forgiveness in poststress cardiovascular recovery, the impact of crying on hormones, and the nature of a sense of humor. An overarching theme, if one exists, might be the empirical exploration of the everyday phenomena of the world.

Orrin Devinsky is professor of neurology, neurosurgery, and psychiatry at New York University (NYU). He directs the NYU Epilepsy Center and St. Barnabas Institute of Neurology. His research on epilepsy includes phenomic-genomic relations, sudden unexpected death in epilepsy, surgical therapies, new medicines and devices, quality of life, cognition and behavior, and neuroinflammation. His research on behavioral neurology includes hyperfamiliarity, delusions, autonomic nervous function, and anterior cingulate cortex functions. He founded the organization Finding A Cure for Epilepsy and Seizures and cofounded epilepsy.com and the Epilepsy Therapy Project. He serves on the boards of these organizations and has served on the board of the American Epilepsy Society and Epilepsy Foundation. His other interests include the history of neuropsychiatry, evolution, anthropology, and animal intelligence.

Albert M. Galaburda is a cognitive neurologist and neuroscientist, specializing in developmental cognitive disorders in adults and children. He received his medical degree from Boston University in 1971, trained in neurology at Harvard Medical School from 1973 to 1976, and began his research on dyslexia in 1979, when with neuropathologist Thomas Kemper, he reported for the first time minor cortical malformations in the brain of an adult dyslexic who had died in an accident. Following that original report, he published several other cases with similar malformations and launched a research program modeling these malformations in rodent models, which continues to this date.

He uses RNAi and transgenic technologies in his present research to induce cortical malformations in rat and mouse brains, which in turn are tested anatomically, molecularly, and behaviorally in collaboration with Glenn Rosen, Joseph LoTurco, and Holly Fitch, respectively. This latest research has shown that manipulation of dyslexia candidate gene homolog's 1 rodent embryos results in molecular interference with neuronal migration, cell autonomous and noncell autonomous effects on cortical development that mimic the changes seen in dyslexic brains, and behavioral changes affecting auditory perception. *Ex vivo* imaging of the brains of genetically manipulated animals discloses changes in cortical circuits affecting corticocortical and corticothalamic relationships.

Galaburda is presently the Emily Fisher Landau Professor of Neurology at Harvard Medical School, and Head of the Cognitive Neurology Unit at Beth Israel Deaconess Medical Center in Boston. He has published more than 150 scholarly articles on various topics of cognitive anatomy, cognitive

neurology, and dyslexia, as well as several books on related topics. Galaburda has received the Pattison Prize in Neuroscience, the Neuronal Plasticity Prize from the IPSEN Foundation of France, Scientist of the Year from the Association for Children with Learning Disabilities (now, Learning Disorders Association), and has been elected to membership in the American Neurological Association. He has delivered the Rita Rudel Memorial Lecture, the Norman Geschwind Memorial Lecture, the Sylvio Conte Decade of the Brain Symposium Lecture, and the Curt von Euler Memorial Lecture, among others. His research is funded by the Eunice Kennedy Shriver National Institute of Child Health & Human Development. His teaching is funded by the National Institute of Neurological Disorders and Stroke.

William Hirstein is Professor and Chair of the Philosophy Department at Elmhurst College, Elmhurst, IL, USA. He received his PhD from the University of California, Davis, in 1994. He is the author of several books, including *On the Churchlands* (Wadsworth Publishing, 2004), *Brain Fiction: Self-Deception and the Riddle of Confabulation* (MIT Press, 2005), and *Mindmelding: Consciousness, Neuroscience, and the Mind's Privacy* (Oxford University Press, 2012). His other interests include autism, sociopathy, brain laterality, sense of self, and the misidentification syndromes.

William G. Iacono is Regents Professor of Psychology, Psychiatry, Law, and Neuroscience; Distinguished McKnight University Professor; Adjunct Professor of Child Development; and Codirector of the Minnesota Center for Twin & Family Research at the University of Minnesota.

He studies the development of common mental disorders, focusing on the genetic liability for substance abuse and antisocial behavior. He is past president of the Society for Psychophysiological Research (SPR). He has also received the Distinguished Contributions to Psychophysiology Award from SPR for his lifetime contributions to this field. In addition, he has been awarded the Distinguished Scientist Award from the Society for a Science of Clinical Psychology. His research is funded by grants from the National Institute of Mental Health, National Institute on Drug Abuse, and National Institute on Alcoholism and Alcohol Abuse. He currently holds a National Institute of Health MERIT (Method to Extend Research in Time) Award for his research achievement. He has published over 350 scientific articles.

John T. Jost is Professor of Psychology at New York University. His research, which addresses stereotyping, prejudice, political ideology, and system justification theory, has appeared in top scientific journals and received national and international media attention. He has published over 90 articles and chapters and coedited four books: *The Psychology of Legitimacy* (2001), *Perspectivism in Social Psychology* (2004), *Political Psychology: Key Readings* (2004), and *Social and Psychological Bases of Ideology and System Justification* (2011). Jost has received numerous honors, including the Gordon Allport Intergroup Relations Prize (three times), Erik Erikson Award for Early Career Research Achievement in Political Psychology, International Society for Self and Identity Early Career Award, Society for Personality and Social Psychology Theoretical Innovation Prize, Society of Experimental Social Psychology Career Trajectory Award, and the Morton Deutsch Award for Distinguished Scholarly and Practical Contributions to Social Justice.

Jerome Kagan is Emeritus Professor of Psychology at Harvard University. His research over the past 57 years has centered on the cognitive and emotional development of infants and children. During the last 30 years, he and his colleagues have concentrated on the temperamental biases called high and low reactivity in infants. He is a fellow of the American Academy of Arts and Sciences and a member of the Institute of Medicine in the National Academy of Sciences. He has received distinguished scientist awards from the American Psychological Association, the Society for Research in Child Development, and the Child-Mind Institute. Kagan received his PhD from Yale University in 1954 and taught at the Ohio State University and Antioch College before joining the Harvard faculty in 1964.

Leif Edward Ottesen Kennair, PhD, is Head of Department at the Department of Psychology, Norwegian University of Science and Technology, Trondheim, Norway. He graduated as a clinical psychologist from the University of Bergen, 1999, and is a specialist of clinical adult psychology (Norwegian Psychology Association), and a qualified cognitive therapist and supervisor of cognitive-behavioral therapy (Norwegian Cognitive Therapy Association). He has worked as a clinical psychologist/chief psychologist at the Nordfjord Psychiatric Centre and as a researcher at St. Olav's Hospital, Trondheim. His research interests span from mainstream clinical psychology efficacy research (generalized anxiety disorder, OCD) to evolutionary psychology (evolutionary psychopathology, the evolutionary psychology of war, mate choice and sexual behavior). Kennair's PhD thesis was on the topic of evolutionary clinical psychology. He has written an introduction to evolutionary psychology, which has been published in Norwegian and Danish. He lectures on evolutionary psychology, behavioral genetics, and personality psychology and is a much-used lecturer for training psychologists and psychiatrists on topics such as cognitive-behavior therapy and treatment of anxiety and OCD.

David E. Presti is a neurobiologist and cognitive scientist at the University of California in Berkeley, where he has taught in the Department of Molecular and Cell Biology for more than 20 years. For more than a decade (1990–2000) he also worked in the treatment of addiction and of posttraumatic stress disorder (PTSD) at the Department of Veterans Affairs Medical Center in San Francisco. His areas of expertise include the chemistry of the human nervous system, the effects of drugs on the brain and the mind, the treatment of addiction, and the scientific study of the mind and the consciousness. He has doctorates in molecular biology and biophysics from the California Institute of Technology and in clinical psychology from the University of Oregon. Since 2004, he has also been teaching neuroscience to Tibetan monks in India in a program initiated by the Dalai Lama. His primary research interest is the relation between mentality, consciousness, and brain physiology, the so-called mind-body problem.

REVIEWERS

We would like to thank the following for their valuable assistance in peer-reviewing the articles within the Encyclopedia of Human Behavior:

HOW TO USE THE ENCYCLOPEDIA

The *Encyclopedia of Human Behavior* is intended for use by students, research professionals, and interested others. Articles have been chosen to reflect major disciplines in the study of human behavior, common topics of research by professionals in this domain, and areas of public interest and concern. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

Articles in the encyclopedia are arranged alphabetically by subject. Complete tables of contents appear in all volumes. The index is located in Volume 3. Because the reader's topic of interest may be listed under a broader article title, we encourage use of the index for access to a subject area, rather than use of the table of contents alone.

Each article contains a glossary, cross-references, and a further reading list. The outline allows a quick scan of the major ideas discussed within each article. The glossary contains terms that may be unfamiliar to the reader, with each term defined *in the context of its*

use in that article. Thus, a term may appear in the glossary of another article defined in a slightly different manner, or with a subtle nuance specific to that article. For clarity, we have allowed these differences to remain so that terms are defined relative to the context of each article.

Each article has been cross-referenced to other related articles in the encyclopedia. Cross-references will always appear at the end of an article. Where multiple cross-references apply to an article, the cross-references will be listed alphabetically. We encourage readers to use the cross-references to locate other articles in the encyclopedia that will provide more detailed information about a particular subject.

The further reading section lists recent secondary sources to aid the reader in locating more detailed or technical information. Review and research articles that are considered to be of primary importance to the understanding of a given subject area are also listed. The further reading lists are not intended to provide a full reference listing of all the material covered in the context of a given article, but are provided as guides.

PREFACE

The social scientists have a long way to go to catch up, but they may be up to the most important scientific business of all, if and when they finally get to the right questions. Our behavior toward each other is the strangest, most unpredictable, and almost entirely unaccountable of all the phenomena with which we are obliged to live.

Lewis Thomas

Psychology, the study of the human mind, has made many rapid strides during the past four decades. There is now, more than ever before, a real need for a standard reference work covering all aspects of human behavior. The *Encyclopedia of Human Behavior* is the most up-to-date and comprehensive collection of reviews currently available. The essays will be of interest not only to clinical and experimental psychologists but also to students in fields such as psychiatry, neuroscience, philosophy, cognitive science, and medicine. Indeed, given the enormous range of topics covered, no one interested in human nature can fail to find something of interest in each volume. The format of the volumes lends itself just as readily to casual perusal as it does to serious inquiry.

My colleagues and I are often asked questions such as: What is the superego? What is repression? How reliable is eyewitness testimony? How much sleep do we need? What do we know of the psychology of laughter, language, cruelty, or politics? Or of love, cunning, and deceit? We have all experienced the frustration of not being able to answer such questions or find the answers quickly without recourse to extensive library research. This encyclopedia should prove to be an invaluable resource in such situations. Also, students of psychology and related health professions will find this collection of articles useful as a starting point when they embark on new research projects dealing with specific aspects of human behavior.

The study of human behavior is an enterprise that covers an enormous variety of subjects, ranging from the minutiae of neurophysiology to such familiar but poorly understood topics as Freudian psychology. Psychology is a science that is still very much in its infancy even though it has had a very long history, almost as long as that of physics and biology. Anyone interested in the history of ideas should be puzzled by the differences between advances in biology and advances in psychology. The progress in biology has been characterized by a number of landmark discoveries, each of which resulted in a breakthrough in understanding, for example, the discoveries of cells, Mendel's laws of heredity, chromosomes, mutations, and most recently DNA and the genetic code. Psychology, however, has until recently been characterized by an embarrassingly long sequence of 'theories,' each of which was really nothing more than a passing fad that rarely outlived the person who proposed it. I have always found this contrast to be quite remarkable and can think of no simple explanation for it other than the fact that human behavior is inherently more complex, quixotic, and difficult to fathom. Fortunately, the picture has changed radically over the past four decades, particularly in psychiatry and cognitive neuroscience. There are two reasons for this change: First, there has been a growing dissatisfaction with metaphorical explanations (Peter Medawar calls explanations of this kind "analgesics," for "they dull the ache of incomprehension without removing the cause") and a healthy trend toward replacing them with more mechanistic explanations. Second, progress has been aided by the advent of several new technological innovations for studying the structure and function of the human brain. This encyclopedia covers as many of these recent advances as possible within a three-volume set.

My own experience is mainly in neuropsychology, medicine, and visual science, and I am therefore indebted to the editorial advisory board, as they selected the authors in other areas and saw each essay through the long process of peer review, revisions, and copy-editing. Most of the entries are by acknowledged experts in the field.

Given the nature and scope of this enterprise, some degree of overlap among the essays was not only inevitable but also desirable since our goal was to ensure that each article was a self-contained summary of one specific aspect of human behavior. Given the space limitations, each author was encouraged to provide an overview and convey the general flavor of an area of research rather than attempt an exhaustive review. The result is a very stimulating and informative collection of essays.

I have no doubt that this work will prove useful to specialists. If it also succeeds in kindling a spark of interest in some aspect of human behavior among undergraduate and graduate students, then our efforts will have been amply rewarded, for no enterprise is more important to the future of our species than an understanding of human nature in all its diverse manifestations.

V S Ramachandran

Glossary

Big-fish-little-pond effect This effect refers to the fact that the evaluation of students' performance differs depending on the average achievement of the class. The same achievement will be perceived as better and will get a better grade when the average achievement of the class is low and will get a poorer grade when the average achievement is high. This effect is observed in teacher grades and makes it difficult to compare grades from different classes or schools.

Carrier variable A carrier variable is a factor that is just an indicator or proxy for other, more specific variables.

A typical example for a carrier variable is age, which is not in itself the cause of certain developmental events but encompasses psychological and biological processes that co-occur with age. Another example for a carrier variable is socioeconomic status which does not per se influence something else but is an indicator of education, intelligence, educational aspirations, and the like.

Organisation for Economic Co-Operation and Development (OECD)

OECD is a union of 30 countries around the world who are committed to democracy and the

market economy. The OECD provides their members with opportunities to compare policy experiences, seek answers to common problems, identify good practice, and coordinate domestic and international policies. Among other activities, the OECD collects data about educational systems and outcomes and commissions international comparative studies of scholastic achievement.

Socioeconomic status (SES) SES of a person or family indicates their possession of economic and social capital or resources. Most frequently SES is assessed by occupation, education, or income or a combination of all.

Standard deviation The standard deviation is a statistical parameter that characterizes the variability within a population or sample. It is the average difference of scores from the mean of the distribution. Together with the arithmetic mean, the standard deviation describes the distribution of scores. A small standard deviation indicates that the majority of scores scatter closely around the arithmetic mean whereas a large standard deviation indicates that the scores spread out widely.

Academic achievement is the general term for performance outcomes in intellectual domains taught at school, college, and university. By confining the definition to intellectual domains, fields such as music and sport are excluded for which certain motor abilities are more important than intellectual abilities. Academic achievement indicates the level of intellectual education of a person, a group, or a whole nation.

This article begins with pointing out the importance of academic achievement for individuals, societies, and as a field of psychological research. After this, it looks at different indicators for and the measurement of academic achievement. An important question refers to the prerequisites or predictors of academic achievement. Because of their special significance for academic attainment, this article focuses on individual characteristics, specifically intelligence, motivation, and personality. Finally, we deal with the issue of equal opportunities in education with regard to gender and socioeconomic status (SES).

Importance of Academic Achievement

The importance of academic achievement can be viewed from different perspectives. Here, we distinguish an individual and a societal perspective as well as the perspective of psychological and educational research.

On an individual level, academic achievement is the most important predictor of vocational careers and, therefore, individual socioeconomic prosperity. This is true because school grades and scholastic achievement tests are used as selection

criteria for jobs and higher education. The strength of the association between academic achievement and indicators of life success is moderate ($r = 0.40\text{--}0.50$). In undeveloped societies that do not use such selection criteria or have no formal education the association between education and individual life success is much weaker or nonexistent. Higher academic achievement opens choices as to what university and course of study one enrolls in and, later, what job one pursues, where, and with whom. These greater numbers of choices make it more likely that a person finds working conditions that fit his/her needs and contribute to personal well-being. At the same time, a higher level of education comes along with increased aspirations and expectations, so that higher academic achievement is not necessarily associated with higher life satisfaction.

On a societal level, the same is true as on an individual level: academic achievement is the most important prerequisite for societal prosperity. The more educated a society is, the higher the chances for a positive socioeconomical development. Because of this established association, the OECD (Organisation for Economic Co-Operation and Development) initiated worldwide comparative studies on scholastic achievement and provides their members with information to monitor their educational systems. National administrations use the results of international scholastic achievement studies to analyze strengths and weaknesses of their educational systems. These large-scale studies have led to an empirical turn in educational policy. Politicians in many countries ground their decisions on data from school achievement studies.

The high individual and societal importance makes academic achievement one of the most investigated issues in psychological and educational research. With the aim of finding ways to foster academic achievement, research tries to identify central prerequisites of learning. On the side of the individual learner, research focuses on characteristics such as intelligence, motivation, and personality. On the environmental side, research investigates how characteristics of the learning conditions to which the learner is exposed (e.g., teaching practices, media use) and characteristics of the overall educational system (e.g., early, late, or no separation into educational tracks) influence academic performance. Besides fostering learning and performance, one further aim of research on academic achievement is to close gaps between groups of learners and, thus, contribute to equal opportunities and a fairer educational system. Much research is done on the issue of the gender gap in education as well as on the gap between learners from different socioeconomic backgrounds.

Taken together, academic achievement is the most important prerequisite for personal and societal prosperity. Moreover, education empowers people to participate in and shape their cultures and societies which is vital for democracy. Therefore, it is an important issue of psychological and educational research to look for the prerequisites of education and ways to improve them. The overall aim is to maximize each learner's academic achievement according to their potentials. Interventions may either focus on individual prerequisites or on characteristics of the learning environment and educational system.

Indicators of Academic Achievement

Academic achievement can be measured in two different ways. On the one hand, there are grades and educational degrees. On the other hand, academic achievement can be measured by standardized achievement tests. Although both types of measurement capture mostly the same underlying characteristic, that is, educational achievement, they are not completely equivalent. It is important to understand the difference in what grades and standardized achievement tests measure because findings of empirical studies vary depending on the indicator of academic achievement.

Grades

Academic achievement in schools and higher education institutions is typically evaluated and quantified by grades. The grade point average (GPA) is the arithmetic mean of all grades that have been received during a certain time. Grades are ecologically valid measures of academic achievement because allocation and selection decisions for higher education and job positions are, to a large extent, based on grades. This makes grades a very important issue for psychological research.

The following box illustrates the functions of grades. As can be seen, grades are supposed to fulfill many different functions. Some of these functions demand that grades measure students' performance as accurately as possible (the functions of feedback, information, and allocation). Other functions might be fulfilled better if grades diverge slightly but

systematically from the actual performance level. For example, when teachers want to reward an increase in performance and motivate students, grades will not reflect the exact performance but will be slightly better. To evaluate the quality of grades, all different functions need to be taken into account. An overall judgment whether grades fulfill their functions also depends on the weight that is given to each function. A person who emphasizes the motivation function of grades will evaluate the quality of grades differently from a person who puts emphasis on the allocation function. This example illustrates that the question of how good grades fulfill their functions cannot be answered by empirical studies alone but that the answer depends on ideological points of view.

Functions of Grades

1. Give students feedback
 - Information about strengths and weaknesses
 - Familiarize with performance evaluations
2. Motivate students
 - Good grades are incentives to continue the good work
 - Poor grades are incentives to improve
3. Discipline students
 - Lack of discipline is reflected by poor grades
 - Some grades specifically evaluate learning behavior
4. Inform third parties
 - Parents, employees, and others get information about students' performance
5. Allocate, select, and legitimize
 - Grades are criteria for the allocation of desired resources (e.g., university admission, scholarships, jobs)

Much research has been devoted to the question of whether teachers' grades actually measure students' performance. The most convincing evidence for the validity of grades is their strong association with standardized achievement tests. Typically this correlation is between $r=0.60$ and 0.70 . Another strong evidence for the validity of grades is that they are the best predictors of future success in academic domains. For example, high school GPA is the best known predictor of college GPA. This is true although across classes and schools different grading standards are used. A major problem of grades is that they depend on the average achievement level of the class. When teachers evaluate students' performance, they use a standard that is adapted to the overall achievement level of the class. The same student will receive better grades in a low performing class and poorer grades in a high achieving class. This phenomenon is also known as a frame-of-reference effect, specifically the big-fish-little-pond effect.

Despite this known distortion of grades due to teachers' different grading standards, school grades are often found to outperform standardized achievement tests in the prediction of future success. This can be explained by the fact the GPA is a highly aggregated measure of performance collected from different teachers, over different subjects, and over a relatively long period of time. Many different single measures of student performance make the GPA very reliable. The fact that grades capture not only pure intellectual capacity but also motivational and personality aspects is not necessarily a disadvantage but contributes to the predictive validity of the GPA for future achievements.

Educational degrees

Educational degrees are another type of indicator of academic achievement. Educational degrees depend directly on the grades accumulated over the educational career. They are the most important prerequisite for admission to higher education and job positions. The first attempt to collect international data about educational outcomes was to compare graduation rates and educational degrees among nations. Because of the differences in the educational systems, such comparisons did not turn out to be very meaningful. Today, educational outcomes among nations are compared by means of standardized achievement tests. Nevertheless, graduation rates and educational degrees are also monitored by international studies on educational achievement because they are important ecologically valid indicators of educational outcomes. For example, the annual study *Education at a Glance*, commissioned by the OECD, reports international comparisons of indicators of the quality of education, such as who participates in education, what is spent on it, and how many students graduate in basic and higher education.

Standardized Achievement Tests

Standardized academic achievement tests measure abilities that are acquired in educational institutions or are important for future success in academic and other domains. Standardized achievement tests vary with regard to the degree to which they are curriculum based. A test that is meant to assess knowledge and skills that have been acquired at school has to be curriculum based, that is, include contents taught at school (e.g., SAT II Subject Tests). Other achievement tests are not curriculum based but assess whether certain competencies have been acquired at a certain age and whether certain criteria are met, that is, certain tasks are mastered. A well-known example of a standardized achievement test that is not curriculum-based is the SAT I Reasoning Test (formerly Scholastic Aptitude Test and Scholastic Assessment Test). The SAT I is designed to measure students' general ability or aptitude for learning. Many colleges in the United States of America base their admission decisions on SAT scores in combination with grades. Because there are wide differences between secondary schools in the United States, tests like the SAT are needed to compare applicants against a common standard.

Different from grades, the only function that standardized achievement tests have is to measure students' achievement as purely as possible. This means that other factors that influence teachers when grading students' performance, such as how much effort a student invested, or whether there is a positive trend that is worth rewarding, must not influence the results of an achievement test. Therefore, standardized achievement tests are a purer measure of achievement compared to grades.

Other examples of standardized achievement tests are the measurements within international large-scale studies of educational achievement (see following box). Typically these studies assess domain-specific abilities, which means that they have to be curriculum based to some extent. Nevertheless, the extent to which international large-scale assessments of scholastic achievement rely on the curriculum depends on the domain in question. In domains in which knowledge is especially dependent on school-based learning, such as in mathematics

and science, the tests are more strongly curriculum based. In other domains, such as languages, learning is relatively more influenced by experiences outside of the school, so that tests for reading comprehension need not be valid according to school curriculum to assess students' reading competencies.

International Large-Scale Assessments of School Achievement

Since the 1950, the OECD collects data about the educational systems and outcomes of their member countries. The data collected in these studies do not only guide educational policies but have made outstanding contributions to the scientific knowledge about academic achievement. This is both due to enormous sample sizes, which provide a solid basis for conclusions, and sophisticated methods that have been advanced in the context of these studies.

In the following, three of the largest and most important international large-scale assessments are listed and characterized by who and what is investigated:

PISA (Programme for International Student Achievement)

- Who: 15-year-olds
- What: Literacy in different domains (mother language, mathematics, science) and cross-curricular competencies (e.g., problem solving)

TIMSS (Third International Mathematics and Science Study)

- Who: Elementary school children, 7th–8th grades and students in last year of mandatory education
- What: Literacy in mathematics and science

PIRLS (Progress in International Reading Literacy Study)

- Who: 4th graders
- What: Mainly Reading Literacy

Do standardized achievement tests measure academic achievement or intelligence or both?

A comparison between results of large-scale assessments of school achievement and intelligence tests indicates a close correlation between the two. This is true both on the level of the individual student as well as on the level of nations. This imposes the question of whether large-scale studies such as PISA actually measure school achievement or whether, instead, they measure intelligence. This is an important question because if it were not mainly school-based learning outcomes that were measured but intelligence, then PISA and the like would not assess the quality of educational systems and would not inform countries about strengths and weakness of their schools. Because intelligence is known to have a strong genetic basis, which means that a large portion of the differences observed in intelligence can be traced back to different genetic endowments, intelligence is often considered to be a relatively stable characteristic. If international large-scale studies of school achievement measured a stable trait instead of educational outcomes, their results would be more of a verdict about which nations are smart and which are not and not a means to assure educational quality.

This line of argumentation is flawed in several ways. First, because of the definition of what intelligence is, it is not reasonable to assume that any complex cognitive performance, such as academic achievement, can be measured without also measuring intelligence. Second, intelligence tests and standardized achievement tests share many methodological characteristics which contribute to a strong association. Therefore, the close correlation does not only reflect shared contents but also shared methods. Third, if the correlation among intelligence

tests and school achievement tests are considered to be too high to justify two distinct constructs, this does not necessarily compromise the concept of academic achievement as measured in large-scale assessment but raises questions about whether intelligence tests function as they are supposed to. It might be argued that extant intelligence tests rely too heavily on school-based learning contents and fail to measure an underlying cognitive potential. Fourth, it is wrong to assume that intelligence is heritable but school achievement is not or less so. Intelligence and student achievement are heritable to a comparable extent. Fifth, there is a widespread misunderstanding according to which heritability means that something is not malleable. Because heritability is a characteristic of the population but not of a single individual, high heritability does not inform us about the limits of individual growth of intelligence or academic achievement given an optimal education.

In view of these considerations, it becomes apparent that the discussion about what exactly is measured with standardized achievement tests is an important one. After all, the answer to be found might be less critical for the measurement of school achievement but more so for the measurement of intelligence.

Standards-based assessment of students' achievement

Standards-based assessment is a special kind of standardized achievement testing. It has all the advantages of standardized tests and their results can be used instead of or as a supplement to traditional teacher grades. The emergence of standards-based assessments is closely related to international large-scale assessments of school achievement. As a consequence of the feedback from international comparative assessments, many countries have changed their educational policies from an input orientation to an output orientation. Input orientation means that the main instrument to assure the quality of education is a detailed description of the contents to be taught (i.e., the curriculum). In contrast, an output-oriented education puts emphasis on the competencies to be acquired and regularly evaluates these competencies by standardized tests. Because these standardized tests are developed with an aim to assess competencies according to educational standards, these tests are called standards-based assessments. Different than for grades, standards-based assessments are usually not or at least not only evaluated by the same teacher who taught the class.

Standards-based assessments have several advantages. Because the evaluation of students' achievement depends on a common, typically nation-wide standard, results of standards-based assessments are comparable across different classes and schools. Different from grades, standards-based assessments do not depend on the general level of achievement in the class. This makes allocation decisions on the basis of standards-based assessments fairer than decisions made exclusively on the basis of grades. Moreover, the evaluation by common standards can harmonize teachers' evaluations across different classes and schools and therefore make teacher-given grades better in terms of comparability. Furthermore, it is argued that standards-based assessments foster students' motivation and their sense of justice. This should be so because standards are more transparent than the evaluation by grades and students often perceive good grades as confined to only a few students. Because standards are based on task mastery rather than social norms, the notion is conveyed

that every student who reaches these criteria can get good evaluations. Finally, standards-based assessments evaluate not only students' performance but also the quality of the work of teachers and schools. If two schools, that are equally funded and whose students come with comparable prerequisites (e.g., SES) differ with respect to their results in standards-based assessments, then the conclusion might be drawn that these different outcomes are a result of better and poorer teaching. Therefore, standards-based assessments also fulfill the function to evaluate schools and to make the quality of schools comparable.

One important danger that is associated with standards-based assessment is the phenomenon called teaching-to-the-test. Once teachers realize what is measured in standards-based tests, they might focus too much on conveying only the knowledge and skills measured by the test and neglect other important areas of learning. Because the tests can only assess competencies that are testable by means of paper and pencil assessments, there is the threat that only these kinds of contents will be taught. As a matter of fact, it is especially difficult to measure cross-curricular competencies, such as complex problem solving or social competencies in a group-testing situation with paper and pencil. Therefore, teaching-to-the-test poses a serious problem for standards-based assessment.

Predictors of Academic Achievement

In the following section, we take a look at those factors known to be most closely related to differences in academic achievement. Because most of the underlying research uses designs that do not allow for unanimous causal interpretations, these factors are called 'predictors' rather than determinants or influences of academic achievement.

Individual Student Characteristics

Individual student characteristics are by far the most important predictors of differences in academic achievement. Taken together, individual characteristics such as intelligence, motivation, and personality explain about half of the differences in scholastic performance. Among these individual characteristics, differences in intelligence are responsible for half of the differences in scholastic achievement. This makes intelligence the most important single predictor of academic achievement. Intelligence explains about 25% of the differences in school achievement. The strength of association between intelligence and scholastic achievement differs depending on whether grades or standardized tests are used as indicators. Intelligence is more closely correlated with results from standardized tests than with grades.

Knowing the history of intelligence testing, the strong association between intelligence and school achievement is unsurprising. Intelligence tests have been developed with an aim to assess children's cognitive potential and guide decisions about the most adequate schools and treatments. Therefore, every new intelligence test has to prove its usefulness and validity by being a good predictor of school performance. But of course these associations cannot and must not be perfect because in such a case the test would not measure anything besides scholastic achievement. Instead, intelligence tests are meant to

assess the cognitive potential of a person largely independently from educational influences. Therefore, intelligence tests use tasks that should be largely free of prior knowledge and school-based learning, such as anagrams, matrices, and the like. Nevertheless, intelligence tests are not completely free of educational influences and any measurement of intelligence always assesses, to some extent, educational influences. It has been shown that attending school has positive effects on intelligence. Therefore, intelligence and academic achievement are closely related not only because intelligence influences academic achievement but also because academic achievements foster intelligence.

Besides cognitive abilities, personality plays an important role for academic achievement. Among the famous Big Five factors of personality (extraversion, neuroticism, openness to experience, agreeableness, and conscientiousness), for some time now, the leading model to describe personality, conscientiousness has proved to be the best predictor of academic achievement. The other factors of personality show only weak or no association with academic achievement. A person who is conscientious can be described as planned, organized, achievement-oriented, ambitious, dependable, and persistent – all of which contributes to better scholastic achievement. Although the relationship between conscientiousness and academic achievement is consistently shown, it is far weaker than the relationship between cognitive abilities and performance. One reason for this is that the Big Five are meant to describe personality in all kinds of contexts and are not specifically designed to explain achievement-related behavior.

Besides these broad personality factors, psychologists who are especially interested in learning and achievement have identified personality dimensions that are more specifically important in achievement situations. These personality constructs can be subsumed under the term achievement motivation. Some of the most investigated constructs of achievement motivation are the need for achievement, ability self-concepts, self-efficacy, task values, interest, intrinsic and extrinsic motivation, and goals. Overall, there is a moderate association between the expression of these motivational constructs and academic achievement. Motivational characteristics are by and large independent of intelligence and are often found to contribute to the explanation of academic performance over and beyond cognitive ability. The strongest relationship is consistently found between domain-specific ability self-concepts and academic achievement. This association is often as strong as the association between intelligence and academic achievement. The relationship between interest or intrinsic motivation and academic achievement is moderately close. This might be surprising because both researchers and practitioners are often convinced that these motivational factors are of paramount importance for performance. It needs to be taken into account that in achievement contexts, learners are often not free to choose whether to engage in a subject or task but feel a pressure to do well regardless of their interest or intrinsic motivation. This explains why interest and intrinsic motivation are often to be found less predictive of academic achievement than expected.

Besides cognitive ability and personality, there is much research on the role of students' study behavior and attitudes, often subsumed under the term self-regulation abilities. Surprisingly, empirical studies often showed no or only weak

associations between the use of learning strategies and learning outcomes. A recent meta-analysis tries to clarify which study habits, skills, and attitudes actually are associated with better outcomes and what might be the reasons why so many studies fail to show these effects. For example, study habits, skills, and attitudes have been shown to be better predictors of college achievement than of earlier school achievement. Nevertheless, even in college the association between self-regulated learning strategies and achievement is weak.

Classroom Characteristics

Surprisingly few classroom and teacher characteristics show consistent positive associations with academic achievement. This is primarily due to difficulties separating single characteristics and investigating their effects. For example, regular and private schools often not only differ with respect to one single characteristic but in several respects (e.g., applied grading standards, teacher education and selection, pedagogical approach, financial, and other resources). Therefore, it is impossible to trace differences in students' academic performance back to one single classroom or teacher characteristic. A second reason is that different teaching styles might lead to similar results so that there is not just one way to enhance students' performance. Teachers might impress their students with their subject knowledge or might place great value on good student-teacher relations and both approaches might serve similarly to motivate students for school-based learning.

Nevertheless, there is one cluster of classroom or teacher characteristics that is consistently connected with differences in academic achievement: Students who attend a class with a high level of discipline and strict classroom management have better learning outcomes. A high level of order in the classroom allows teachers to spend more time-on-task and on contents rather than on nonsubject-related matters. Time-on-task is the single-most important classroom characteristic that explains differences in school achievement. Teachers who have good classroom management skills provide clear conduct rules and consistently sanction positive and negative student behavior. In well-managed classrooms, teachers formulate clear assignments so that students know what to do and do not lose time solving uncertainty. All of these characteristics contribute to better student learning and achievement.

Educational System Characteristics

International large-scale studies on student achievement provide solid data regarding the association between characteristics of the educational system and student achievement. However, the same problems that apply to comparisons of classrooms also apply to the level of the educational system. Educational systems usually differ in many aspects so that it is difficult to trace better student achievement back to one single characteristic of the educational system. Often only the combination of different characteristics goes along with enhanced achievement. For example, Finland – one of the leading countries with regard to student achievement – does not separate students into different tracks. Children with and without special needs are taught in the same class. Copying this characteristic would make no sense without also copying the small

class sizes and good student–teacher relation with extra special needs teachers. Neither a comprehensive school nor small classes are per se associated with better student performance; but in the right combination, these characteristics make a difference.

On the level of the educational system, there are some characteristics that are consistently associated with better mean levels of academic achievement. One of these is the percentage of children attending kindergarten and preschool: the more children get preschool education, the better a nation's mean level of student achievement later in school. Institutionalized preschool education is especially important for children who lack a stimulating environment at home. Preschool education helps to compensate unequal prerequisites and to detect special needs or other ability deficiencies, such as dyslexia or language problems, for which special aid can be given even before school age.

A second characteristic of the educational system that is consistently associated with better student achievement is the use of high-stakes tests, such as central exams and standards-based assessment. There are many ways to explain this association. One can argue that with a national curriculum and curriculum-based tests teachers have better goal clarity and place more importance on teaching what students need to know to do well on the tests. In its extreme, this goal clarity might turn into teaching-to-the-test, which is undesirable, because competencies not assessed in the test, that still might be important, are neglected. Therefore, teaching-to-the-test is a serious danger that comes along with high-stakes testing. Another reason for the association between use of high-stakes tests and better school achievement might be that countries employing high-stakes tests place more importance on education and invest more effort in raising the educational level. Establishing high-stakes testing is usually a consequence of a country's participation in international large-scale studies of academic achievement and the wish to monitor educational outcomes more closely. Therefore, a plausible explanation for the association between high-stakes testing and student achievement is that nations more concerned with the quality of education make more use of high-stakes tests. The last reason might be that the use of high-stakes tests trains students to do better on standardized achievement tests as used in international scholastic achievement studies. For example, the typical type of tasks and answering formats in high-stakes tests and standardized achievement tests are very similar, so that regularly taking high-stakes tests at school will train students to do better on standardized achievement tests.

Besides the mean level of student achievement, a second important indicator of educational quality is the extent of differences between students' achievement. It is desirable that students' achievement is not only high on average but also that the differences between students' achievement are not too large. This can be explained by the example of early tracking. One characteristic of the educational system that has been shown to enlarge differences between students is an early separation of children into educational tracks stratified for level of achievement. Empirical evidence indicates that in countries with an early separation into educational tracks, the standard deviation of scholastic achievement as measured with standardized achievement tests increases from elementary school to secondary school. In countries with late or no

separation into educational tracks, the standard deviation decreases over the school years. Another undesirable effect of earlier tracking is a stronger association between children's school achievement and family background characteristics such as SES. For example, Germany is one of the few countries that separate students as early as grade 4. In Germany, the upper and lower 5% of the achievement spectrum show the greatest divide compared to all other nations. At the same time, in Germany the association between children's school achievement and their families' SES is the strongest. These results from international school achievement studies have led to a discussion to abolish the early separation either by prolonging elementary school or by merging different types of secondary schools.

Equal Opportunities and Academic Achievement

One important aim of psychological research on academic achievement is to shed light on reasons for differences in education that come along with characteristics that, per se, have no bearing on education. As two examples for such characteristics, we pick gender and SES.

Gender Differences

At the end of the twentieth century, in many countries it is girls and not boys who earn better school grades and higher educational degrees. The gender gap in educational achievement is both a theoretically challenging and practically relevant topic. A connected question is why girls are not using their educational advantages and transferring them into higher achievements later in life. Women are still unrepresented in higher job positions and earn less than their male colleagues.

A variety of reasons for the gender gap in education have been put forward. The influences of changing cultures on children's educational outcomes are visible in similar trends taking place throughout the developed world: the more developed a country is and the more it aspires equal opportunities for both sexes, the better girls are at school. For example, in rural areas of China, girls are still found to do worse than boys in school. In Hong Kong, girls outperformed boys in school only after a Western outlook had been adopted in addition to the traditional Chinese culture. Evidence from international large-scale studies shows that the gender gaps in math and reading are associated with the degree of women's emancipation that is realized in a country. For example, in Scandinavian countries, which score high on women's emancipation, the gender gap for mathematics is smaller and in some cases even nonexistent, whereas in reading, girls have an even bigger head start than on OECD average. In contrast to this, in countries that have no culture of women's emancipation, such as Turkey, girls do markedly worse in math than boys and their advantage in reading is comparably small. Thus, girls' better school achievement is related to societal changes in attitudes toward equal opportunities for men and women.

Besides such societal influences, gender differences in individual characteristics, such as cognitive ability, personality, and motivation, have been proposed as explanations for the gender gap in academic achievement. Gender differences in cognitive

ability can be excluded as an explanation for girls' better academic attainment for several reasons. First, most researchers agree that there are no gender differences in general intelligence. If differences in general intelligence are found, then they are in favor of boys. Second, gender differences in specific intelligence components are too weak to explain the observed differences in school achievement. It is often found that girls have an advantage in verbal intelligence and boys' in numeric intelligence. Nevertheless, these ability differences are too small to explain the observed differences in school achievement. Third, even when differences in intelligence are statistically controlled, girls have been shown to get better grades. Therefore, differences in cognitive ability are not the explanation for gender differences in academic achievement.

The most promising candidates that explain gender differences in academic achievement are gender-typical differences in personality and motivation. Girls are typically more intrinsically motivated for school-based learning. Boys, on the hand, show on average lower school-related learning motivation and, at the same time, have fewer self-control resources to counterbalance their low motivation. Their higher self-control allows girls to regulate their emotions and behavior, and respond to demands at school even if they are not interested in what they have to do. Moreover, whereas in girls' peer groups it is absolutely acceptable to be good at school and conform to school rules, boys' peer groups rather reward oppositional behavior and sanction boys who do too well at school. Another assumption is that girls succeed in school because of their more agreeable personalities. Teachers are known to reward agreeable behavior with better grades. Taken together, these differences in girls' and boys' personality are important explanations for girls' better school achievement.

If a better fit of girls' personality and motivation to the school environment is the reason for girls' advantages in academic achievement, then there are two possibilities to enhance boys' achievement: either change boys' characteristics or change the school environment. According to the first alternative, interventions that enhance boys' intrinsic motivation for school-based learning and foster their self-regulatory competencies are a viable way. According to the second alternative, the school environment needs to be cleared of such characteristics that unfairly favor girls but do not actually foster or assess achievement. For example, if grades are used to reward agreeable behavior, then teachers need to be trained to keep their evaluations free of such influences and find other ways to ensure discipline in the classroom. Another way to ensure that boys conform to school rules is to sanction violations of rules consequently and strictly. If boys do not have the chance to violate rules, then the differences between girls' and boys' behavior become smaller and might, as a consequence, diminish differences in academic achievement. At this time, these suggestions are not tested empirically. More research is needed to see whether these are viable ways to decrease the gender gap in school achievement.

Socioeconomic Status

The SES of a person, family, or other social group indicates their possession of economic and social resources. Most frequently, SES is assessed by occupation, education, income, or a

combination of all. It is a general finding that the SES of a family is associated with children's academic achievement and their highest educational degrees. According to meta-analyses and international large-scale studies of school achievement, the strength of the association between SES and children's academic achievement is moderate ($r = 0.30-0.40$). The strength of association reported varies markedly depending on the indicators used to measure SES and academic achievement, age of children, and whether the full range or a restricted range of SES and achievement was investigated.

Because SES has per se no bearing on a child's achievement, the association between SES and academic achievement is commonly considered as evidence for social injustice and unequal opportunities. The most convincing evidence that SES actually is associated with injustice comes from studies showing that two students, one from a family with low SES the other from a high SES home, have different chances to acquire higher educational degrees even if they have the same ability according to standardized tests.

But why is the family SES associated with children's academic achievement? The way to find an answer to this question is to look behind the label SES and find those factors that are known to be prerequisites for academic achievement. SES itself is just a carrier variable that is associated with other factors that are actual causes of differences in academic achievement. For example, it is well established that a higher SES, on average, goes along with higher intelligence and higher aspirations and engagement for education. Parents who possess such favorable characteristics pass these on to their children, either by providing them a stimulating environment or via genes. Parents who have high aspirations for their children provide them with a more supportive environment and, at the same time, have children who are more likely to have high aspirations themselves. It can be shown that large parts of the association between family SES and children's school achievement are explained by parents' and children's sharing of personal and environmental characteristics that contribute to better academic achievement. This is an important finding because it shows that the association between family SES and children's achievement is not per se an indicator of social injustice. Instead, it indicates that desirable resources are distributed unequally among families and that societies must make deliberate choices whether to compensate for different starting positions or whether to let those differences become even larger.

What can be done to avoid unequal opportunities with regard to SES? On the level of the educational system, the evidence is clear that early tracking increases dependability of academic achievement on family attributes. One recommendation to reduce the association between SES and academic achievement is to keep students together in one type of school throughout middle school and even high school. Another recommendation is to use not only grades for admission decisions to the next level of education but also standards-based assessments. To assess something with different measures is always a good way to validate each single measure. On the one hand, teachers might be influenced by their knowledge of the families' background whereas standardized tests are not. On the other hand, some standardized tests are even more strongly associated with SES than grades. Therefore, it is important to base vital decisions on more than just one source of

information. Again, this is a field in which more research is needed to find the best way to produce equal opportunities with respect to families' social and economic background.

Glossary

Cognitive-behavior therapy (CBT) A common type of counseling based on the belief that using both cognitive therapy and behavioral therapy is more effective than just one of these types. The two components of the therapy seeks to help the client identify and change harmful or dysfunctional thinking, emotional and behavior responses.

Diagnostic and Statistical Manual of Mental Disorders (DSM) The DSM is published by the American Psychiatric Association and provides a common language and standard criteria for the classification of behavioral and mental disorders, including the addictive disorders discussed in this article. The current version is the fourth edition, known as DSM-IV.

Nicotine dependence Nicotine is present in tobacco products (e.g., cigarettes, cigars, tobacco snuff) and like other physically addictive drugs such as alcohol and cocaine, can lead to dependence. Signs of dependence include frequent use, repeated urges to use, and withdrawal symptoms when the person cuts down or stops using a tobacco product.

Pathological gambling As defined by DSM-IV, pathological gambling is a persistent and recurrent maladaptive disorder that disrupts one's life as evidenced by five or more of the following diagnostic criteria: preoccupation with gambling; needing to gamble with larger amounts of money in order to achieve the same level of excitement; repeated unsuccessful attempts to cut down or stop gambling; feelings of restlessness or irritability when trying to cut back or stop gambling; gambling to escape problems or unpleasant emotions; chasing losses; lying to family member or hiding evidence of one's gambling; committing illegal acts to support one's gambling; jeopardizing significant relationships; and relying on others to relieve a desperate financial situation.

Problem gambling Whereas pathological gambling is a clinical diagnosis with specific diagnostic criteria, the term

'problem gambling' is a broader construct that identifies individuals who exhibit some problems with their gambling but who do not meet diagnostic criteria for pathological gambling. This level of problem severity is sometimes referred to as subthreshold or subclinical problem gambling.

Substance use disorders DSM-IV recognizes two substance use disorders (SUDs) Abuse and dependence. The two diagnoses are defined by distinct sets of symptoms. Substance abuse is generally considered to represent a milder SUD, compared to substance dependence, and its symptoms focus on life disruptions and negative consequences to the user. DSM-IV substance abuse requires meeting 1 of 4 criteria that represent recurrent psychosocial consequences related to substance use (e.g., school grades dropped due to substance use, interpersonal relations damaged due to substance use, substance-related legal problems), and hazardous substance use (e.g., driving when intoxicated). DSM-IV substance dependence requires meeting 3 of 7 criteria within the same 1-year period, and identifies a compulsive pattern of substance use despite the continuation of negative consequences. Dependence criteria include physical symptoms (i.e., a high level of tolerance, a recurrent withdrawal syndrome), prioritizing substance use over other activities (i.e., much time spent using, reducing activities in favor of drug use), and impaired control over use (i.e., used more or longer than intended, difficulty cutting down or abstaining from use, use despite adverse physical and psychological consequences of substance use). In keeping with the notion that dependence is a more severe condition than abuse, meeting criteria for dependence overrides a diagnosis of abuse for a given substance. Although there are differences across drugs in the extent to which certain criteria may be relevant, the same criteria are used across all substances, with the exception that DSM-IV does not include a nicotine 'abuse' diagnosis, and withdrawal is not a criterion for dependence on cannabis or hallucinogens.

Introduction

In the adolescent literature, the past 20 years have been characterized by a rapid growth of research in the understanding of developmental psychopathology and adolescent development. This emerging research area has greatly advanced our understanding of the extent and nature of addictive disorders among adolescents. We recognize that addictive behaviors, as they pertain to youth, represent a broad construct as it does

for adults. However, there are relatively large research literatures that address three broad domains of addictive disorders for adolescents: nicotine dependence, other substance use disorders, and pathological gambling. Thus we have organized this article around the description of the three addictive disorders from clinical, epidemiological, and treatment perspectives. But first we address several developmental considerations that pertain to the construct of addiction as applied to adolescents.

Developmental Issues

Historically, addictions have been defined with reference only to the compulsive – like the use of a psychoactive substance – disorders (including nicotine) that temporarily alter reward-based chemicals in the brain. Many experts now consider behavioral addictions as legitimate members of the spectrum of addictive disorders; these include ‘psychological dependencies’ on gambling, food, sex, and shopping.

All addictive disorders are reflected by individuals pursuing rewards or relief by substance use or other behaviors, and are characterized by impairment in behavioral control, craving, inability to consistently abstain, and diminished recognition of significant problems with one’s behavior and interpersonal relationships. Thus, the essence of addiction is the recurring compulsion felt by an individual to engage in some specific activity in the presence of harmful consequences to the individual’s health, mental state, or social life. Like other chronic diseases, addiction involves cycles of relapse and remission, and many individuals do not achieve stable recovery until after several courses of treatment. Also, some individuals obtain successful recovery without formal treatment.

Several issues are relevant here as we consider the importance of the context of adolescence and addictions. We briefly discuss the following three contextual issues: etiology, identification of clinical significance, and applicability of addiction diagnostic criteria for adolescents.

Etiology

A traditional view in the developmental literature is that adolescents may be more vulnerable than adults to addiction. Indeed, the vast majority of adults with an addictive disorder began their indulgence during the critical developmental period of adolescence. Also, recent and converging evidence suggest that the substance-based addictions develop more

quickly and with less exposure to the particular substance during adolescence compared to the same during adulthood. Multiple factors clearly play roles in fostering the development of addiction, including genetics, peer influence, management of stress, parenting, and the motivational push to explore the world to learn to be an adult. Also, delays in social and emotional functioning, diminished respect toward authority, and tendencies to be self-absorbed and to minimize negative consequences may contribute to involvement in addictive behaviors.

Brain Development

One emerging view is that adolescent vulnerability to addictive disorders is significantly influenced by the way their brain grows. Basic and clinical data support the stance that adolescence is a neurodevelopmentally critical period of great vulnerability for risk-taking, experimentation with substances, and acquisition of addictive disorders.

Recent studies on this subject support the view that the neurodevelopmental basis for this vulnerability is associated with the maturation of a particular region in adolescent brains. The region of the brain that monitors impulse and motivation, the frontal cortex, is not fully formed during adolescence (see [Figure 1](#)). Adolescent impulsivity and novelty seeking as a transitional trait behavior may be explained in part by maturational changes in the frontal cortical region. These developmental processes may not only advantageously promote learning drives for adaptation to adult roles, but may also confer greater vulnerability to the addictive actions of drugs. This brain region’s quick-fire change that is relatively unique to adolescence may translate to teenagers being more likely than children and adults to try out new experiences and to be more impulsive and take risks. These findings suggest that for adolescents, addictive disorders are neurodevelopmental disorders.

Figure 1 Gray matter maturation. Reproduced from Gogtay N, Giedd JN, Luck L, et al. (2004) Dynamic mapping of human cortical development during childhood through early adulthood. *Proceedings of the National Academy of Sciences of the United States of America* 101: 8174–8179.

Inherited Characteristics

A wealth of family and twin studies provide strong support to the fact that genetic factors play a major role in the development of addictive disorders. An additional support for this is the theory that states that during childhood, the genetic liability for addictive disorders manifests as an underlying deficit in the young person's ability to regulate and control impulses, often referred to as the dysregulation syndrome. This liability is also seen as an antecedent to several behavioral disorders that commonly coexist with addictive disorders, such as conduct disorder, oppositional defiant disorder, and attention-deficit hyperactivity disorder (ADHD). A related group of antecedents to addictive behaviors that may also have a genetic basis are negative affect disorders, such as anxiety disorders and depressive disorders. It has been hypothesized that young people suffering from these disorders engage in addictive behaviors to alleviate the underlying negative emotions of anxiety and depression.

Environmental Influences

Many nonbiological factors also influence the likelihood of developing an addictive disorder, and there is converging data indicating that these factors generalize across a range of addictive disorders. Key environmental factors that *increase* risk for an addictive disorder for youth are affiliation with delinquent peers, lack of involvement in prosocial activities (e.g., participation in extracurricular school activities), lack of conventional values, and poor parenting practices (e.g., distant relations with the child; poor supervision and monitoring; poor role modeling). Another environmental factor pertains to the ease of access and availability of the addictive 'agent' (i.e., drug, gambling venue, etc.). Two dramatic examples of this pertaining to youth in the United States are the following: (1) the substances abused the most by youth are those that are the most available and accessible to them – legal substances

such as tobacco and alcohol, and (2) the dramatic expansion of legalized gambling in the United States is consistent with the recent increase in gambling by teenagers.

Identifying Clinical Significance

It is true that relatively few teenagers who use drugs or gamble, even regularly, will become addicted. Nonetheless, it can be difficult to determine when involvement in addictive behaviors by adolescents will have no negative consequences, when it may involve short-term and minimal health effects, or when it may be associated with serious negative long-term repercussions. As will be discussed later in this article, the high prevalence rate of drug use and gambling by teenagers gives some credence to the notion that these behaviors are a normative part of youth. When adolescents use drugs, it is typical that they use legal drugs (alcohol or tobacco) and use them within a social context. Gambling by adolescents often occurs with peers and involves making informal, social bets (e.g., who will get the better test score). The large majority of drug-using youth will not progress beyond the use of the so-called gateway drugs of alcohol and tobacco, and we can say with similar certainty that most youth gamblers will not develop a gambling problem.

However, it is also the case that adolescence may be a particularly vulnerable period to develop an addictive disorder or an addition problem. For example, young people show higher rates of alcohol problems compared to older age groups. [Figure 2](#) below shows that among youth aged 15–20 years old, 12.2% met an official definition of an alcohol dependence disorder within the past 12 months. This rate was much higher than the other age groups.

There is a similar association between early onset gambling and increased risk for adult gambling problems. Data collected during 2001–2003 from the US National Comorbidity Survey Replication Study found that adults with a pathological gambling disorder reported first gambling significantly earlier than gamblers without a history of pathological gambling (mean

Figure 2 Prevalence of past year DSM-IV alcohol dependence: United States, 2000–2001. Reproduced from Grant BF, et al. (2004) *Drug and Alcohol Dependence* 74: 223–234.

age 16.7 vs. 23.9 years). Then there is the issue of *current* problems associated with addictive behaviors during youth. Later in this article we provide more details about prevalence rates, but in a general sense the rates among adolescents of each of our target addictive disorders are appreciable. One example: Based on the National Household Survey data, it is estimated that 11% of youth (12–18 year olds) meet a current DSM-IV diagnosis for a substance use disorder.

Applicability of Addiction Diagnostic Criteria for Adolescents

A related issue is the applicability of formal diagnostic criteria for addictive disorders to adolescents. The three addictive disorders we discuss in this article – nicotine dependence, substance use disorders and pathological gambling – are defined by DSM-IV. However, adolescent-specific definitions of these disorders do not exist in the DSM system, a concern that does not sit well with many experts who can point to some existing criteria that are not relevant for youth and can identify other symptoms that are adolescent specific and clinically relevant and yet are not included in the current diagnostic nomenclature. We will return to definitional issues in upcoming sections.

Three Adolescent Addictive Disorders

We now turn our attention to the three domains of adolescent addictive behaviors for which there is a relatively substantial empirical literature – nicotine dependence, other substance use disorders, and pathological gambling. Each subsection will provide an overview of clinical characteristics and definition, epidemiology, etiology, and treatment.

Nicotine Dependence

Clinical Characteristics and Definition

The primary tobacco product used by adolescents is the cigarette, so this subsection will focus solely on this source of nicotine. Experimentation with cigarette smoking is a common phenomenon among adolescents, with upward of 46% of high school seniors reported having previously tried smoking. While not all adolescents who try smoking progress to habitual smoking, data from the Monitoring the Future Study (MTFS) reveal that over 12.3% of high school seniors reported smoking daily. Rates of smoking continue to increase during late adolescence/emerging adulthood (from age 18 to 24), resulting in the highest rate of smoking (23.9%) among all age groups. Factors that influence progression beyond initial experimentation may be quite distinct from those that influence first trials with cigarettes. For example, social influence processes are well-established predictors of initial experimentation, but mood/emotional factors may be more important than social influences in determining progression beyond initial trials with smoking.

We know that the vast majority of current adult smokers began their smoking careers by the age of 18. Given the association between smoking in adolescence and subsequent health

problems in adulthood, the initiation and maintenance of smoking during adolescence and young adulthood represent genuine public health concerns. In addition, mounting evidence links smoking with health problems (e.g., respiratory and cardiovascular) during adolescence. The notion that adolescent smokers are addicted to nicotine and thus driven by compulsive drug-seeking behavior represents a serious concern above and beyond that posed by the associated health risks. Indeed, the Surgeon General in 1994 concluded in a published report that “most adolescents [who smoke] are addicted to nicotine and report that they want to quit but are unable to do so; they experience relapse rates and withdrawal symptoms similar to those reported by adults.”

The notion that most adolescent smokers are nicotine dependent should have a considerable impact on prevention, treatment, and policy at multiple levels. However, the vast majority of research on nicotine dependence has focused on adult smokers, and relatively few attempts have been made to document the emergence of nicotine dependence among adolescents. Indeed, Alexander Prokhorov and colleagues, nicotine research experts, speculated that “The lack of interest in the study of nicotine dependence in adolescents might be explained by the prime orientation of adolescent research on the prevention of smoking onset along with skepticism with respect to the ability to develop an appreciable degree of nicotine dependence during the relatively short period of adolescence.” More than a decade later a paradigm shift in the field is placing increasing attention on the need for research to identify the factors that may promote smoking behavior and to examine the emergence of nicotine dependence in young people.

Epidemiology

Reducing smoking prevalence is an important national health objective in the United States. Whereas cigarette smoking had steadily decreased between 1997 and 2004, the National Health Interview Survey (NHIS) indicates that cigarette smoking prevalence has remained steady at 20.8% since then. Smoking prevalence is higher among men (23.9%) than women (18.0%), and among different racial groups, those of Asian (10.4%) and Hispanic (15.2%) descent have lower smoking rates than Caucasians (21.0%), African-Americans (23.0%), or American Indians/Alaskan Natives (32.4%). There are also higher rates of smoking among those with the lowest socioeconomic status.

As noted earlier, smoking behavior most often begins in adolescence, with 20% of 8th graders reporting some experience with cigarettes. Although adolescents may under-report smoking behavior for a number of reasons, including social undesirability, fear of disclosure, or inaccurate recall, tobacco has remained the substance most often used on a daily basis by high school students for over 30 years, according to responses from successive cohorts of the MTFS. To track trends in cigarette smoking among adolescents and young adults, the MTFS researchers have administered a series of national surveys that assess cigarette, alcohol, and illicit drug use over time. Results show that in the 1980s, smoking rates remained steady among adolescent smokers, though they declined in adults. In the early 1990s, cigarette smoking among 8th and 10th graders

rose by 50% before declining steadily in the second half of the decade. The decline in smoking among high school students has decelerated in recent years, however, and most daily adolescent smokers report smoking half a pack or more per day.

A closer examination of these data reveals some factors that might go some way toward explaining such trends in cigarette smoking among youth. Increased cigarette prices reduce cigarette smoking among adolescents, and not smoking sharply reduces risk of using alcohol and illicit drugs. Importantly, men are more likely to progress from occasional to regular smoking, as are those who hold more positive smoking outcome and affect regulation expectancies.

Whereas regular (e.g., daily) smoking is a hallmark of nicotine dependence in adults, adolescent smokers can apparently exhibit symptoms of dependence with only occasional use, often before the onset of daily smoking. To date, despite various validated nicotine-dependence questionnaires, there is no universally accepted tool for identifying or measuring nicotine dependence in adolescents. Joseph DiFranza and his colleagues suggest that loss of autonomy over one's behavior might be the most salient feature of nicotine dependence in adolescents, rather than quantity or frequency of tobacco use. Indeed, the development of a single symptom of nicotine dependence appears to predict continued use, indicating that loss of autonomy and dependence might have a strong temporal (and perhaps causal) relationship.

Etiology

The conventional description of the natural history of dependent smoking is that individuals first try smoking in early to mid-adolescence and gradually escalate their frequency of smoking over a 2- or 3-year period to the point where they are smoking daily. Daily smokers continue to escalate cigarette use over the next several years as they develop into chronic, heavily dependent smokers. Though this description is consistent with national survey data, this pattern represents an average that does not convey the wide variety of patterns that can occur during the emergence of nicotine dependence. To date, little research has contradicted this pattern, though we expect this may be due to the expectation that heavy daily smoking is necessary for the emergence of nicotine dependence. That is, the vast majority of smoking studies have measured dependence symptoms *only* among respondents who meet clearly established smoking patterns (e.g., daily use), and this approach precludes the examination of dependence symptoms at nondaily levels of use. This approach derives from an implicit assumption governing the field; that is, that an isomorphism exists between smoke exposure (i.e., amount smoked) and symptoms of dependence. However, emerging evidence suggests the relationship between smoking exposure and the symptoms of withdrawal and dependence is far from perfect.

Research findings from the lab of one of the authors (Kassel and Conrad) bear on the question of whether adolescent smokers – even those who smoke relatively infrequently – manifest signs and symptoms of nicotine dependence. They assessed the acute effects of nicotine on positive (PA) and negative affect (NA) in a group of 15–18 year olds. A matched group of nonsmokers served as a comparison group. This is

probably the first study conducted in the United States in which nicotine was administered to adolescent smokers under controlled laboratory conditions. The findings conformed to a negative reinforcement model of nicotine effects and strongly suggested that, even among young (mean age = 17.5), light smokers (5.5 days a week smoked; 3.5 cigarettes a day), nicotine dependence and resultant withdrawal symptoms appear to serve as motivating factors governing smoking behavior.

Several interesting and important findings also emerged from correlational analyses. Craving was significantly correlated with nicotine dependence ($r = 0.60$), NA management expectancies ($r = 0.37$), boredom relief expectancies ($r = 0.53$), boost in expired air carbon monoxide (CO; an index of smoke exposure) derived from smoking the cigarette ($r = 0.40$), and pre-post-smoking reduction in NA ($r = -0.38$). In addition, the measure of nicotine dependence demonstrated significant correlations with recency of smoking (the more dependent the participant was, the more recently he or she had smoked; $r = -0.40$), number of cigarettes smoked on the study day ($r = 0.49$), and NA management expectancies ($r = 0.32$). Taken together, then, these findings suggest that even young, relatively light smokers exhibit signs and symptoms of nicotine dependence (albeit at low levels) and that symptoms of nicotine dependence are correlated in meaningful ways with other smoking-related characteristics.

Nevertheless, the pathways to becoming a smoker are clearly complex and governed by a host of genetic, social, pharmacological, and psychological determinants. While social factors (e.g., peer affiliations and peer socialization) have emerged as potent and reliable predictors of smoking initiation and experimentation, some evidence suggests that heightened levels of stress and negative affect, manifestations of psychopathology associated with affective distress and anxiety, are linked to progression in smoking status and nicotine dependence among adolescents. Thus, distinguishing the processes that govern smoking initiation and experimentation from those that underlie progression to nicotine dependence is of particular importance in examining smoking patterns in adolescents and young adults.

Findings from cross-sectional and longitudinal studies show that adolescents who experience significant levels of affective distress are more likely to smoke, and many researchers have inferred that these adolescents smoke because it alleviates negative affect. However, ascribing causal (within-subject) mechanisms based on results derived from cross-sectional (between-subject) analyses may not always be appropriate. Although only limited empirical work has been devoted to answering the question of whether smoking genuinely influences emotional response in adolescents, several studies do offer some insight into the motives associated with adolescent smoking. Though not a direct indicator of nicotine dependence, the subjective effects experienced by smokers are likely to reflect the role of nicotine (and other constituents of tobacco smoke) in governing smoking behavior. A number of studies point to the importance of affect management as motivation for smoking among young smokers. For example, several studies have found that adolescent smoking initiates commonly reported 'smoking to relax' and 'stress reduction' as important motives for smoking. More recent studies by Johnson and colleagues

also reveal significant endorsement of emotional reinforcement motives among adolescent smokers, with a large proportion attributing their smoking to its reputed ability to facilitate affect regulation. Correspondingly, a number of recent investigations found that smoking in response to negative affect was the most frequently endorsed motive among adolescent smokers.

Treatment

There are a number of obstacles to overcome when considering treatment options for adolescent smokers. First, intervention efforts are most often impeded by irregular smoking patterns among this group, as most teenagers smoke under limited circumstances and, perhaps most importantly, do not view their behavior as a serious problem. At this transitional life stage, adolescent smokers are also often concerned with privacy and autonomy. Most smoking cessation programs are tailored to adult regular smokers and are therefore less accessible to an adolescent occasional smoker. Ultimately, successful interventions are careful to tailor the treatment to the individual and protect confidentiality.

Currently, cognitive-behavioral therapy (CBT) is the treatment most often recommended for adolescent smokers who want to quit, in the absence of youth-specific treatment options. Previous research has focused on the frequency and duration of treatment sessions, comparing the effectiveness of longer sessions offered once per week to shorter sessions offered several times per week, often with a contingency management component that provides tangible reinforcement for maintaining abstinence. Studies show that abstinence rates do not vary as a function of session length or frequency. As such, this finding might represent an opportunity to tailor treatment to the individual, based on convenience and preference.

Medical-based or pharmacological treatments used in conjunction with CBT have also garnered increasing empirical scrutiny in adolescents. Generally, the nicotine patch appears safe to use with smokers as young as 13 years old. The patch, as compared with placebo, decreases cigarette craving and withdrawal symptoms, though it ultimately appears to have no effect on abstinence rates. Bupropion, an antidepressant deemed efficacious as a smoking cessation aid in adult smokers, has also been found effective in adolescent smokers, although it is usually employed in conjunction with brief counseling or family support.

Alternative smoking cessation programs have recently focused on using different media outlets to offer counseling services. In the short-term, Internet-based virtual reality applications, monitored by a trained counselor, result in enhanced 1-week abstinence rates, fewer smoking days in the past week, and fewer cigarettes smoked in the last week for those treated than those receiving no treatment. Web-assisted tobacco intervention programs that combine interactive quizzes with self-assessment and feedback show promising results in reducing intentions to smoke, increasing resistance to smoking, and decreasing heavy cigarette use.

Other studies indicate that brief visits with the pediatrician in a medical office setting can increase the adolescent's readiness to quit. One study offered four brief individual weekly sessions in the medical office, while a home-based Internet intervention was accessible for 24 weeks. Whereas no group differences in abstinence rates were observed, those who continued to smoke

showed fewer smoking days in the office condition compared to the Internet intervention. Most important was the rapid decline in accessing the Internet-based intervention: by week 3 of the study; access had dropped to less than one third of all participants. Among the most popular Web pages were those offering discussion support groups, followed by quit plan pages. Interaction pages were accessed more often than informational pages, and men accessed fewer interactive pages than women. These patterns of use hold important implications for the design of future Web-based applications and their inclusion as a component of smoking cessation treatment.

On an individual treatment level, brief self-help interventions appear generally effective with adolescent smokers who are less nicotine dependent. School-based programs, however, are both prevention and treatment focused in nature, and are thus able to target a larger range of smokers. Standard support within school settings usually comprises abstinence-based lessons. Adding eight, 1-hour no-smoking lessons over the course of 2 years, in addition to support from school nurses, reduces the likelihood that students will smoke regularly or at all in the past month. School-based tobacco use interventions are also effective in reducing overall smoking prevalence, smoking initiation, and smoking intentions in the short term. Unfortunately, relatively few studies perform long-term follow-up, and among those that have, little evidence has been found for school-based prevention programs. In light of these mixed findings, some researchers suggest that schools frame cigarette smoking as an example of a real-world problem in order to further develop critical thinking skills. The best school-based programs are interactive in nature and teach skills to resist drug offers and prodrug influences, correct misperceptions that drug use is normative, and increase social and personal competence.

On a more community-based level, previous studies indicate that well-funded mass-media campaigns targeted at the general population and implemented at the state level, in addition to a comprehensive tobacco control program (e.g., restricting easy access to tobacco products by removing cigarette vending machines; compliance checks at points of purchase to enforce the minimum age law) are associated with reduced smoking rates in adolescents. Also, as we noted above, raising the cost of tobacco products is generally associated with reductions in tobacco use among youth.

Other Substances Use Disorders (Excluding Nicotine)

Clinical Characteristics and Definition

Substance involvement ranges along a continuum of severity that includes abstinence, experimentation, occasional use, regular use, and heavy use and associated problems. Most of the population engages in minimal to occasional use, with increasingly smaller proportions involved in more regular and heavy, chronic levels of substance use. For individuals at the higher end of the substance involvement continuum, the presence of a substance use disorder (SUD) reflects a categorical determination (i.e., disorder is present or absent) that an individual's substance use results in significant impairment in functioning or subjective distress associated with need for treatment.

DSM-IV SUDs were developed based on clinical experience and research involving adults. When applied to adolescents,

DSM-IV SUDs have demonstrated validity as markers of an adolescent's level of substance involvement and associated impairment in functioning. However, certain limitations of DSM-IV SUDs when applied to youth also have been identified, highlighting the importance of developmentally informed assessment of substance-related problems. An important limitation of DSM-IV SUDs when applied to adolescents involves the threshold used to determine the presence of SUD. Some adolescents may report substance-related symptoms, but fall short of meeting criteria for a DSM-IV SUD, either because the symptoms reported are not included among the diagnostic criteria or because the number of symptoms does not meet the threshold for diagnosis. Some youth who report substance-related problems do not meet SUD criteria, and are known as 'diagnostic orphans.' The diagnostic orphans typically report one to two dependence symptoms, and do not meet criteria for a diagnosis of abuse. Research suggests that although diagnostic orphans do not meet criteria for a SUD, they report similar levels of substance use and impairment in functioning as youth with an abuse diagnosis. Diagnostic orphans appear to represent 'missed' cases of SUD that are particularly important to consider when assessing adolescent substance involvement.

Another limitation of DSM-IV SUD criteria when applied to adolescents involves adequate coverage of substance-related problems that are relevant to youth. For example, substance dependence criteria focus on failed attempts to quit or cut down, behaviors that are commonly reported among adults in addictions treatment. However, due to adolescents' typically shorter histories of substance use compared to adults, adolescent substance users may report a pattern of frequent, heavy substance use, that has not yet progressed to attempts to cut down or stop use. In this regard, DSM-IV SUD criteria are limited in capturing a compulsive pattern of use among those who have not yet tried to cut down or stop substance use, resulting in possible under-identification of youth who may benefit from intervention. As another example, the abuse criterion regarding substance use in a hazardous situation is often met by recurrent episodes of driving while intoxicated among adults. However, this criterion applies less to youth who are not driving or who have limited access to a vehicle. Among younger adolescents, symptoms such as recurrent substance-related blackouts, passing out, or risky sexual behavior, may indicate hazardous use, and although they are not explicitly included in DSM-IV SUD criteria, they need to be considered when evaluating adolescent substance users.

Developmentally informed assessment of substance involvement aims to minimize false positive and false negative symptom assignments in order to increase overall validity of SUD diagnoses, particularly when applied to adolescents. Specifically, certain SUD symptoms may manifest differently in adolescents (e.g., drop in school grades due to marijuana use), compared to adults (e.g., marijuana-related impairment in job performance). Other symptoms may have a different meaning in adolescents and adults due to the developmental context in which the symptom occurs. For example, youth may report the dependence symptom as 'spending much time trying to obtain alcohol, drinking, or getting over its effects' due to difficulties in obtaining alcohol as a result of their status as minors, rather than due to a compulsive pattern of use, which is the intended meaning of the symptom. In addition, some youth may report

symptoms of dependence (e.g., withdrawal) at relatively low levels of use. Careful querying is needed to ensure that the adolescent understands what is being asked, particularly for relatively complicated phenomena (e.g., clinically significant tolerance, withdrawal) in order to avoid false positive symptom assignments and over-diagnosis.

Epidemiology

The prevalence of substance use rises steadily over ages 12–21, then levels off after young adulthood. There are two periods of peak risk for substance use initiation. One risk period occurs in early adolescence, around ages 13–14, coincident with pubertal maturation, and the other period occurs during the transition from late adolescence to early adulthood, around ages 18–21. The substances most commonly used by adolescents (ages 12–18) include alcohol, tobacco, and marijuana. The sequence of substance use initiation typically begins with use of alcohol and tobacco, which may be followed by use of marijuana, and possible progression to use of other illicit drugs. The 'gateway hypothesis' has been proposed to explain the fairly predictable sequencing of substance use initiation, and states that use of a substance early in the sequence leads to the use of the next substance in the sequence. Support for the gateway hypothesis has been debated, since environmental factors such as drug availability may influence the sequence of drug use initiation for a given individual. Regardless of the actual temporal ordering of substance use initiation, progression to higher levels of use within a type of substance, or to the use of other types of substances, is probabilistic, and not inevitable.

Initiation of alcohol use by early adolescence (e.g., prior to age 15), although relatively infrequent, has been associated with greater risk for subsequent development of an alcohol use disorder. Results from Monitoring the Future (MTF), a national school-based survey, indicated that in 2009, 15% of 8th graders, 30% of 10th graders, and 43% of 12th graders reported alcohol use in the past month. Early exposure to alcohol may reflect alcohol use in a religious context, or only sips or tastes of alcohol. However, the particular concern with respect to early exposure is when a young person engages in a risky pattern of alcohol use, which involves consumption of five or more drinks in a row, a pattern described as 'heavy episodic drinking' or 'binge drinking.' Data from the 2008 National Household Survey on Drug Use and Health (NSDUH) indicate that 9% of youth (ages 12–17) reported an episode of heavy drinking in the past 30 days. Although the prevalence of episodic heavy drinking among adolescents has gradually declined in the past decade, the absolute prevalence of this risky pattern of alcohol use among youth in recent years remains cause for concern.

According to the 2008 NSDUH, the prevalence of illicit drug use among 12–17 year olds has declined significantly in recent years, from 12% in 2002 to 9% in 2008. However, 2009 MTF data suggest that the prevalence of marijuana use may be increasing slightly among adolescents, in tandem with a decline in adolescents' beliefs regarding the risks associated with marijuana use. Among illicit drugs, marijuana is the substance used most often by adolescents. In 2008, 7% of 12–17 year olds reported marijuana use, whereas use of cocaine or heroin was reported by <1% of youth. Although,

overall, marijuana is the illicit drug used most often by adolescents, there are important age differences in the type of substance most often used. Among 12–13 year olds, nonmedical use of prescription medication (e.g., pain relievers, tranquilizers) was slightly more prevalent than marijuana use (in 2008: 1.5% vs. 1.0%, respectively). In contrast, among 14–17 year olds, marijuana was the illicit drug most often used (in 2008: 5.7% among 14–15 year olds, and 12.7% among 16–17 year olds), followed by nonmedical use of prescription medication (3.0% among 14–15 year olds, and 4.0% among 16–17 year olds). The age differences in the relative prevalence of types of illicit drug use emphasize the importance of evaluating non-medical use of prescription medication, particularly among younger adolescents (ages 12–13), who may have access to prescription medications (e.g., opiate-based pain relievers, sedatives) in their homes.

Among adolescents who progress from initial use to SUD, the time to onset of SUD occurs, on average, within 3 years of first use of a substance. The relatively rapid progression to SUD among adolescents underscores the importance of early detection and intervention to prevent escalation of substance use. The prevalence of SUD increases with age through adolescence, and reaches a peak in young adulthood. In 2008, 7.6% of 12–17 year olds met SUD criteria in the past year, compared to 20.8% of 18–25 year olds. The most common SUDs among youth aged 12–17 involve alcohol, marijuana, and tobacco. From 2002 to 2008, the prevalence of alcohol abuse or dependence among 12–17 year olds declined from 5.9% in 2002 to 4.9% in 2008. Over the same time period, abuse or dependence on illicit drugs also declined from 5.6% to 4.6% among 12–17 year olds, primarily due to a decline in marijuana use disorders. Among past month cigarette users aged 12–17, one out of three adolescents was estimated to be dependent on nicotine. In addition to youth who met criteria for an SUD, an additional 17% of adolescents were estimated to be ‘diagnostic orphans,’ who reported substance-related problems, but did not meet criteria for a SUD. Limited information from national survey data exists on the proportion of youth who meet criteria for more than one SUD. Youth who meet criteria for at least one SUD may engage in a pattern of polysubstance use, typically involving use of alcohol, marijuana, and tobacco. Adolescent polysubstance use suggests a concentration of substance-related problems within a subgroup of youth who often experience problems with several substances that have negative effects on multiple areas of functioning (e.g., at home, at school, legal involvement).

The gender gap in substance use prevalence, whereby males generally had higher prevalence of substance use compared to females, has narrowed in recent years, particularly among adolescents. In the 2008 NSDUH, among 12–17 year olds, the proportion of current drinkers was similar for males and females (14.2% and 15.0%, respectively). Likewise, there was little difference in the prevalence of current cigarette smoking among males and females (9.0% and 9.2%, respectively) in this age group. Male and female youth also had similar rates of illicit drug use (9.5% and 9.1%, respectively). Although males had slightly higher prevalence of marijuana use compared to females (7.3% and 6.0%, respectively), females had higher prevalence of nonmedical use of prescription drugs (3.3% and 2.5%, respectively). With regard to prevalence of SUD, adolescent females

had slightly higher prevalence (8.2%) of past year substance abuse or dependence compared to males (7.0%), although there was little difference by gender in rates of illicit drug use. The narrowing of the gender gap in rates of substance use, with females surpassing males in rates of use for certain substances (e.g., misuse of prescription drugs) and in meeting criteria for SUD, calls for increased efforts to reduce adolescent substance use, particularly among adolescent females.

National survey data indicate some ethnic differences in substance use prevalence. Among 12–17 year olds, for most substances, American Indian and white adolescents generally had the highest rates of use, followed by Hispanic and black youth, and Asian youth tending to report the lowest rates of substance use. In 2008, 17.2% of American Indian adolescents and 16.3% of white adolescents reported recent alcohol use, compared to 14.8% of Hispanic youth, 10.1% of black adolescents, and 5.7% of Asian youth. For illicit drugs, past year use, which primarily involved marijuana, was reported by 31.3% of American Indian youth, 19.7% of white adolescents, 17.6% of black youth, 18.8% of Hispanic adolescents, and 9.8% of Asian youth. In parallel with the relative prevalence of substance use across ethnic groups, white adolescents had higher rates of past year SUD compared to black and Hispanic youth (9%, 5%, and 7% respectively). The higher rate of SUD among white youth reflects the higher prevalence of alcohol use disorders in this subgroup. Ethnic differences in the prevalence of substance use and SUDs suggest the potential utility of culturally tailored prevention and intervention efforts.

Etiology

Developmental contexts and transitions in biological, psychological, and social domains that are unique to adolescence influence the emergence and progression of substance involvement. In particular, ongoing brain development during adolescence involves a normative delay in the maturation of behavioral inhibitory systems in relation to neural systems associated with reward processing. The relative immaturity of inhibitory control systems during adolescence has been proposed to underlie a developmentally normative increase in risk taking and sensation-seeking behavior, such as substance use during adolescence. Pubertal maturation during early adolescence also may contribute to risk for initiating substance use, particularly among early maturers, who may have greater access to substances through affiliation with older peers. In addition, animal models suggest that adolescents tend to be less sensitive to the sedative effects of certain substances (e.g., alcohol) compared to adults. Adolescents’ lower sensitivity to alcohol’s sedative effects helps to explain the pattern of heavy episodic drinking observed among adolescents in both animal models and humans. These biologically based aspects of development, which occur during adolescence (e.g., relative immaturity of inhibitory control systems, early pubertal maturation, adolescent sensitivity to drug effects), foster conditions associated with peak risk for initiation to substance use. Although experimentation with substance use typically begins in adolescence, heavy substance use at a time when the brain is continuing to develop has been associated with possible neurocognitive impairment and multiple adverse outcomes (e.g., substance-related injury, impaired school performance).

A developmental model of substance involvement proposes that risk and protective factors influence the onset and escalation of substance use during adolescence. Risk factors (e.g., substance using peers) predict onset and progression of use, whereas protective factors (e.g., parental monitoring) interact with risk factors to delay the onset of substance use and reduce the likelihood that substance use will escalate. The main domains of risk and protective factors include those associated with the individual (e.g., genetic liability for substance use disorder, temperament, co-occurring psychopathology, reasons for use, stressful life events), family environment (e.g., parental substance use, availability of substances in the home), peer relations (e.g., substance using peers), and school and neighborhood contexts (e.g., drug dealing that occurs in the neighborhood). These factors are organized in a hierarchical, nested structure, such that some individual factors (e.g., temperament, attitudes toward substance use) are generally more strongly predictive of substance use than the immediate social environment (e.g., family, peer group), and the school or neighborhood contexts within which an adolescent is embedded. These interacting systems operate at multiple levels (e.g., ranging from public policies and media exposure to peer norms and family rules regarding substance use) in influencing an adolescent's risk for substance involvement over time.

Risk and protective factors interact dynamically to influence adolescent substance use. For example, risk and protective factors may evolve over time (e.g., parental monitoring may decrease with age), may have developmentally specific effects (e.g., transition to high school or college) or persistent effects (e.g., sequelae of sexual or physical abuse), or be differentially salient at certain points in development (e.g., increasing salience of peers, relative to family, with age). Some risk factors may be specific to a certain substance (e.g., positive attitudes toward alcohol use), whereas others may increase risk or protection across substances more generally (e.g., parental neglect). Factors that predict transitions between levels of use within a given substance also may differ (e.g., social reasons for use may predict early onset of substance use, whereas coping reasons for use may predict progression to heavy use). Some research suggests that the cumulative number of risk factors, more than any specific type of risk factor, predicts level of substance involvement in adolescents. A developmental model of substance use recognizes individual differences in the timing and pace of development, and multiple pathways toward and away from substance involvement. In addition, the risk and protective factors that influence the course of substance involvement may differ across subgroups, defined for example, by gender and ethnicity.

Treatment

Few adolescents meet criteria for a DSM-IV SUD report receiving treatment. Among youth ages 12–17, <1% received treatment for substance use, although 8% had a DSM-IV SUD. In part, the discrepancy between the proportion of youth with an SUD and the proportion who receive treatment occurs because adolescents seldom initiate treatment. Most youth in publicly funded treatment are court-mandated to treatment, or are referred by the school or family. In accord with typically short histories of substance use and emerging substance-related problems, the majority of adolescents are treated in

outpatient programs. Youth with more chronic, heavy patterns of substance use, who have not been able to reduce use as outpatients, may benefit from more intensive intervention offered in residential treatment. Adolescents (ages 12–17) represented 12% of admissions to publicly funded substance abuse treatment in 2007. Two out of three youth who presented to treatment for substance use in 2007 reported cannabis as their primary drug, 8% reported alcohol, 2% reported opiates, and 2% reported cocaine as their primary drug.

Substance use treatment for adolescents has largely been adapted from programs shown to be effective with adults. The most widely used treatments for adolescent substance use include the Minnesota Model, which is based on the Twelve Steps of Alcoholics Anonymous; CBT focused on relapse prevention, motivational enhancement interventions, and family-based interventions. Specialized programs, such as multi-systemic therapy, also have been developed to address the multiple treatment needs (e.g., family, psychiatric, legal) of substance using youth in the juvenile justice system. Studies of the effectiveness of pharmacological treatment for adolescent substance use are limited. No single type of treatment for adolescent substance use has been shown to be clearly superior to any others. The role of external pressure in bringing adolescents to treatment suggests the importance of increasing adolescents' readiness to change substance use behavior, and of motivational enhancement interventions in facilitating reductions in substance use. For youth who experience problems in multiple areas of functioning, a comprehensive and coordinated set of interventions is needed to facilitate positive outcomes. Adolescents may require more than one episode of treatment to facilitate the long-term maintenance of treatment gains.

Treated adolescents generally show reductions in substance involvement compared to pretreatment levels of use, as well as improvements in psychosocial functioning. However, individuals show different trajectories of posttreatment substance involvement. Following treatment, prototypical short-term trajectories of substance involvement include stable low, stable high, increasing, and decreasing patterns of use. Most youth are in stable low or decreasing use trajectories immediately following treatment. Longer-term trajectories treated youth followed into young adulthood include stable abstinence, infrequent use, gradually decreasing substance involvement ('slow improvers'), and persistent high substance involvement. Most adolescents who followed into young adulthood were 'slow improvers' or infrequent users, with smaller proportions in the stable abstinence and persistent high substance involvement trajectories. For polysubstance users, treatment tends to have a generalized, rather than substance-specific effect on substance use (e.g., alcohol and marijuana tend to change together). Individuals in stable abstinence and low substance involvement trajectories after treatment generally had better emotional, interpersonal, and family functioning in young adulthood compared to those in chronic use trajectories. Improvements in school functioning tend to occur early, roughly within a year after treatment, while improvements in other areas, such as family relations, tend to emerge 2 years after treatment. Although many treated adolescents show reductions in substance involvement and improvement in psychological and social functioning, treated adolescents continue to show greater overall impairment in functioning compared to a community

comparison sample over long-term follow-up. Adolescent-onset SUD can delay or disrupt the development of cognitive and social skills, with effects that persist into adulthood.

Predictors of adolescent treatment outcomes have been examined at the time of treatment admission, during treatment, and following treatment. At treatment admission, the presence of co-occurring psychopathology, such as conduct problems, depression, and symptoms related to sexual or physical abuse, signal risk for a persistent pattern of substance use. During treatment, factors that have been associated with better outcomes among adolescents include longer duration of treatment, treatment completion, greater readiness to change substance use, and family involvement in treatment. Although treatment may help to increase or maintain an adolescent's motivation to reduce substance use, the nature of the adolescent's environment (e.g., family, peers) and activities (e.g., leisure time activities) outside of treatment is essential to maintaining treatment gains over time. Posttreatment factors associated with better outcomes among adolescents include aftercare involvement, low levels of peer substance use, and continued commitment to abstain from substance use.

More chronic and severe trajectories of substance involvement may reflect the impact of co-occurring psychopathology (e.g., conduct problems, depression) in complicating the course of recovery. Not only does co-occurring psychopathology affect treatment outcomes, but it also may play a role in the timing of SUD onset, the rate of SUD development, severity, and duration. The co-occurring conditions most commonly associated with adolescent substance involvement include conduct problems, mood disorders (e.g., depression), ADHD, and physical or sexual trauma. A majority (roughly 60%) of adolescent substance users in a community sample were found to have a coexisting psychiatric condition, such as ADHD or conduct disorder. Among youth in substance use treatment, more than half are estimated to have one or more of these coexisting disorders. Comprehensive interventions that address the substance problems and co-occurring problems are indicated to support long-term positive outcomes in youth with coexisting conditions.

Pathological Gambling

Clinical Characteristics and Definition

Gambling is the act of wagering or betting money or something of value on an event with an uncertain outcome with the intent to win more money or things of value than was wagered. Gambling involves risking something of value, including money, for the chance of winning more than you risked. For adolescents, gambling is viewed as an adult activity that they can participate in fairly easily, such as playing poker for money with their friends, and without upsetting their parents too much, "Oh, they are only playing cards, good, I was afraid they were smoking or drinking." Gambling behavior among adolescents ranges from no gambling to experimentation to occasional or regular social gambling to excessive and problematic gambling. This continuum is skewed toward most youth gambling rarely or occasionally and some youth gambling excessively. Adults play commercial or legal forms of gambling such as slot machines at casinos or buy lottery

tickets, whereas youth tend to play informal games amongst themselves such as poker or betting on sports or games of skill such as video games. The legal age for gambling varies across jurisdictions but is most commonly between 18–21 years of age. Some youth celebrate reaching the legal gambling age birthdays by visiting a casino. Some underage youth play commercial games such as the lottery by obtaining lottery products from legal-age gamblers, including family members.

Adolescents can exhibit pathological gambling or gambling addiction. There is not a separate or different definition of pathological gambling for adolescents; however, it is exhibited slightly differently in youth. For example, an adult pathological gambler may be absent from work in order to gamble, whereas an adolescent may be absent from school in order to gamble. Adults may lie to their spouse about their gambling, whereas adolescents may lie to their parents about their gambling. Adults may spend their paycheck on gambling when the money is supposed to pay for food and housing, whereas Adolescents may wager their pocket money or their iPod or video game player. Adolescent gamblers cannot lose their house, or spouse or family, or file for bankruptcy, but they can exhibit adolescent-specific adverse consequences. Gambling at any group is considered to be a problem when it interferes with the individual's relationships with friends and family or their school and work obligations. Adolescent problem gambling has been characterized as persistent gambling behavior that leads to negative personal consequences, including the loss of money and things of value, and negative consequences to the person's social network including the alienation of family and friends. Not only can early gambling lead to later gambling problems, gambling during the formative years can lead to current gambling problems.

A small number of youth gambling assessment instruments have been developed to assist clinicians in identifying youth who may have a gambling problem. For example, a recently developed instrument was created specifically for adolescents, the Canadian Adolescent Gambling Inventory (CAGI). It contains items associated with symptoms of pathological gambling, such as preoccupation, loss of control, and chasing one's gambling losses by accelerating one's gambling involvement.

Epidemiology

It is important to examine the larger cultural context in which gambling occurs. The gambling industry has experienced unprecedented expansion in the past three decades. Commercial gambling in the United States has expanded out beyond Atlantic City, New Jersey and Las Vegas, Nevada to nearly every convenience store across America and nearly every computer with access to the internet. Gambling is advertized in all forms of media and youth are exposed to this promotion on a daily basis. The availability of gambling venues varies by region, such as state lotteries or tribal casinos, but commercial gambling has become much more accessible to the general public in the past 30 years. The gambling industry is also enjoying a more favorable public image as a socially acceptable activity for the general public as opposed to its public image in the past as a vice. Citizens are encouraged to gamble by their state

governments that benefit from the proceeds. With this rapid growth of the gambling industry and the shift from a negative to a positive public sentiment toward gambling have come concerns about youth gambling.

Most youth have gambled at least once in their lifetime. The National Research Council recently reviewed existing youth surveys and reported that between 39% and 92% of youth reported gambling at least once in their lifetime and that the median rate was 85%. In terms of recent gambling, the NRC concluded that between 52% and 89% of youth have gambled in the past year and that the median rate was 73%. Whereas the majority of youth have gambled in their lifetime and in the past year, most do not experience any adverse consequences from their gambling. Gambling for most youth is an infrequent and inconsequential past time. Gambling for some youth is part of adolescent experimentation with adult behaviors, for example, some adolescents celebrate reaching the legal gambling age with a visit to a casino.

While the literature is fairly consistent about the extent of youth gambling participation, there is much less agreement on the prevalence of problem and pathological gambling among youth. Rates of past year pathological gambling range from as low as 0.3% to as high as 9.5% with a median of 6%. Rates of combined past year problem and pathological gambling range from 11.3% to 27.7% with a median of 20%. The estimates of lifetime problem and pathological gambling range from 7.7% to 34.9% with a median of 15.5% (NRC, 1999). For lifetime PG only, estimates range from 1.2% to 11.2% with a median of 5%. These wide-ranging estimates are thought to be largely due to using different methodologies, such as telephone versus in-school survey administration, different assessment tools, and different cut scores.

Nevertheless, these and other surveys provide some consistent findings: the majority of youth have gambled in the past year, more boys engage in gambling than girls, older youth tend to gamble more than younger youth, a small percentage of youth are frequent gamblers, and an even smaller percentage may be considered problem or pathological gamblers.

A related epidemiological issue is whether rates of youth gambling is on the rise. A recent review of youth gambling surveys around the globe found that the evidence for changes in youth gambling rates over time is mixed and varies by location and methodology. For example, an examination of a series of youth surveys in the state of Minnesota concluded that there has been a decline in general gambling participation rates from 1992 to 2007. Another informative survey is from the Annenberg Foundation; since 2002 they have conducted annual telephone surveys of about 900 youth in the United States between the ages 14 and 22 (www.annenbergpublicpolicycenter.org). They recently reported weekly card playing among 14–17 year old boys peaked in 2005 and has continued to decline in 2006, 2007, and 2008. The Minnesota survey found a similar trend with respect to card playing. It would appear that youth gambling, including problem gambling, while showing occasional fluctuations for specific games, for the most part has not been on the rise over the past two decades. While this is good news, there still remains a small but significant portion of the youth population who are excessive gamblers and who are experiencing adverse consequences as a result of their gambling.

Etiology

Research into the etiology of youth problem gambling is in its infancy. The most common etiology studies are those that look at psychosocial correlates of youth problem gambling. These studies have found a number of correlates including being male, antisocial behavior, peer deviance, tobacco use, alcohol use, drug use, parental/familial gambling, school behavior problems and academic failure, and impulsivity.

Also, there is emerging evidence that genetic factors may contribute to adolescent gambling behavior. Family studies have shown that problem gambling is familial; adolescent problem gamblers are more likely to report having at least one parent with a history of problem gambling compared to nonproblem adolescent gamblers, and twin studies have shown that genetic factors influence gambling behaviors among young adult males.

Another etiological factor to consider with youth gambling is indirectly provided by research that has shown that youth problem gambling is associated with other psychiatric disorders, including other addictions, mood disorders, and ADHD. It is thought that problem gamblers seek out the stimulation of gambling because their natural resting state is one of being either under stimulated or over stimulated. For example, depressed individuals may seek out gambling for stimulation and hyperactive individuals may seek out gambling to calm their senses by focusing on the gambling activity. One study found that young problem gamblers also reported having ADHD symptoms and another study found that young adults with childhood ADHD symptoms that persisted into young adulthood reported greater gambling problem severity than young adults with no ADHD or those with childhood ADHD that did not persist into young adulthood. This research suggests that young problem gamblers may have impulse control deficits and these deficits may have a neurological or biological basis. Further research will be required to examine the neurological basis of impulse control deficits in young problem gamblers, but there appears to be a link between impulse control and executive function deficits and adolescent problem gambling.

Another possible determinant of youth problem gambling is the widespread and growing availability of legal forms of gambling. Gambling is now available in nearly every convenience store and every computer connected to the Internet. This widespread availability has the added effect of a growing social acceptance of gambling. Where gambling was previously considered a vice and participation was discouraged, it is now considered entertainment and participation is encouraged. While most jurisdictions have age restrictions for legal forms of gambling, underage adolescents have found ways to participate, such as having legal-age adults buy lottery tickets for them.

The adult etiological literature points to the importance of cognitive distortions or illusions in the development of problem gamblers, and these factors have been discussed in light of adolescent problem gambling as well. Cognitive distortions associated with gambling involve the following: an illusion of control where the individuals believe they can control the outcome of a gambling event; the false or mistaken belief that the person can win money playing games of chance; a failure to understand the laws of probability, odds, and independence of random events; and a tendency to underestimate one's losses and overestimate one's wins.

A final etiological consideration pertains to neurodevelopment. As we noted in the introduction, recent advances in understanding important neurodevelopmental events during adolescence occur in brain regions associated with motivation, reward, and decision making. It has been hypothesized that the relative immaturity of these developing brain regions may contribute to adolescent impulsivity and risk taking, including gambling. Clearly, a common factor thought to underlie gambling is the tendency toward general risk taking and a lack of control of one's impulses. Gambling is a risky activity, and in that respect is similar to other high-risk behaviors such as tobacco use, alcohol use, drug use, and unprotected sexual activity.

Treatment

There has not been much attention given to treatment for youth problem gambling in the literature. This would seem contradictory given that on the one hand, we have estimates of youth problem gambling that are higher than adult estimates. On the other hand, we have few if any adolescents presenting themselves for treatment services. There are several possible explanations for this disparity: youth problem gambling rates may be inflated due to biases in survey tools; youth are less likely to present themselves for treatment of any disorder, problem gambling included; and parents – a main referral source for teenagers receiving clinical care – are not very likely to recognize problem gambling in their child or they do not consider gambling as a risk behavior that merits concern. Regardless of the apparent discrepancy in youth and adult prevalence rates, there have been some efforts to examine adolescent treatment options for problem gambling. Treatment options for adolescents, like assessment tools, are typically adaptations of adult methods. Current research work in this area is on the development of behavioral treatment methods.

The reality is that there are few treatment programs for adolescent problem gamblers. However, there are several efforts to protect youth from the negative consequences of problem gambling with primary prevention efforts. These efforts have fallen into two camps, either abstinence or harm reduction. Abstinence approaches attempt to delay the onset of gambling in order to reduce gambling problems. Harm reduction approaches attempt to promote responsible gambling behavior and enhance skills needed to maintain control when gambling through teaching youth about the facts of gambling as well as the risks associated with gambling. This approach also addresses the cognitive distortions and misperceptions that youth may have about gambling, such as a belief that they are 'lucky' and therefore can win money gambling. Also, some programs take a broader approach by targeting a number of related high-risk behaviors such as tobacco use, alcohol use, drug use, along with gambling. Most youth problem gambling prevention programs have not been rigorously evaluated and therefore, there is a need for the systematic evaluation of these programs.

Summary

Adolescence is a developmental period that involves significant biological, psychological, and social changes, including rapid growth in physical and mental capabilities. This is also a period

of increased sensation-seeking behavior, such as use of drugs and alcohol. Nearly half of all teenagers have tried at least one illicit drug, and three out of four have used alcohol by their senior year.

Recent advances in developmental psychopathology have lead to a greater understanding of many knowledge areas of adolescent addictive disorders, including prevalence, clinical course, and treatment. We have focused here on three core addictive disorders for which a relatively large empirical literature exists – nicotine, other psychoactive substances, and gambling. Beyond these disorders, other adolescent behavioral 'indulgences' are emerging in the research and clinical literatures. These include internet addiction, excessive video game playing, and sex addiction. Clinical, epidemiological, and treatment perspectives on the full spectrum of addictive disorders in adolescents will benefit from continued research and clinical work.

Adolescence

S L Gray, C L Culpepper and D P Welsh, University of Tennessee, Knoxville, TN, USA

© 2012 Elsevier Inc. All rights reserved.

Adolescence is the transitory period between childhood and adulthood. This period is characterized by biological, cognitive, social, and psychological development. Historically, this period of development has been described as tumultuous, which is sometimes attributed to increased emotions and an undeveloped prefrontal cortex. Empirical research has shown that adolescence is not characterized by the degree of 'storm and stress' that was once believed. Nonetheless, adolescence is a period in which there is a tremendous amount of growth and change in adolescents. The purpose of this article is to provide an accurate account of adolescent development. This article will review the primary changes that occur within an adolescent as well as the contextual factors that influence and facilitate those changes.

Primary Changes in Adolescence

During adolescence, youth experience a multitude of changes. These changes affect their physical appearance, cognitive development, and emotional development. Moreover, they not only affect the individual, but also the relationships and networks built with others. The first part of this article examines the primary changes that take place in adolescence, and the possible effects of those changes. It is important to note that although these changes apply to all adolescents, the rate and pattern of changes varies between individuals.

Biological Foundations

The transition from childhood to adolescence is clearly identified by the biological changes occurring on the inside and outside of a child's body. These hormonal and bodily changes make up the developmental stage called puberty, which typically occurs during early adolescence. The onset of puberty is predominantly determined by genetic patterns, but can also be affected by environmental factors. Historically, the onset of puberty has been known to begin between 9 and 16 years of age. Most commonly, puberty begins at age 11 for females and at age 12 for males. The onset of puberty has decreased markedly over the past decades but has recently leveled off.

Puberty is characterized by a fluctuation in hormones, which are chemicals secreted by the endocrine glands. The endocrine system controls the hormonal changes associated with puberty using a negative feedback system. When hormonal levels fall too low, the endocrine system reacts to the low level of hormones by causing the release of more hormones into the bloodstream. Specifically, the hypothalamus, located in the brain, responds to the decreased level of hormones in the blood system by releasing substances that stimulate the pituitary gland, which is also located in the brain. The pituitary gland then stimulates the gonads (the ovaries in females and the testes in males) to release more sex hormones. When the level of sex hormones falls too low, the

hypothalamus and pituitary gland stop stimulating the gonads and they stop producing sex hormones. With the onset of puberty, the levels of sex hormones in the body increase substantially. At puberty, the hypothalamus becomes desensitized to sex hormones and requires a significantly higher level of hormones in the body before the hypothalamus and pituitary gland stop stimulating the gonads to release more hormones.

There are two types of hormones that are known to affect puberty differently in males and females: androgens and estrogens. Androgens are male sex hormones and estrogens are female sex hormones. Testosterone, an androgen, plays a major role in male pubertal development; while, estradiol, an estrogen, plays a major role in female pubertal development. Nonetheless, both males and females have androgens and estrogens.

Weight, body fat, and a hormone called leptin are correlated with the onset of puberty. Higher weight and a higher percentage of body fat have been linked to early pubertal development, especially in females. Adolescents living in developing countries without enough food for adequate nutrition begin puberty earlier than adolescents in developed nations. Leptin is also thought to signal the beginning and the progression of puberty. Levels of leptin, which are higher in females than males, are linked to the amount of body fat in females and the amount of the hormone androgen in males. An increase in leptin is thought to signal an adequate amount of body fat for reproduction.

There are some sociocultural and environmental factors that have been linked to the onset of puberty. Researchers have found that cultural differences and early experiences may be correlated with the early onset of puberty. Empirical findings suggest that the absence of a father, geographic distance between family members, child mistreatment, and low socioeconomic status (SES) have also been linked to early onset of puberty.

Cognitive Development

The transition from childhood to adolescence is also marked by changes in cognitive development. There are distinct structural changes in the brain that occur during adolescence. These changes are seen in the corpus callosum, prefrontal cortex, and amygdala. The corpus callosum connects the right and left hemispheres. During adolescence, the corpus callosum thickens, which improves the adolescent's ability to process information. An adolescent's prefrontal cortex, which houses reasoning, decision-making ability, and self-control, continues to develop during adolescence. Responsible for emotion regulation, the amygdala matures earlier than the prefrontal cortex. Empirical evidence has shown that although adolescents experience a vast array of emotions, the prefrontal cortex continues to develop well into adulthood; therefore, adolescents may not have as much control over their emotions as they will when their prefrontal cortex is fully mature.

In the past, researchers thought that brain cells could not be generated after early childhood, but recent research has discovered that people produce new brain cells throughout their lives. Factors such as exercise can aid the brain in producing new cells. The adolescent brain also has some plasticity. In childhood as well as adolescence, the brain is able to repair itself. However, the earlier a brain injury occurs, the more likely that recovery will be successful.

Several theories have been used to explain brain development from childhood through adolescence. One of the most prominent theories, articulated and investigated by Jean Piaget, proposed that adolescents work to understand their world because the making of meaning is hardwired and serves a biological purpose. Adolescents construct their world using schemas, defined as mental concepts or frameworks that help organize and understand information. Adolescents use assimilation (incorporation of new information) and accommodation (the adjustment to new information) to organize their schemas.

Piaget articulated four stages that describe cognitive development: sensorimotor, preoperational, concrete operational, and formal operational stages. The formal operation stage is typically reached during adolescence. This stage consists of reasoning in abstract, idealistic, and logical ways and is characterized by the development of problem-solving skills and formation of hypotheses.

Lev Vygotsky introduced a theory that views knowledge as situated and collaborative. Specifically, Vygotsky believed that knowledge is distributed among people and their environments and knowledge can best be attained through interaction with others through cooperative activities. Vygotsky emphasized the social contexts of learning. One of his most important concepts is the zone of proximal development (ZPD). ZPD describes a range of tasks that require assistance from adults or mature peers.

In later years, other theories were developed that spoke of the use of information processing and psychometric testing to assess adolescents' cognitive development. However, Piaget and Vygotsky's theories are still commonly used to explain adolescent cognitive development. All of these views take into account the genetic as well as the environmental influence on adolescent cognitive development.

Identity

As puberty occurs and cognitive processes are developing, adolescents are also forming a sense of self. An adolescent's sense of self consists of his or her identity. Identity incorporates self-understanding, self-esteem, and self-concept. Self-understanding is an individual's cognitive representation of the self. The development of an adolescent's self-understanding is complex and can be affected by many internal and external factors. Adolescents, unlike children, describe themselves within various contexts. Research on adolescence has shown that an adolescent's sense of self can fluctuate. This sense of self can also be contradictory, because of the multiple roles adolescents play in different relationship contexts. One explanation for this contradiction can be found in the real versus ideal theory. This theory states that adolescents have an ideal or imagined self and this ideal view of themselves contradict their actual view

of themselves. Some theorists believe that this contradiction is maladaptive, while other theorists believe that this contradiction can provide motivation and drive toward future goals.

Adolescents, unlike children, often compare themselves to their peers, are more self-conscious, and more preoccupied with their self-understanding. Even though most adolescents employ introspection, they also look to their friends and other peers for self-clarification and self-definitions. In Eastern countries, adolescents may also tend to look to family members to aid with this process as their cultural norms place a high value on family relationships and social categories. This search for self-clarification and self-definition can affect the adolescent's self-esteem and self-concept. There is evidence to suggest that adolescents have a lowered sense of self-esteem when compared to children, and this decline usually occurs in middle school. Male adolescents usually report higher self-esteem than female adolescents, but this gender-gap typically decreases as adolescents move into adulthood.

Erik Erikson proposed a theory of human development that consists of eight stages. Most adolescents, he believed, fall within his fifth stage: identity versus identity confusion. Erikson proposed that during this stage, adolescents have to decide their identity, their goals and causes, and the direction of their life. Erikson believed that adolescents experiment with many different roles and identities while they are trying to 'find themselves'. He labeled this exploratory period as a moratorium period. If adolescents use adaptive methods to explore their identity, they will achieve identity formation. If adolescents use maladaptive methods to explore their identity or they do not explore their identity at all, they will experience identity confusion.

James Marcia empirically investigated Erikson's ideas and identified four statuses, which help to simplify Erikson's theory. The four statuses, identity diffusion, identity foreclosure, identity moratorium, and identity achievement, capture the adolescents' exploration of alternatives and commitments toward a direction in life. This construct of identity is biased toward the Western, masculine ideals of individualism, as opposed to relatedness. Adolescents from Western countries may conceptualize identity achievement as a self-directed objective in which individualization and independence is highly valued. However, adolescents from Eastern countries may conceptualize identity achievement as more relational and interdependent. Some research has shown that individual characteristics are valued in Eastern countries; however, these characteristics tend to be more collectivistic in nature and place higher values on attending to others, fitting in, and harmonious interactions.

Although different cultures place differing values on an individual's characteristics, the function of self-definition in regard to identity development can be seen across cultures. Recent views of identity development propose that it is a gradual process that continues into adulthood. It is important to study adolescent identity development because during adolescence, youth begin to integrate the physical, cognitive, and emotional development, forming a better understanding of their sense of self.

Moral Development

Moral development can be defined as thoughts, behaviors, and feelings regarding standards of right and wrong. There have

been numerous theories of adolescent moral development, but one of the most influential theories was created by Lawrence Kohlberg. Kohlberg's theory of moral development emphasizes adolescents' reasoning about moral issues. He proposed that the way in which an individual reasons changes throughout life and his model includes six sequential stages of moral development. Kohlberg studied the moral reasoning of fifty males over the course of 20 years and there was clear evidence that each participant followed the same developmental sequence through the stages of moral development. His participants did not skip any of the developmental stages and there was no regression. Empirical evidence also suggests that the stages are culturally universal, especially the first four stages. This research also suggests that the rate of development and the final stages that people achieve vary between individuals and groups.

Kohlberg's model consists of three levels of reasoning about moral issues: preconventional reasoning, conventional reasoning, and postconventional reasoning. Within each level are two stages. In the preconventional reasoning level, moral reasoning is controlled by external, concrete consequences. People functioning at this level of development make moral decisions based on whether they will be rewarded or punished by their decisions. Youth, in the beginning stages of adolescence, are usually at this preconventional level of reasoning. In the conventional reasoning level, moral reasoning is controlled by internal and external factors. Moral decisions at the conventional level are based on conforming to and upholding the rules, expectations, laws, and conventions of society. Most adolescents are said to be at this level of reasoning. The third level of reasoning, postconventional reasoning, is thought to be achieved at or after the age of 20. This level is characterized by moral principles that are internalized. Moral decisions at the postconventional level are based on understanding society's rules, then formulating and internalizing a personal moral code that emphasizes principles of justice: individual rights, equality, and human dignity and a concern for the welfare of the larger community.

Carol Gilligan has argued that Kohlberg's orientation toward justice represents a male perspective that is more commonly found in Western cultures. Gilligan proposed that moral development is built on a concept of care. This type of morality focuses on responsibility to others, values relationships, and seeks to help. The concept of care also emphasizes sensitivity to social context, whereas justice emphasizes the application of rules and principles. Gilligan believes that conceptualizations of morality as care based represents a more female perspective, as well as the perspectives of societies that value collectivism.

Other theories of moral development emphasize moral behavior instead of moral reasoning. The social cognitive theory of moral development assesses the difference between the adolescent's ability to produce moral behavior (moral competence) and his or her ability to implement moral behaviors in specific situations (moral performance). Social cognitive theorists believe that the adolescent's moral performance is not guided by abstract thinking, but by rewards, punishments, and motivation.

Behaviorists also emphasize moral behavior. These theorists use imitation, rewards, and punishment to explain why adolescents display different moral behaviors. When adolescents are

positively reinforced (rewarded) for a behavior that is considered moral, they are more likely to repeat that behavior. When adolescents are punished for a morally unacceptable behavior, they are more likely to decrease that behavior. There are other factors and situations that mediate these processes. Empirical research has found that adolescents will not display the same moral behavior when put in diverse social settings. For example, an adolescent is more likely to cheat if being pressured by a peer. Even though other factors may affect the outcome, overall adolescent moral behavior can be predicted by reinforcement.

Moral development, like so many other areas, does not begin in adolescence and will not end in adolescence. It is important to study moral development during adolescence because cognition, identity, and other parts of the adolescent are actively developing during this stage as well. Adolescence is an important developmental stage because there are so many internal and external influences that are at work during this period of life.

Contextual Areas of Interest Regarding Adolescent Development

Adolescent development can be affected by numerous contextual factors. The context in which an adolescent grows up, the experiences they face, and the situations they encounter will frame their development as they approach adulthood. Because adolescents will experience different contextual factors under different situations, it is important that each of these factors be explored. The remainder of this article highlights contextual factors regarding family, peers, romantic relationships, school, work, and cultural concerns.

Family

One of the most important contextual factors that can affect adolescent development is family dynamics. Research has shown that parents have a significant effect on the ways in which adolescents develop. Previously, adolescent relationships with parents were conceptualized as tumultuous and generally full of conflict. However, research over the past several decades has revealed that relationships are more positive and less tumultuous than previously considered. Although adolescence is a time of self-exploration and emerging autonomy, parents who respond in an understanding manner to the changes adolescents face generally experience less turmoil in the home. In addition, parents who expect that adolescence will be a tumultuous experience are more likely to have adolescents who experience more conflictual family relationships. The guidance provided by parents during this time period is crucial in helping the adolescent transition into becoming a responsible adult. Parents aid in this transition by helping the adolescent form his/her own moral standards, in addition to supporting, encouraging, and providing learning opportunities for them.

Parenting styles

Different parenting styles may be an important contextual factor in terms of adolescent development. Parenting styles have been

conceptualized into four different categories (authoritarian, authoritative, indulgent/permissive, neglectful) that range on levels of responsiveness and control. Authoritarian parents tend to take a more unresponsive, or parent-centered role, and are generally demanding while exerting a high level of control over their children. Their adolescent children tend to be dependent, submissive, and overly conforming in the presence of their parents and other authorities. However, when out of the presence of authorities, these adolescents tend to be rebellious, defiant, hostile, and resentful. In contrast to authoritarian parents, indulgent/permissive parents tend to take a more responsive, or child-centered role, and are generally undemanding while exerting a very low level of control over their children. Adolescent children of indulgent/permission parents tend to lack self-regulation skills, and often disregard rules and regulations. Because they are used to getting their way, they generally are not as socially adept as other adolescents. Neglectful parents are generally unresponsive to their children, while also being undemanding and showing little control. Adolescents who grow up in these families tend to suffer the most as they may get into a lot of trouble and engage in more risky behavior. These adolescents also tend to be self-rejecting and may feel inferior to others. In contrast to neglectful parents, authoritative parents are responsive, accepting, and child-centered, while also setting clear limits for their children. This authoritative parenting style has been found to be associated with more positive adolescent developmental outcomes. Adolescents from these families tend to be more socially and academically competent. They also exhibit higher levels of self-esteem and demonstrate more person control than other adolescents. It is important to note that these parenting styles are not always completely independent of one another. Parents may mesh different styles together and/or use different styles with different children. Interestingly, even within the same family unit, parents may be utilizing completely different parenting styles. For example, an indulgent/permissive mother, paired with an authoritarian father, may cause an adolescent to experience a great deal of uncertainty and confusion.

Attachment styles

During adolescence, early attachment styles begin to shift in accompaniment to adolescents' need for autonomy. Although, it is normal for adolescents to feel a desire to remain close to their parents, their emerging adolescent attachment style does not require as much dependency on their caretaker. However, having a secure base in which to return is key as adolescents make the journey toward becoming more autonomous, or independent. Early attachment theorists John Bowlby and Mary Ainsworth put forth that developing a secure attachment to caregivers as an infant serves as a foundation that adolescents use for healthy psychological development. The development of a secure attachment allows children to feel safe while exploring their environment. Insecurely attached adolescents avoid or distance themselves from their parents, show an unusual amount of fear toward their parents, or show ambivalence or resistance toward their parents. However, it is important to note that normal adolescent attachment functioning can falsely resemble this insecure attachment style (which has developed from infancy and early childhood). Adolescent attachment theorists highlight that adolescence is a period in which attachment styles transform from hierarchical

parent-child attachments to codependent peer-peer attachments (in which both persons offer and receive support). In adolescence, with the goal of autonomy and self-other differentiation in mind, attachments with peers become a main focus. Even under distressing situations, adolescents may purposefully resist seeking comfort from parents as they are striving for autonomy. This purposeful distancing may be experienced as uncomfortable by both parents and adolescents at times and represents a transforming shift in attachment style from infancy and early childhood. Because adolescents are in a transition period, this shift in attachment needs can be conflicting and confusing. As adolescents distance themselves from adult caregivers, they are able to explore more of their emotional interior and problem-solving techniques on their own. Knowing that adult attachment figures are readily available when necessary helps facilitate this process. Early attachment styles and adolescent attachment experiences with peers can color the way in which adolescents experience the world around them and typically guide adolescents' expectations regarding future relationships with other people. Adolescents who developed a secure attachment to their parents from early childhood show more self-confidence, have better peer and romantic relationships, and are less likely to engage in behavior problems such as juvenile delinquency and drug abuse compared with insecurely attached adolescents.

Siblings and birth order

Having siblings can greatly impact the development and experiences of an adolescent. In American households, about 80% of adolescents have siblings. Research has shown that siblings are often utilized as a source of support for adolescents. Communication between siblings usually occurs more naturally, and the exchange of information is more direct than with parents. Adolescents may confide in a sibling in order to discuss difficult or taboo topics, relying on the experience and/or opinions of a sibling. However, although siblings may serve as sources of support for each other, sibling conflict is not uncommon. Chronic conflict among siblings can have a negative effect on adolescent development, especially when the parent's relationship with the adolescent is also tumultuous. Studies have found that depression among adolescents is higher when sibling conflict is reported at greater frequencies. Sibling conflict tends to be higher when parents treat siblings very differently and favor one sibling over another. Sibling conflict tends to decrease in adolescence compared with childhood probably because siblings spend less time together during adolescence than in childhood. As adolescents begin to emerge into adulthood, conflictual relationships with siblings tend to further decrease, and the intensity of tension between siblings may diminish.

Birth order has also been noted by many for its impact on adolescent development. Although there is some inconsistency in the findings regarding the effects of birth order, a few trends are noteworthy. Typically, firstborns are held to a higher standard of social, academic, and professional accomplishments than their younger siblings. This is commonly felt and expressed by firstborns as a theme of their childhood and adolescent years. Conversely, lastborns tend to be perceived as the perpetual 'baby' of the family. Some siblings may complain about the lastborns' ability to become self-sufficient and

independent, especially when parents are indulgent toward their lastborn. In general, middle children are characterized as being the negotiators of the family. Additionally, middle children are generally noted to have problems gaining equal attention from their parents; thus, they may engage in more problematic or attention-seeking behavior. These trends in birth order are not always representative of all families, and many exceptions can be found across siblings.

Family structures: Divorce and stepfamilies

With the divorce rate being over 50%, many adolescents are reared in single-family homes, blended homes, or other non-traditional living situations. One study estimated that nearly 40% of children born into intact families will eventually become children of divorced families. Divorce can disrupt the connection between adolescents and parents, causing a rift during key adolescent developmental phases in which parent connection is desirable. Most research regarding adolescent development in the context of divorce has shown negative outcomes for adolescents, especially when compared to adolescents from intact homes. Although most adolescents go through a difficult period, in which their functioning is impaired immediately after the divorce, most return to normal functioning after a brief period of disruption. The majority of adolescents from divorced families are functioning and developing normally after adjusting to the family transition. However, small subsets of adolescents continue to experience prolonged distress. Research suggests that high continued parental conflict following divorce is associated with poorer adolescent functioning.

School

Adolescents spend a very large percentage of time at school with teachers and peers. The type of school an adolescent attends, and the experiences he or she derives from that school will have an effect on their development and future transition into adulthood. Specifically, school size, teachers, and peers are factors that may contribute to an adolescent's school experience. Previously, educational psychologists focused heavily on classroom climate and how students fit with their classmates. Now, researchers study the social climate of the school, in addition to individual factors that may affect students. For example, smaller schools have been linked to increased amounts of prosocial behavior. Arguably, smaller classrooms also provide an environment that encourages a higher standard of teaching and learning. Many students may feel lost in the crowd at very large middle and high schools. This feeling may overwhelm many students, discouraging them from finding their niche, or becoming involved in activities. Isolated students may be left behind educationally and socially, which leaves these students more susceptible to joining antisocial peer groups or cliques.

Teachers not only serve as persons who provide formal education for adolescents, but many times these individuals also serve as additional role models and mentors for students. Their classroom management strategies help students learn time management skills and self-monitoring techniques, in addition to learning actual classroom material. Skilled teachers

plan classroom activities in a manner that challenges students, and generally prevents academic and emotional problems. Adolescents who are in well-managed classrooms may show greater levels of autonomy, self-confidence, and academic achievement.

Peers make up a large amount of an adolescent's school experience. While it is not uncommon for adolescents to occasionally report feeling ostracized at school, or feeling isolated, it is of concern if these negative experiences become common. Peers may engage in teasing or other antisocial behaviors, especially in larger schools with less monitoring capabilities. Bullying is the act of physically or emotionally hurting another peer, generally at school. A national survey showed that approximately one-third of adolescents were either being bullied, or were themselves bullies. The most common form of bullying is disparaging comments about looks or speech. Almost equal to that, adolescent girls report being the subject of sexual comments and gestures. The effects of bullying can be harsh for some adolescents. A few studies have found that common consequences of continued bullying involved depression, lack of interest in school, suicidal ideation, somatic complaints, and/or avoidance techniques. Research has also found that a large number of boys who bully others in middle school are likely to be convicted of a criminal offense in early adulthood.

Although school can be a negative experience for many adolescents, these experiences may be altered with individual attention and focus on academic and social competence. This is especially true for adolescents from lower SES backgrounds. Because these adolescents may have underlying barriers to academic achievement, additional tutoring and social integration is required. Some students may find school difficult due to learning difficulties, or problems with attention disorders. While larger schools tend to be less desirable due to subsequent large classroom and less individualized programs, some larger schools may be able to provide more resources to students with these types of learning difficulties. In addition to the formal education process, schools are an important contextual factor regarding adolescence because they provide a platform for career exploration, friendship development, and extracurricular activities.

Work

Most late adolescents have a part-time job in addition to attending school. Working can allow adolescents to develop professional skills, a strong work ethic, and can help with money management. The money earned from a part-time job also can also provide adolescents the freedom to purchase personal consumer items (e.g., trendy clothes, music, etc.). Depending on the place of employment, working may also serve as another source of social integration. Many adolescents work in establishments that also employ many of their peers. Thus, work may allow adolescents the opportunity to socialize with peers who are not in their network of friends.

Despite the fact that numerous benefits to working exist, several negative factors are also associated with working. In general, for most adolescents, as the number of hours spent working increases, school grades suffer. This is especially true for adolescents working more than 20 h per week. Typically,

adolescents who must balance school and work often must sacrifice one for another. A homework assignment may go unfinished in order to work a shift; or conversely, a work shift may be skipped in order to pull an all-nighter on a homework assignment. Although having a balance between work and school can be beneficial, it starts to become problematic when ongoing sacrifices must be made in either domain. Adolescents who work may not be able to participate in extracurricular activities or sports that require a large time commitment.

Peer Relationships

Friendships

Peer relationships, including close friends and romantic partners, are an extremely important contextual factor for adolescents. Different from childhood, adolescents spend a much greater amount of time interacting with their peers. One study found that adolescents were spending about 2 times as much time with their peers than their parents, even over weekends, outside of formal school time. Adolescents have the most contact with their peers during school hours; however, they also spend time with friends after school, and may develop friendships through church, work, or extracurricular activities.

Peers relationships serve numerous purposes for adolescents. A basic purpose of peer interaction is social integration. It is important for adolescents to feel wanted and included in social groups. Persons who are socially integrated show fewer psychological signs of distress, including depression. Peer relationships also provide a context for developing social skills. Adolescents learn how to interact with others by learning how to maintain their own friendships. Peer relationships allow adolescents to navigate through conflict management, listening, empathy, and intimacy skill building.

The importance of friendship can be summarized within six basic domains: companionship, stimulation, physical support, ego support, social comparison, and intimacy. The variety of these domains demonstrates the importance of close friendships for adolescents. Contributing more heavily to the developmental goals for adolescence, ego support, social comparison, and intimacy are particularly noteworthy. Friends provide reassurance, support, and encouragement during times of uncertainty for many adolescents. This ego support allows adolescents to maintain a reasonable level of self-esteem. Friends also provide a source of social comparison, such that adolescents can gauge themselves against friends. Adolescents engage in social comparisons for a variety of reasons, including identity development, and may be interested in how their academic achievement, body image, popularity, and romantic involvement compares to others. Lastly, adolescents are starting to develop intimate, close relationships with their peers. These intimate relationships allow adolescents the ability to explore self-disclosure and trust.

Because adolescent peer relationships serve so many important functions, it is also important to understand why many adolescents do not achieve close friendships. Sociometric status refers to the degree to which adolescents are liked or disliked by their peers. This concept is gauged by asking participants to rank order and nominate other peers for 'most-liked' and 'least-liked' roles. Five different categorizations of peers have been established: popular, rejected, and

neglected. Popular individuals are often nominated as someone's best friend, and typically do not receive many 'least-liked' votes. They tend to be good communicators, enthusiastic, confident, and happy. Their internal states and external behaviors both contribute to their ease in developing close friendships. Conversely, rejected individuals receive many 'least-liked' votes and few best friend votes and tend to be characterized as aggressive, arrogant, tactless, and annoying. Neglected adolescents do not receive either 'best friend' or 'least-liked' votes and tend to be overly timid, shy, or lacking in enthusiasm. Rejected adolescents tend to be lonelier than neglected adolescents and are more likely to develop psychological problems. As loneliness is a rather subjective experience, some research suggests that there are cultural differences regarding how isolation is experienced. However, adolescents do universally demonstrate a need for belonging and acceptance.

Groups, crowds, and cliques can develop as a means of inclusion, and exclusion, for many adolescents. Groups tend to form around a similar purpose, activity, or special interest. For example, athletic teams, religious groups, and clubs can all make up a group. These groups have social norms and roles that members follow in order to be included. Groups can infuse a sense of companionship, purpose, and accomplishment among adolescents. Group membership may provide a certain level of intrinsic satisfaction, in addition to extrinsic rewards for participation. Groups comprising different clubs, organizations, and teams are typically associated with positive psychosocial developmental outcomes.

Crowds are entities that tend to form based on reputation, and membership may be involuntary. These classifications make up terms such as the, 'jocks,' 'goths,' 'preppies,' etc. Adolescents may belong to a crowd based on the type of behaviors they engage in (e.g., 'druggies'), their SES standing (e.g., 'preppies'), or their level of social integration (e.g., 'nobodies'). These large collections of individuals may not interact and/or socialize together, although smaller branches of friendships (groups or cliques) may develop within the crowd.

Cliques are smaller, more intimate, sets of friends that may have formed based on inclusion in a larger group or crowd. Cliques tend to involve no more than 12 people (typically about 5 or 6 people), and mostly comprise adolescents who attend school together. Both positive and negative outcomes can be associated with the development of cliques. Because of the in-group and out-group processes, some adolescents may feel socially isolated if they are not members of a social clique. Cliques may also encourage antisocial behavior, such as teasing, toward others who are not members of a particular clique. However, cliques do allow small groups of friends to become closer, which can serve as an additional support system for many adolescents.

Peer relations are also influenced by gender, SES, and culture. Adolescents tend to select friends who are similar to themselves in age, gender, SES, and ethnicity. Girls tend to focus more on interpersonal interactions within their friendship, striving to maintain high levels of intimacy and self-disclosure; while boys tend to focus more on activities, giving less attention to self-disclosure and intimacy. Adolescents from middle and upper SES groups tend to be more socially integrated and take more leadership roles within friend groups. Those from lower SES groups, or those from minority groups, may seek friendship

among themselves. Groups and cliques that form based on minority or cultural status may serve as a source of social integration and to ward off isolation.

Romantic relationships

In addition to the development of more intimate and consistent bonds with peers for the purpose of developing friendship, adolescence is a time in which peers can also serve as possible romantic partners. It is not uncommon for adolescents to identify themselves as 'dating,' 'having a boyfriend/girlfriend,' or 'going-out with someone.' One study found that among 17-year-olds, ~70% reported that they were currently in a romantic relationship, or had been within the previous year and a half. Thirty-six percent of 13-year-olds, and 53% of 15-year-olds, also reported romantic relationships in that study. Comparisons across studies have been difficult due to differing language usage among researchers. For example, some studies may ask, 'Are you in a serious relationship,' while other studies may ask, 'Are you involved romantically with another person?' These questions may elicit different responses, thus making the empirical comparison of data difficult. Nevertheless, numerous studies have emphasized the importance of understanding the development of romantic relationships in adolescence.

Adolescent romantic relationships are characterized as having many different functions. In addition to courtship for the purposes of marriage, these relationships can also serve as a platform to further explore the socialization process. Dating may also assist with building intimacy, companionship, identity, and achievement. Further, adolescent romantic relationships provide an arena for sexual experimentation and sexual identity development. Adolescence is a time of exploration within numerous fields, and romantic relationships can aid in that exploration process.

Early adolescents (ages 10–13) tend to spend more time simply thinking about potential romantic interests rather than actually interacting with them. At this time, adolescents are still acquiring basic skills regarding how to interact with potential romantic partners. As they are exploring their initial attractions to romantic partners in general, they are also making social comparisons to their friends' 'progress' in this dimension. Early adolescents who get involved early in dating and sexual relationships are at risk for problematic developmental pathways involving problems with alcohol, drugs, truancy, and educational underachievement. Middle (ages 14–17) and late (ages 18–21) adolescents tend to engage in more formal dating practices and sexual behaviors. Adolescents who begin dating later rather than earlier, and engage in sexual behaviors only in the context of dating relationships, are not more likely to show problematic behaviors than their nondating peers. Findings also have suggested that 'light' sexual behaviors (e.g., hugging, kissing, etc.) among adolescents are linked to more committed relationships and healthier relationships with parents. Heavy sexual behaviors (e.g., intercourse) were not linked to any higher levels of psychological distress or behavior problems in late adolescence. Late adolescents may engage in sexual behaviors as a sign of their commitment and intimacy.

Most research regarding adolescent romantic relationships and sexual behaviors focus on mixed-gender relationships. However, although many sexual minority adolescents in

same-gender romantic relationships will undergo similar experiences, these adolescents may also experience more difficulties interpreting their feelings and behaviors within the context of societal norms and expectations. Research has shown that many individuals identify their first same-sex experience (i.e., attraction, behavior, self-labeling) during adolescence. Unfortunately, many sexual minorities risk experiencing verbal and physical abuse, which may encourage sexual minority adolescents to feel uncomfortable proclaiming their romantic and sexual orientations.

Culture and Social Trends

From a holistic perspective, the concept of culture encompasses any specific group's way of thinking and being including their cultural norms, values, and beliefs that are passed on from one generation to the next. Not all individuals who associate with a particular culture will continuously identify with their group's norms, values, and beliefs. It is not uncommon for individuals to question or reject certain aspects of their cultural background. These rejections, or cultural violations, may not be well received by others within their cultural group. However, individuals may develop a strong sense of ethnocentricity especially during adolescence. In other words, they may begin to favor their own cultural group over others.

SES and ethnicity

Historically and globally, two groupings that have been commonly used to establish culture are ethnicity and SES. Ethnicity is typically based on an individual's race, religion, heritage, and/or language. An individual's SES, or class, is typically based on an individual's economic, occupational, and/or educational status. Because adolescents often have similar occupational and educational statuses, their SES classification is based upon their parent's status within these areas. Research has shown that an adolescent's ethnicity and SES may have an effect over their development. One study found that adolescents who come from impoverished families, and who reside in crime-ridden neighborhoods, are at greater risk for negative developmental outcomes, including higher levels of psychological distress and poor academic success. Additionally, research has also shown that parents from higher SES groups are less likely to utilize authoritarian parenting styles and physical punishment. Conversely, lower SES parents were found to utilize more directive parenting strategies and physical punishment.

The culture of SES can also affect an adolescent's development by encouraging or discouraging self-efficacy and self-gratification. For example, parents from higher SES groups are more likely to encourage their children to explore, take initiatives, and delay gratification. Self-exploration and delayed gratification expectations are likely to encourage children to stay in school longer, and obtain higher paying jobs that value critical thinking skills, autonomy, and creativity. Conversely, parents from lower SES groups are more likely to be concerned with conformity and discipline. These trends within lower SES communities may stem from concerns regarding employment, safety, and a general ability to care for self and family. Additionally, persons from lower SES communities typically hold jobs in

which autonomy and creativity are not valued. Therefore, the ability to conform and be disciplined is highly desirable. It is not uncommon for parents to pass these values and expectations, based out of SES backgrounds, onto their children. Notably, however, parents from lower SES groups who place a high value upon education are more likely to have children who achieve a high level of academic success, which can later provide higher paying careers.

In addition to SES, ethnicity also may play a significant role in adolescents' lives. Because ethnic minority groups are more likely to experience poverty, many issues surrounding ethnicity tend to be confounding factors that overlap with SES issues. Ethnic minorities may be unjustly categorized as 'inferior' in educational or occupational realms as a result of their ethnic makeup. However, it has been commonly found that environmental and economic factors account for a large amount of ethnic minorities' difficulties within these areas. Nevertheless, ethnicity within itself may also play a significant role in adolescents' lives. Ethnic minority adolescents are often at risk for experiencing the effects of negative stereotypes and prejudice. These experiences, which may include unwarranted teasing and harassment, can cause ethnic minority adolescents to experience greater levels of psychological distress and feelings of inadequacy.

Media

Today's adolescent is likely to be extraordinarily technologically savvy. Adolescents are large consumers of a variety of different media outlets, including television, computers, cell phones, video games consoles, CD/MP3 players, and digital cameras. Nearly a culture within itself, technology has shaped and guided the way in which adolescents experience the social world around them. With approximately two-thirds of adolescents having a television in their bedroom, it is not surprising that time spent watching television still takes up the greatest portion of an adolescent's daily activities outside of school. Increased levels of television consumption are generally associated with lower academic success, more passive learning styles, and less active lifestyles. Generally, late adolescents make a shift from television consumption toward other media outlets, such as computers and CD/MP3 players. Researchers have recently noted a significant increase in the amount of time adolescents spend on the Internet. Many adolescents use the Internet for a variety of reasons, including entertainment, social, and academic purposes. Although Internet use can be extremely beneficial to adolescents, certain concerns regarding exposure to inappropriate material exist. Among adolescents, about 44% have visited a sexually explicit adult website; and about 25% have visited a website containing racially motivated hate material. Many adolescents use the Internet to visit social networking websites, such as Myspace and Facebook. These websites allow adolescents the opportunity to socialize and interact with peers over an electronic format. Although enjoyed by the majority of adolescents, these websites can also facilitate passive-aggressive 'web-fights,' or cyber-bullying between peers, and may serve as a source of stress for a portion of adolescents.

Overall, culture and social trends not only have an effect on adolescent development independently, but also can affect how other contextual factors are manifested. Families, friendships, romantic relationships, work, and school can all be affected by

an adolescent's culture and prevailing social trends. For example, an adolescent's culture may dictate certain expectations regarding romantic relationships and dating scripts to which adolescents must adhere. Social trends, such as the popularity of cell phones, texting, and the use of social networking websites (i.e., Facebook and Myspace) greatly affect the manner in which adolescents communicate with parents and peers.

Summary

Adolescence is a transitory period in which an individual shifts from childhood into adulthood. For most, this period is a time of physical, social, and emotional changes. The development that occurs within adolescence is key in setting the stage for adulthood. The age range when an individual will experience adolescence will vary depending on maturity and cultural norms. However, researchers have recently begun to conceptualize adolescence as spanning more years than previously believed. Because adolescence is filled with ambiguity and uncertainty in many areas, self-exploration and identity development are important goals within this transitory period. Although a portion of adolescents will experience a significant amount of turmoil during this time that may interfere with healthy development, most will make the transition into adulthood successfully.

Glossary

Anabolic process A metabolic process that builds molecules from smaller units.

Catabolic process A process that releases energy in the form of ATP through the breakdown of larger molecules into smaller units.

Catecholamines A class of neurohormones, including epinephrine, norepinephrine, and dopamine, that are involved in various central and peripheral processes.

Glucocorticoids A class of steroid hormones that act to maintain glucose homeostasis and circadian rhythm, contribute to carbohydrate metabolism, and are involved in

arousal, stress response, and cognitive functions such as mood and memory.

Gluconeogenesis The production of new glucose molecules that are utilized in metabolic processes.

Hyperplasia Abnormal increase in proliferation of cells in organs or tissues that is above what is considered normal.

Metabolism The sum of all catabolic and anabolic processes that occur within an organism to help sustain life.

Type II diabetes A disorder that is characterized by insulin resistance brought on by chronically elevated blood glucose levels, stress, obesity, and other factors.

Introduction

The adrenal gland and its hormones are responsible for many functions that ultimately impact human behavior. The release of adrenal hormones into the peripheral bloodstream impacts global functioning, starting with changes in cellular metabolism and expanding to include alterations in mood, alertness, and attention that in turn lead to measurable changes in behavior. Examining the influence of hormones released from the adrenal gland on homeostatic processes, as well as the consequences of disease states that hinder normal adrenal functionality, demonstrates the importance of this endocrine gland and its many chemical messengers.

The purpose of this article is to discuss the role of the adrenal gland and its function in human behavior. An overview of the organization and anatomy of the adrenal gland is given, followed by an explanation of the hormones associated with the different parts of the adrenal gland. Hormone synthesis and release and the regulation of glucocorticoids, aldosterone, androgens, and catecholamines are described. The impacts of these hormones on metabolic functions, mood, and reproduction are also discussed.

Anatomy and Physiology of the Adrenal Gland

The adrenal glands are small endocrine organs located directly above the kidneys. The adrenal gland is made up of the inner adrenal medulla encased by the outer adrenal cortex. These regions are morphologically distinct and produce hormones that play important roles in essential physiological processes, including stress response, regulation of blood pressure, and production of sex hormones. The following sections discuss the hormones associated with the adrenal cortex and the adrenal medulla. The synthesis of these hormones and their receptors is discussed, as well as the connections of the adrenal cortex and adrenal

medulla to the hypothalamus–pituitary–adrenal (HPA) axis and the sympathetic nervous system (SNS), respectively (Figure 1).

Adrenal Cortex

The cortex of the adrenal gland is responsible for the synthesis and secretion of glucocorticoids, aldosterone, and dehydroepiandrosterone (DHEA). It consists of three layers: the zona glomerulosa, the zona fasciculata, and the zona reticularis. Each layer is responsible for different functions associated with the synthesis and release of certain hormones. The zona fasciculata is responsible for the storage and release of glucocorticoids; the zona glomerulosa is responsible for the synthesis and release of mineralocorticoids; and the zona reticularis is responsible for the release of androgens.

Glucocorticoids

Glucocorticoids (i.e., cortisol and corticosterone) are produced in the zona fasciculata of the adrenal cortex and are synthesized from plasma cholesterol. Glucocorticoids are vital to the circadian rhythm, glucose metabolism, arousal, and cognitive functions, such as memory and mood. Cortisol is also the main hormone associated with the physiological stress response in humans, whereas corticosterone is the hormone equivalent to cortisol in most rodents. However, in humans, corticosterone is a precursor in the synthesis of aldosterone, which is discussed later. When cortisol is synthesized, it begins with the conversion of cholesterol to pregnenolone and then it is converted to 17 α -hydroxypregnenolone. This is then converted to 17 α -hydroxyprogesterone and then to 11-deoxycortisol, which is converted to cortisol.

Glucocorticoids are released following activation of the HPA axis and are considered an integral part of the body's response to a stressor. Though there has been much debate about what a stressor is in relation to the individual, for the purposes of this article a stressor is defined as either an environmental or psychological occurrence that activates the stress response (i.e., the HPA axis and the sympathoadrenal

[†]Deceased.

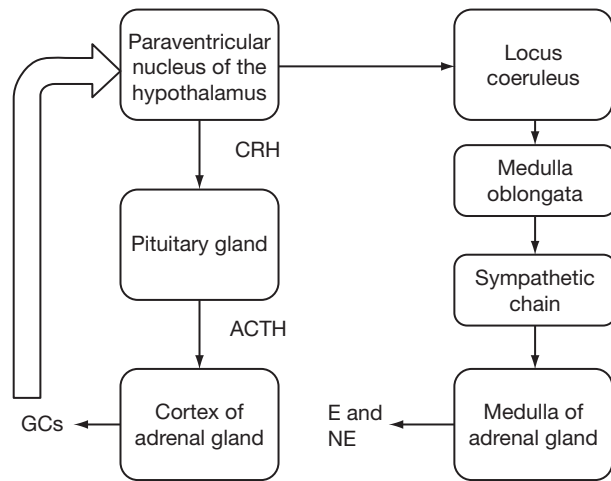

Figure 1 Overview of the hypothalamus–pituitary–adrenal axis and sympathetic nervous system in relation to the stress response. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropin hormone; GCs, glucocorticoids; E, epinephrine; NE, norepinephrine.

medullary (SAM) system). When a stressor is perceived, the paraventricular nucleus (PVN) of the hypothalamus is activated, causing the release of corticotropin-releasing hormone (CRH). CRH is released through the blood into the hypothalamic–pituitary portal system, where it travels to the pituitary gland. Once in the anterior pituitary gland, adrenocorticotropin hormone (ACTH) is released. ACTH travels via the bloodstream to the adrenal cortex where it binds to the melanocortin 2 receptors (MC2-R), activating glucocorticoid release via a second messenger pathway.

The release of cortisol from the adrenal cortex is regulated by the ACTH that is released from the anterior pituitary gland following release of CRH from the hypothalamus. When ACTH is released from the pituitary gland, ACTH binds to the MC2-Rs located on the zona fasciculata cells of the adrenal cortex. This receptor is a G protein-coupled receptor, which when activated causes an increase in intracellular cyclic adenosine monophosphate (cAMP) to activate protein kinase A (PKA). Activation of PKA causes two distinct cellular responses that allow for more cholesterol to be used for the synthesis of adrenal hormones. First, this converts cholesterol esters into free cholesterol that can be used for creating glucocorticoids. Second, the increase in free cholesterol increases the steroidogenic acute regulatory protein (StAR) expression, allowing for an increase in cholesterol being transported to the mitochondria, which is then converted into pregnenolone.

Once released from the adrenal cortex, glucocorticoids (primarily cortisol in humans; corticosterone in rodents) travel throughout the body via carrier proteins in the bloodstream. Normally, the vast majority of cortisol in humans travels bound to transcortin (also called corticosteroid-binding protein, CBP), an α globulin protein, or by serum albumin, a nonspecific steroid hormone carrier. These carrier proteins are produced primarily in the liver instead of the adrenal gland and can be influenced by liver disease as well as estrogen levels during pregnancy. In addition to cortisol, transcortin also binds to progesterone, aldosterone, and its precursor 11-deoxycorticosterone, while serum albumin is involved in

maintaining osmotic pressure as well as binding to substances such as fatty acids, thyroid hormones, and other fat-soluble compounds. Normally, cortisol remains bound and inactive until reaching the target tissue, with less than 10% of available hormone free to bind glucocorticoid receptors (GRs) so that the pool of available hormone remains steady in spite of changes in the level of hormone being released from the adrenal cortex. However, under conditions of severe stress or during certain disease states (such as sepsis), the level of glucocorticoid production may increase above the capacity of available carrier proteins, increasing the proportion of free hormone and enhancing its impact.

Once free glucocorticoids reach a target tissue, they bind to intracellular transcription factor proteins known as GRs, which are part of the family of nuclear receptors that bind steroid and thyroid hormones, as well as vitamin A metabolites. Typically, these receptors remain in the cytoplasm, bound to a hetero-oligomeric group of proteins that occlude the DNA-binding regions but leave the ligand-binding site open. When glucocorticoids enter the cell and bind to the GR, a transformational change occurs and the GR dissociates from the protein complex, exposing the DNA-binding regions. The receptor enters the cell nucleus and binds to the promoter regions of target genes that contain glucocorticoid-response elements (GREs) that influence the expression of several gene products such as those involved in immunosuppression, anti-inflammatory activities, and the creation of adipose cells. After binding has occurred, the receptor dissociates from the GRE and remains in the nucleus for an extended period before returning to the cytoplasm. There are also nongenomic effects of glucocorticoids, which occur rapidly and can affect cell membrane properties through activation of membrane-bound or intracellular GRs. Although the mechanisms of these effects are not entirely clear, studies of isolated synapses have revealed unique binding sites for steroid hormones in presynaptic terminals that could directly modify neurotransmitter release and other activities dependent on calcium levels directly. For example, the administration of exogenous glucocorticoids led to increased aggression in male rats and enhanced lordosis responses in females within minutes, an effect not seen when other steroid hormones were administered (such as testosterone or estradiol). Such effects are considered nongenomic because they occur much faster than processes that rely on the GR complex and because pharmacological blockades of GRs do not eliminate these effects.

Cortisol is one of the few hormones that have a circadian rhythm associated with basal levels. This hormone has an increase in levels just before a person wakes up in the morning, roughly 1–2 h before awakening. Cortisol levels continue to oscillate throughout the day, with their lowest levels being around the beginning of the sleep cycle, usually the beginning of the dark cycle. This rhythm was once believed to be regulated by the suprachiasmatic nucleus (SCN), which received input about the light/dark cycle via input from the retina. It has been shown that those who are completely blind do have circadian rhythms controlled by the SCN; however, their rhythms are usually either shorter or longer in duration than those who have functioning retinas. In addition, lesion studies of the SCN have shown that the cortisol circadian rhythm continues to occur, indicating that this circadian rhythm is

not solely regulated and controlled by the SCN. It is unclear how this particular rhythm is maintained without the SCN and what additional areas of the brain may be involved in the maintenance of circadian rhythms, specifically the cortisol rhythm.

The effects of acute stressors tend to differ from those seen following chronic stress. The stress response system was designed to maintain homeostasis during times of crisis, but when chronically activated, dysregulation and damaging effects may occur. The hippocampus is particularly vulnerable to the negative effects of chronic stress. Trauma in early life is associated with dysregulation of the HPA axis such that these individuals are more prone to high stress reactivity and blunted negative glucocorticoid feedback, as well as increased vulnerability to anxiety, mood, and substance abuse disorders. The extent of this dysregulation can be seen in animal subjects exposed to early life stress, where evidence of neuronal loss and reduced dendritic volume is present in the adult hippocampus. The loss of hippocampal neurons is also associated with chronic illnesses such as depression, where it is associated with cognitive dysfunction. Normally, the hippocampus can regenerate neurons and dendrites to repair damage following trauma, but in the brains of individuals under chronic stress or disease, these processes are blunted and damage persists.

Glucocorticoids and behavior

Glucocorticoids not only play a vital role in stress response but also produce widespread effects physiologically and behaviorally. As described earlier, the level of glucocorticoids in the bloodstream fluctuates based on circadian rhythms. The maintenance of a normal circadian pattern of glucocorticoid release is necessary for physical and mental health.

Individuals with inherited or acquired pathologies of the glucocorticoid system suffer from a variety of negative symptoms and physical effects. The following section examines the behavioral impact of glucocorticoids in normal individuals, as well as the consequences of disease states affecting this system.

Several genetic mutations that result in varying levels of transcortin deficiency, which either decrease the binding affinity for cortisol or result in complete loss of transcortin production, have been discovered in humans. Clinically, these individuals presented with depression, fatigue (especially when stressed), hypotension, and other symptoms of adrenal insufficiency, despite tests demonstrating that cortisol levels in the bloodstream were low-normal or normal. These genetic anomalies could be a possible factor in poorly understood conditions, such as chronic fatigue syndrome and some idiopathic chronic pain disorders, and the importance of maintaining normal free glucocorticoid levels should be emphasized in clinical settings.

Normal GR functionality is vital for an effective and timely response to glucocorticoid release. In humans, mutations in the gene coding for the receptor can selectively alter the binding properties of the GR, leading to glucocorticoid insensitivity in target tissues that express mutated GRs. This condition leads to excess activation of the HPA axis, increased levels of ACTH release, adrenal hyperplasia, and excessive production of all cortical steroids. In some of the milder cases, the mutation results in lower GR-binding efficacy and the effects are beneficial to the individual: increased glucocorticoid resistance,

enhanced insulin sensitivity, lower fasting blood sugar, lower cholesterol levels, and a lower risk of dementia, cardiovascular disease, and type II diabetes. In addition, male carriers of these types of mutation tend to be taller and more muscular while females tend to have smaller waist sizes and weigh less. On the other hand, mutations that lead to enhanced glucocorticoid sensitivity tend to be less beneficial, producing a metabolic phenotype that increases the risk of cardiovascular disease and is associated with higher BMI, elevated cholesterol levels, and lower bone density. Individual variation in GR sensitivity may have a profound effect on overall health, and further clinical examinations could reveal important targets for treatment in affected individuals.

Glucocorticoid effects on metabolic activity Although the behavioral response to glucocorticoids is difficult to isolate from the effects of catecholamines in humans, animal studies can examine the impact of exogenous glucocorticoids in adrenalectomized or normal subjects. Such studies have revealed important physiological and behavioral aspects of the glucocorticoid system. Under normal conditions, glucocorticoids influence metabolic processes and liver enzyme production. Depending on the target tissue, these activities may be anabolic (requiring energy) or catabolic (producing energy). In the liver, glucocorticoids increase the production of enzymes necessary for gluconeogenesis (an anabolic process) while the response in muscle and adipose tissue increases the breakdown of carbohydrates, proteins, and lipids for energy in the form of adenosine triphosphate (ATP) (a catabolic process). Glucocorticoids also inhibit the activities of insulin, preventing glucose from entering cells and enhancing catabolic processes as cellular glucose levels fall. The amino acids and/or fatty acids that are by-products of catabolic breakdown exit the cell and can be utilized in the liver for gluconeogenesis. Chronically elevated glucocorticoid levels (under chronic stress conditions or glucocorticoid resistance) lead to persistent hyperglycemia and increase vulnerability to insulin resistance and type II diabetes.

Glucocorticoids are necessary to maintain homeostasis and they also play an important role in recovery in the aftermath of injury or disease. Glucocorticoids are involved in catecholamine synthesis and reuptake in sympathetic nerve terminals, which regulate the level of vascular smooth muscle tension in response to changes in blood pressure and enable blood flow to reach active tissues (such as skeletal muscle) during acute stress. Glucocorticoids also demonstrate permissive effects on the sympathoadrenal system during acute stress, allowing norepinephrine (NE) and epinephrine (E) to exert full effects on the liver, blood vessels, and other tissues. The processes that occur during the initial alarm phase of acute stress require an adequate store of liver glycogen for breakdown; free fatty acids may be used to perform gluconeogenesis, but persistent activation of the HPA axis can lead to loss of muscle tissue, hyperglycemia (leading to type II diabetes), and deterioration of immune and vascular tissues.

Endocrine functions are also influenced by social factors in human and animal populations. In societies where a strict social hierarchy exists, lower-ranking members demonstrate adrenal hyperplasia, deterioration of immune tissues, and increased vulnerability to disease. In addition, excess release

of glucocorticoids impairs the functioning of the reproductive system. In females, high levels of cortisol are associated with increased risk of miscarriage and infertility, which influences individual reproductive success.

The impact of glucocorticoids on reproductive behavior involves both physiological and psychological effects. Glucocorticoids can act directly on the hypothalamus and pituitary gland to inhibit the release of gonadotrophins or gonadotrophin-releasing hormone or interact with gonadal tissues to alter the response to luteinizing or follicle-stimulating hormones. The administration of exogenous glucocorticoids is associated with decreased gonadotrophin release, an effect which also appears in response to chronic stress but is less consistent during acute stress. Cortisol has also been shown to enhance negative feedback from estrogens and reduce its enhancement of gonadotrophin-releasing hormone receptor expression.

In females, inhibition of luteinizing hormone (LH) activity leads to inconsistencies in the reproductive cycle, including an extended follicular phase and impaired uterine maturation during the luteal phase. These effects reduce the probability of egg fertilization and implantation. Higher levels of cortisol are also associated with an increased risk of miscarriage during early pregnancy. Increased glucocorticoid release also has a marked effect on sexual receptivity and proactive behaviors that are likely due, in part, to increased vigilance and anxiety during stress as well as decreased estrogen levels in the bloodstream. Normally, estrogen acts to facilitate genital sensitivity to tactile stimulation, which enhances sexual receptivity.

For pregnancies that are carried to term, maternal stress has been associated with shorter gestation periods and smaller babies. Infants born to mothers with high cortisol levels during the third trimester tend to show more signs of negative affect (negative facial expressions, crying/fussiness) and tend to be rated as more difficult by their mothers. Maternal behaviors are also altered, with several species demonstrating less affection and infant-directed behaviors in mothers with high glucocorticoid levels. The combination of prenatal stress and distant parenting also influences the stress reactivity of the infants, causing enhanced emotionality and anxiety during infancy and increased susceptibility to mood disorders and substance abuse in adulthood.

In males, the effect of glucocorticoids on the gonadal hormones is similar, with a significant decrease in testosterone as a result. Although deficits in testosterone are not sufficient to impair fertility, reproduction is inhibited by the disruption of erectile function. Inhibition of the parasympathetic system during stress also prevents the development of an erection, and excess sympathetic activity can result in premature ejaculation if an erection forms. These effects, in addition to decreased libido, have a severe impact on reproductive capacity in males.

Mood The HPA axis influences cognition and mood through GRs and MRs located in the prefrontal cortex, hippocampus, amygdala, and limbic system. While the administration of exogenous glucocorticoids or GR agonists has been shown to enhance acute cognitive performance in some laboratory tests, assessments following chronic administration produced evidence of impaired working memory, verbal memory, learning (as assessed by repeated administration of a verbal memory

task), and memory retrieval. The effects of acute administration may be a result of temporarily enhanced vigilance and attention that is associated with the acute stress response, while repeated administration mimics the detrimental effects that result from chronically elevated glucocorticoid levels. Glucocorticoids disrupt normal metabolic activity in the hippocampus, a process that increases neuronal loss following stroke or seizure and increases the rate of loss as an individual ages. Glucocorticoids have also been implicated in increased vulnerability to neurotoxins and glutamate excitotoxicity.

GRs in the limbic system and prefrontal cortex enable HPA axis activity to influence mood and other psychological states. Disturbances in the HPA axis and glucocorticoid system are associated with mood disorders, with multiple studies demonstrating elevated cortisol levels and impaired GR negative feedback in patients diagnosed with mood disorders. Although acute administration of glucocorticoids sensitizes serotonin (5-HT)-1A autoreceptors, chronically high levels of glucocorticoids lead to desensitization and impaired functioning of these receptors has also been identified in patients with mood and anxiety disorders. Elevated cortisol appears to be a sign of poor prognosis, and these patients seem to be particularly resistant to treatment and more vulnerable to relapse. The relationship between glucocorticoids and depression is of particular interest due to the pattern of HPA axis dysregulation seen in patients with major depression. While older depression models focus on serotonin and NE, more recent studies have presented clear evidence of the relationship between the HPA axis and depression, as well as many potential targets for novel treatment. Individuals with major depression demonstrate elevated blood cortisol levels as well as glucocorticoid resistance, a condition that interferes with normal negative feedback pathways. Experimental treatment with substances that alter HPA axis activity has demonstrated positive results, but further studies are needed to identify the best possible targets and to evaluate any potentially negative effects of long-term use. In addition to HPA dysregulation, major depression is also associated with progressive degeneration of the hippocampus, amygdala, and prefrontal cortex, seen in patients with major depression. These effects are likely mediated by a combination of excess glutamate activity induced by glucocorticoid activity and a loss of gamma-aminobutyric acid (GABA)ergic and serotonergic activity, which has been shown to protect against hippocampal neuronal loss in experimental subjects.

Aldosterone

Aldosterone is classified as a mineralocorticoid, and though it is produced in the adrenal cortex, its regulation is not through the HPA axis, but rather through angiotensin II and serum potassium levels. The purpose of aldosterone is to maintain fluid and electrolyte balances within the body. Aldosterone is produced in the zona glomerulosa of the adrenal cortex. Synthesis begins with the conversion of cholesterol to pregnenolone. Pregnenolone is converted to progesterone, which is then converted to 11-deoxycorticosterone. 11-Deoxycorticosterone is converted into corticosterone and then to aldosterone.

Aldosterone release is regulated by the renin-angiotensin system of the kidney. This system is activated in response to activation of the SNS. This process begins when NE is released from the SNS and acts on the juxtaglomerular (JG) cells of

the vascular arteriole of the renal glomerulus. This causes the release of renin, which is then converted into angiotensin II. Angiotensin II travels to the zona glomerulosa of the adrenal cortex and stimulates the release of aldosterone. When aldosterone is released, it causes an increase in sodium levels within the blood, causing an increase in blood pressure. This increase in blood pressure signals the JG cells of the kidney to decrease production of renin, which in turn reduces aldosterone secretion.

The mineralocorticoid receptors (MRs) are not well understood in terms of how they are activated or even their makeup. Due to the high affinity nature of glucocorticoids to these receptors, it is unclear how aldosterone binds to these receptors in competition with other hormones. In addition, the location of these receptors has been somewhat paradoxical. The studies that have been undertaken to understand MRs have found a greater number of these receptors in the hippocampus as opposed to the epithelial tissues that mineralocorticoid hormones would target. That is not to say that these receptors do not exist in the epithelial tissue; however, their number pales in comparison to those that have been found in the hippocampus. Additional research is needed to understand how aldosterone binds to MRs, given the lower circulating levels and lower affinity to these receptors compared to glucocorticoids.

Androgens

The innermost layer of the adrenal cortex releases androgens – steroid hormones that impact the development of male sex organs and secondary sexual characteristics. The primary androgen produced by the adrenal cortex is dehydroepiandrosterone (DHEA) (and the sulfate metabolite, DHEA-S), which is a precursor to sex hormones such as estradiol and testosterone. Isolating the role of DHEA has been difficult due to the significant impact of these metabolites and the fact that no specific nuclear receptor has been identified for DHEA. Originally, DHEA was thought to be biologically inactive, serving only as an alternative source of sex hormones, but research in the last few decades has revealed important systemic and behavior effects that result from the release of this hormone.

Early research indicated a possible role for DHEA as an antiglucocorticoid hormone when it was shown that the relative balance of DHEA to cortisol is modified by stress (in favor of cortisol) and that coadministration of DHEA and dexamethasone produces a decrease in the effect of glucocorticoids on cytokine release (IL-4 and IL-6) and lymphocyte suppression. Further, the administration of DHEA impairs fear conditioning in rats through activation of sigma-1 chaperone protein receptors. The role of DHEA in glucocorticoid antagonism appears to be a vital part of the body's antistress system, despite the absence of clear nuclear receptor activities. Though its role in sex hormone production is also essential for normal functionality, DHEA is by no means an inactive precursor.

The synthesis of DHEA in the brain appears to occur independently of the adrenal gland, but its activities may also impact global functioning and thus bear mentioning. In humans, levels of DHEA in the bloodstream peak in the second decade of life, declining thereafter throughout an individual's lifetime. Evidence of DHEA-S's neuroprotective activities in the hippocampus suggests that loss of this hormone through age or chronic stress may be related to increased risk of neuronal loss. In a small study of middle-aged and older adult

patients with depression and/or low blood DHEA levels, the administration of exogenous DHEA led to temporary improvements in depression scores and enhanced some cognitive abilities during the treatment period. Unfortunately, a number of double-blind, placebo-controlled studies employing exogenous DHEA in normal, healthy, older adult patients failed to detect cognitive improvements, suggesting that not all older individuals experience behavioral or cognitive declines as a result of age-associated decreases in DHEA. Further, individuals born with a mutation in the gene for the enzyme required for the conversion of pregnenolone to DHEA demonstrate sexual infantilism, hypertension, and hyperkalemia but do not suffer from cognitive deficiencies, indicating that exposure to maternal DHEA during early development is sufficient for normal brain development; however, older adults with this condition have not been closely studied. In rodents, DHEA was found to bind to the N-terminus of microtubule-associated protein 2 (MAP2) cytoskeletal proteins in the brain, which are involved in the extension of neuronal axons and dendrites. The involvement of DHEA in neural development and plasticity may be required during early life but becomes less important after childhood, when puberty-induced changes lead to increased conversion of DHEA to sex hormones involved in the expression of secondary sex characteristics.

In addition to MAP2 binding, DHEA and DHEA-S also act as noncompetitive antagonists at GABA subtype A receptors and enhance *N*-Methyl-D-aspartate (NMDA)-mediated release of NE in hippocampal neurons through activation of the chaperone protein sigma-1. The enhancement of NMDA activities may explain some of the improvements in memory functioning seen in depressed and elderly patients, but others have suggested that cognitive changes may be due to reduced anxiety from DHEA-mediated antiglucocorticoid effects. Indeed, it was shown that the administration of DHEA in ovariectomized rats reduced behavioral signs of anxiety and was associated with enhanced learning in several maze paradigms. There is also evidence of DHEA and DHEA-S neuroprotective effects following stroke or spinal cord injury. Mice and rats treated with DHEA demonstrated significantly less white matter loss in ischemic stroke models while mice treated with DHEA in conjunction with spinal cord injury showed significant improvements in motor functionality relative to vehicle controls. Moreover, DHEA has been shown to protect against neurotoxicity induced by glutamate or amyloid β protein, which may explain why significant declines in DHEA levels in the elderly and patients with depression or posttraumatic stress disorder (PTSD) are associated with increased cognitive decline and/or exacerbated symptomatology. Decreases in DHEA levels normally associated with aging have less of a direct impact, but may increase vulnerability to neuronal loss in the presence of cardiovascular disease and/or chronic stress. Interventions to reduce chronic stress have showed that cognitive – behavioral techniques prevented HIV-associated declines in DHEA and led to increases in available DHEA in normal, healthy adults, suggesting that tipping the balance of DHEA to cortisol in favor of the former may diminish some of the negative impacts of stress. More research is needed to fully understand the mechanisms leading to age-related DHEA declines, and why most healthy, older adults do not exhibit neurological impairment as they age.

Adrenal Medulla

The adrenal medulla is responsible for the storage and release of the catecholamines, NE, and E. This article focuses on the behavioral effects of NE and E. The adrenal medulla is made up of chromaffin cells that contain granules composed of catecholamines, adenine nucleotides such as ATP, proteins, and lipids. In humans, there are two types of these cells: E-storing cells and NE-storing cells. There are subtle differences between these two types of cells. For example, E-storing cells contain more glycoprotein compared to NE-storing cells. The ratio of E-storing cells to NE-storing cells differs among species.

The synthesis of catecholamines in the sympathoadrenal system occurs in the adrenal medulla. Synthesis begins when tyrosine is converted to dihydroxyphenylalanine (DOPA) that is then converted to dopamine. Dopamine is converted to NE by the enzyme dopamine β -hydroxylase, and NE is converted to E by the enzyme phenylethanolamine *N*-methyltransferase (PNMT). PNMT is an important enzyme in the conversion of NE to E, and its synthesis is controlled by cortisol. Although 80% of the catecholamines released from the adrenal medulla are E (and 20% NE), only about 10% of circulating catecholamines are E from the adrenal medulla, indicating that extra-adrenal sources of catecholamines, especially of NE, contribute more to circulating levels.

The adrenergic receptors are G protein-coupled receptors and contain two classes of adrenergic receptors: α and β . Within the α class, there are two main types of receptors: α_1 and α_2 ; and within the β class, there are three main types of receptors: β_1 , β_2 , and β_3 . The α class of receptors share dual roles, the most notable being that of causing vasoconstriction on arteries and veins, more specifically the arteries to the heart. The α_1 receptors are mainly responsible for contraction of smooth muscle and are located on the smooth muscle in the gastrointestinal system, blood vessels, and the bronchioles located in the lungs, to name a few. These receptors also aid in sodium reabsorption by the kidneys in connection with the renin-angiotensin system. The α_2 receptors are responsible for preventing release of insulin and glucagon from the pancreas. The β_1 receptors are mostly found in the heart, where they work to increase heart rate and contractility. They are also found in the kidneys, where they work to promote the release of renin to stimulate aldosterone release. The β_2 receptors are found on smooth muscle and work to decrease gastrointestinal motility, increase vasodilation to the skeletal and cardiac muscles, and increase bronchodilation. The β_3 receptors are found in adipose tissues and work to increase fatty acids in the blood.

Connection to the SNS

The adrenal medulla, the part of the adrenal gland responsible for catecholamine release, is directly innervated by the SNS. However, during a physiological stress response, the adrenal medulla is not the only source of catecholamines. The supraspinal structures responsible for the activation and release of catecholamines from the adrenal gland begin with activation of the PVN of the hypothalamus. The PVN has catecholaminergic and noncatecholaminergic projections to the locus coeruleus (LC), which then has catecholaminergic projections to the medulla oblongata. The medulla makes projections to preganglionic fibers of the dorsal and intermediolateral gray area of

the spinal cord. There are some projections to the ventral horn of the spinal cord from the medulla; however, this is somewhat minimal. The preganglionic fibers from the medulla have cholinergic projections to the postganglionic fibers of the sympathetic chain. These postganglionic fibers directly innervate the adrenal medulla, causing the synthesis and release of the catecholamines E and NE. Additional sources of NE are released following activation of the LC and the postganglionic fibers of the SNS to the target organs.

Catecholamines and behavior

The release of E and NE from the adrenal medulla and sympathetic ganglia rapidly elicits a number of measurable changes in an individual. Specific effects within a tissue tend to be associated with the type of adrenergic receptor that is expressed by the cells. While α receptors are associated with vasoconstriction in the circulatory system (increasing blood pressure), β receptors are associated with vasodilation of the bronchi of the lungs and increased heart rate and strength of ventricular ejection. Overall, sympathoadrenal activity leads to dilation of the pupils, piloerection, increased sweating, metabolic activity, and strengthening of muscles, as well as decreased activity in the gastrointestinal tract. Some cognitive functions are actually enhanced, including attention and memory formation. The interaction of the HPA axis, amygdala, and hippocampus during stressful situations or traumatic events allows for the formation of fear memories, which can be triggered upon exposure to a stimulus associated with the event. From an evolutionary perspective, these are necessary for animals to learn to avoid dangerous situations in the future, such as the location of a predator's den. Unfortunately, these memories can be quite resistant to extinction and under certain conditions may lead to posttraumatic symptomatology. In humans, for example, the continual immediate recall of these fear or traumatic memories can lead to the development of PTSD. Patients with this disorder experience symptoms associated with recalling these events, such as recurrent or intrusive thoughts and dreams about the event. Additionally, there may be environmental or psychological cues that give the individual a feeling that the event is recurring. Disturbances in sleep, appetite, and mood are not uncommon for individuals with PTSD. It is unclear how catecholamines interact with the HPA axis, hippocampus, and the amygdala, and what role they may play in the development and maintenance of PTSD.

Disorders of the Adrenal Cortex

Cushing's syndrome

The pathological condition of hyperadrenalism is known as Cushing's syndrome. Patients demonstrate adrenal hyperplasia, primarily in response to excess ACTH release from the anterior pituitary gland, as well as hypercortisolism and excess androgen production. Excess ACTH may be caused by pituitary adenomas, hypersecretion of CRH from the hypothalamus, or ectopic tumors that release ACTH (such as an abdominal carcinoma), while hypercortisolism can result from adrenal adenomas or chronic glucocorticoid treatment. Regardless of the source of the syndrome, Cushing's patients generally present with

abdominal and upper back (buffalo hump) fat deposits and a rounded, swollen appearance in the face (moon face) as well as problems with acne and hirsutism (excess facial hair). The majority of patients also demonstrate hypertension, elevated blood sugar, and protein deficiency in tissues other than the liver due to the metabolic effects of excess cortisol. Protein loss in the skeletal muscles causes severe weakness, and loss of lymphoid proteins severely compromises the immune system and increases vulnerability to infection. Many patients also develop collagen weakness and skin abnormalities, as well as osteoporosis.

Addison's disease

Hypoadrenalism, also known as Addison's disease, results from insufficient levels of adrenocortical hormones secondary to adrenal atrophy. The majority of cases are caused by autoimmunity against the adrenocortical tissue, although tuberculosis and some cancers may also destroy the adrenal tissue. Patients present with severely diminished extracellular fluid volume, hyponatremia, hyperkalemia, and slight acidosis as a result of aldosterone deficiency. Complete absence of mineralocorticoid secretion can lead to shock and death within days. The loss of cortisol inhibits the ability to maintain a normal resting glucose level between meals and slows metabolic functions throughout the body. Without cortisol, the body cannot respond normally to stress, and common infections may be lethal in Addison's patients. These patients may also present with characteristic pigmentation of the skin and mucous membranes in response to enhanced release of ACTH and melanocyte-stimulating hormone in the absence of normal negative feedback provided by the adrenocortical hormones. These patients can lead relatively normal lives if supplemental mineralocorticoids and glucocorticoids are provided on a daily basis.

Summary

The adrenal glands play a vital role in homeostatic mechanisms that are necessary for survival and recovery when the body is subjected to internal and external stressors. Although these organs exist outside the central nervous system, hormones released from the adrenal cortex and medulla have a significant impact on neurological processes and overt behavior, while also acting peripherally to alter metabolic and immunological processes. The significance of normal adrenal and HPA axis functionality is readily observed when dysregulation or disorders are present. Chronic, uncontrollable stress can lead to insulin resistance, blunted negative glucocorticoid feedback in the limbic system, elevated basal glucocorticoid levels, and

enhanced stress reactivity. Long-term exposure to elevated glucocorticoid levels is also associated with atrophy of the hippocampus and progressive cognitive dysfunction with aging. Pathological adrenal insufficiency is characterized by fatigue, slowed metabolic function, and abnormal electrolyte levels and blood pressure, and can lead to death if not treated. On the other hand, excess adrenal secretion leads to hypertension, elevated blood glucose, and protein insufficiency, which weakens skeletal muscles and collagen in the skin and increases vulnerability to osteoporosis. Continued research into the factors that influence adrenal gland functions and disease states is essential for the creation of novel therapies that could prevent dysfunction and the deleterious consequences of chronic stress and adrenal disorders.

Glossary

Aggression Any behavior that is intended to harm another person who does not want to be harmed.

Antisocial behavior Any behavior that either damages interpersonal relationships or is culturally undesirable.

Aggression had existed for a long time before people became interested in studying it. Dinosaurs, birds, insects, Neanderthals, indigenous tribes, and almost our entire evolutionary lineage adopted aggression as a useful survival tool. Killing, violence, and intimidation proved quite useful in obtaining food, sex, territory, and other resources, among all the species. When humans evolved as hunters and gatherers and settled into smaller living communities, aggression became a particularly constructive asset. Males could use aggression to win mates, provide protection, and hunt other animals. Females could use aggression to defend offspring and guard domestic capital. In these ways, our most aggressive ancestors were also the most successful in passing on their genes to future generations, thus providing us with a highly effective blueprint for survival.

However, aggression became less and less adaptive as we continued to evolve. Small tribes transformed into complex societies. Individual effort was unable to compete with group success. Over millions of years, humans became (and continue to be) highly *social* creatures as they learned to bank on cooperation and interdependence for survival. In turn, aggression toward others seemed more likely to hinder group progress than promote it. Men and women were forced to resort to more accommodating behaviors in order to live longer, healthier lives, and ultimately increase their chances of making a splash in the gene pool.

It is both peculiar and astounding, then, that aggression has come to characterize so much of our subsequent history. The rapid rise of interpersonal violence within early societies, the widespread occurrence of murder throughout the Middle Ages, and the countless casualties from any one of the hundreds of wars, all demonstrate our consistent proclivity toward aggression and violence. In fact, we experienced only 26 days of world peace (defined as the absence of international wars) in all of the 40 years following the Second World War. Although numerous sources suggest that overall aggression has been on a steady generational decline, its occurrence and effects are considerably prevalent even today.

Why has something seemingly so maladaptive and detrimental to our survival not been left behind by evolution? How have we developed into such a socially dependent species while failing to learn from our most destructive social mistakes? What can we do to change our behavior before it becomes too late? Where can we find the answers?

Such is the pursuit of the psychological study of human aggression. Though the act itself is certainly not a recent phenomenon, modern scientific research on aggression has

revealed a great deal of insight into its many characteristics, causes, and means of reduction.

What Is Aggression?

In social psychology, aggression is typically defined as any behavior that is intended to harm another person who does not want to be harmed. It is distinct from violence, which is usually defined as extreme physical harm with injury or death as its goal. Violence is a specific form of aggression. All violence is aggressive; not all aggression is violent.

Importantly, this definition of aggression highlights three critical features. First, aggression must be an actual behavior. It is not an emotion, thought, or memory, but a real-life observable behavior, such as a punch or a verbal curse. Second, aggression must be purposeful and intentional. The person who uses aggression very much intends to harm the other person; it is not an accident or by-product. Third, aggression always involves undesired harm to the other party; the victim must not want to be harmed. Thus, autonomous behaviors such as masochism and suicide do not qualify as aggression.

Aggression takes a variety of forms and can vary in function. While its general definition remains constant, it is important to distinguish between these individual components.

Forms of Aggression

Aggression is often expressed in distinct forms, typically falling within each of three sets of criteria. First, aggression can be physical, verbal, or relational. Physical aggression refers to using physical behaviors to harm others, and includes behaviors such as hitting and shooting. It is the form of aggression most clearly linked with violence. Verbal aggression refers to using words to harm others, and includes behaviors such as screaming and cursing. Relational aggression, also known as social aggression, refers to harming a person's relationships, feelings of acceptance, or social inclusion, and includes behaviors such as talking about others behind their backs or intentionally excluding a person from one's own group of friends. The social pain involved in relational aggression can be more lasting than physical pain.

Second, aggression can be direct, indirect, or displaced. Direct aggression refers to an aggressive act against a person who is physically present while it occurs. This would include aggressive behaviors such as kicking another person or

yelling at a person to his or her face. In contrast, indirect aggression is expressed when the victim is absent. This would include aggressive behaviors such as destroying property or spreading rumors.

Sometimes people displace their aggression against an innocent substitute target. In the classic Freudian example of displaced aggression, a man is angered by his boss at work and kicks his dog when he gets home from work, rather than retaliating directly against the boss. In addition, the victim does not always have to be completely innocent. In triggered displaced aggression, the target commits some kind of minor offense, which in turn causes a person to aggress. For example, the man who was berated by his boss might come home to find that the dog has spilled some of its food on the floor. Displaced aggression is used primarily when the primary target is not available (e.g., when the man's boss leaves work early) or when retaliation against the target may result in undesirable consequences (e.g., the boss might respond by firing the man).

Third, aggression can be active or passive. Active aggression is expressed when the aggressor resorts to explicitly harmful behavior toward the victim, such as slapping or yelling. On the contrary, passive aggression refers to failure on the aggressor's part to act in a helpful way, or withholding some helpful behavior, such as 'forgetting' to inform someone of important information or deliberately showing up late for an important group meeting.

Direct and active forms of aggression can be quite risky, leading to injury or even death. Thus, most people prefer to use indirect and passive forms of aggression instead.

Functions of Aggression

Aggressive acts may also differ in their function. Consider two examples. In the first, a husband finds his wife and her lover together in bed. He takes his rifle from the closet, and shoots and kills both individuals. In the second, a 'hitman' uses a rifle to kill another person for money. The form of aggression is the same in both examples (i.e., physical aggression caused by shooting and killing victims with a rifle). However, the motives appear quite different. In the first example, the husband appears to be motivated by anger. He is enraged when he finds his wife making love to another man, so he shoots them both. In the second example, the 'hitman' appears to be motivated by money. The 'hitman' probably does not hate his victim. He might not even know his victim, but he kills the person anyway for the money. To capture different functions or motives for aggression, psychologists make a distinction between reactive aggression (also called hostile, affective, angry, impulsive, or retaliatory aggression) and proactive aggression (also called instrumental aggression). Reactive aggression is 'hot,' impulsive, angry behavior that is motivated by a desire to harm someone. Proactive aggression is 'cold,' premeditated, calculated behavior that is motivated by some other goal (obtaining money, restoring one's image, restoring justice).

Although the function of aggressive behavior is important to consider, recent research suggests that it is almost impossible to distinguish between reactive and proactive aggression. Real-life scenarios are typically not as distinct and unambiguous as the husband and hitman examples.

Measurement of Aggression

Aggression is scientifically measured inside and outside the laboratory. Field research conducted outside the lab looks at statistics to establish a correlation between aggression and predicting variables. Instances of violence and aggression such as school shootings or violent crimes are analyzed after they occur, and factors such as gender, poverty, and age are examined to determine what conditions might have led the aggressors to act in such ways.

Aggression is also studied behaviorally in the lab. Given the practical and ethical restraints of using human participants, researchers have developed a number of creative methods to address the issue. They cannot give the participants in their studies guns, knives, or even boxing gloves. Today, there are three primary ways in which laboratory aggression is measured. First, the 'hot sauce paradigm' measures aggression by requiring participants to indicate the amount of hot sauce an ostensible partner, who very much dislikes spicy food, should consume. Second, in the 'bungled procedure' paradigm, participants are asked to shoot a human target with a type of pellet gun, but before they are able to do so, the equipment experiences a 'malfunction' and they never actually use the gun. Aggression is measured by the type of gun and number of bullets chosen by the participant.

The third method is perhaps the most common. Participants are asked to participate in a competitive reaction time task, in which they press a button as quickly as possible in a series of trials with an ostensible partner. The 'loser' of each round is shocked by the opponent, who sets the degree of stimulation. The newer model uses blasts of noise through headphones, adapted from the original paradigm that used physical shocks. Noise levels are randomized throughout the task, and aggression is measured by analyzing the responses of the target participant when given the opportunity to 'blast' his or her partner. In other variations of the paradigm, participants earn money for participating in the study, and they can subtract money from their ostensible partner.

Why Do We Use Aggression?

It is indisputable that people use aggression in a wide variety of ways. In turn, many theories have been developed in an attempt to explain why we so often aggress against others. The main theories are summarized in the following sections.

Instinct Theories

Instinctive theories of aggression state that aggressive behavior is simply an innate survival tendency, inherent in many species. According to these theories, first advanced by Charles Darwin, violence and aggression are unmotivated, automatic forces that occur naturally and have been passed down as an adaptive evolutionary trait; we are wired to be aggressive in order to increase our chances of survival. We do not learn to be aggressive or become aggressive after certain life experiences. Rather, as political philosopher Thomas Hobbes stated, "we are naturally violent creatures."

Sigmund Freud believed that all humans are born with both a 'life instinct,' which creates, sustains, and promotes life, and a 'death instinct,' which destroys life. According to this

psychoanalytic view, we stop short of destroying ourselves because the life instinct overpowers the death instinct, and diverts our harmful urges outward toward others. Therefore, the basis of aggression lies within the internal battle to preserve our own life.

Building on Freud's ideas, ethologist Konrad Lorenz proposed that aggressive urges can build up, in much the same way that hydraulic pressure causes fluids to build up within a restricted space, and that these urges must be released in some way. Subsequently, we engage in aggressive behavior to release our natural pent-up levels of aggressive instincts.

Research refuting instinctive theories reveals that aggression does not seem to be completely unmotivated. There is even evidence to suggest that humans actually derive pleasure from harming others who have provoked them.

Frustration–Aggression Theory

Frustration–aggression theory, proposed in 1939 by a group of researchers from Yale University, was summarized in two bold statements: (1) “the occurrence of aggressive behavior always presupposes the existence of frustration” and (2) “the existence of frustration always leads to some form of aggression.” Whereas instinct theories focused on internal factors that increase aggression, the frustration–aggression theory focused on external factors. However, it readily became apparent that not all aggression results from frustration, and not all frustrations lead to aggression. Besides an inclination to aggress, frustrations actually stimulate a number of different inclinations such as an inclination to escape or to find a way around the obstacle to the goal. The revised theory proposed that the inclination that eventually dominates is the one that is most successful in reducing frustration. In other words, people learn through experience what actions are effective in reducing aggression. This idea opened the door for learning theory explanations of aggression (see next section).

The frustration–aggression theory provides a good explanation of why poverty is a consistent predictor of aggression and violence. It is frustrating not to be able to obtain basic needs such as food and shelter.

Fifty years later, Leonard Berkowitz revised the frustration–aggression theory by proposing that all unpleasant events – not only frustration – deserve to be recognized as important causes of aggression. The idea is that unpleasant events (including frustrations) automatically produce primitive fight or flight reactions. When we experience an unpleasant event, we want to stop it or leave. The occurrence of aggression depends on how the unpleasant event is interpreted and on the presence of aggressive cues. For example, if a person has just seen a violent movie and is pushed from behind while exiting the theater, he or she may very well act in an aggressive manner.

Learning Theories

The frustration–aggression theory was seminal to the development and popularity of other situational explanations of aggression. These explanations went against the assumption that people are aggressive because they are born that way.

Learning theories of aggression are based on both operant and classical conditioning. Operant conditioning, the defining

feature of behaviorism, proposes that behavior is motivated by pursuit of pleasure and avoidance of pain. Classical conditioning, as famously demonstrated by Ivan Pavlov's experiments involving dogs, proposes that behaviors are determined by the learned pairing of two or more stimuli.

Other learning theories of aggression go beyond simple conditioning. In his social learning theory (also called observational learning theory), Albert Bandura theorized that observation and imitation are at the root of aggressive behavior. In Bandura's studies, children who observed an actor hitting a 'bobo' doll (a large, inflatable toy clown) imitated the actor's aggressive behavior and also hit the 'bobo' doll. Bandura proposed that aggression is not simply a mindless mimicry of another's behavior, but also involves cognitive inferences, generalizations, and interpretations. For example, if a child sees one parent hit the other across the face following an altercation, the child may not only imitate the action, but may also conclude that it is acceptable to hit someone who provokes you. Recent research has revealed that this process of learning-from-imitation even has a neurological basis. 'Mirror neurons' identical to those that are fired when one is performing a behavior are fired also in response to observing someone else perform the behavior.

Social-Cognitive Theories

As learning theories increased in complexity, they gave rise to theories that focused on higher cognition and information processing. These social-cognitive theories focus on how thoughts influence behaviors. One social-cognitive theory, developed by Rowell Huesmann and colleagues, focuses on scripts. The term script is borrowed from theater. In a play or movie, a script tells the actor what to say and do. The fundamental element in a script is the vignette, defined as 'an encoding of an event of short duration,' consisting of both a perceptual image and a 'conceptual representation' of the event. A simple vignette might consist, for example, of an image of one person hitting another (image) in anger over something the other person has done (a conceptual representation). A script consists of a sequence of vignettes. Such scripts define situations and guide behavior: the person first selects a script to represent the situation and then assumes a role in the script. Once a script has been learned, it may be retrieved at some later time as a guide for behavior.

A second social-cognitive theory, developed by Kenneth Dodge and colleagues, focuses on attributions, which are the explanations people make about why others behave the way they do. For example, if a person trips you, a hostile attribution would be that the person did it on purpose to hurt you. Aggressive people tend to make hostile attributions.

A third social-cognitive theory, developed by Craig Anderson and colleagues, is called the General Aggression Model. According to this model, aggression is the result of situational and personality factors that influence internal states such as thoughts, feelings, and physiological arousal (e.g., heart rate).

What Causes Aggression?

While much is still unknown, research has shown that there are three major causes of aggression: nature, nurture, and the

environment. The factors are not mutually exclusive or even independent; often they act together.

Nature

Gender differences

Gender differences in aggression are apparent from a very early age, and appear to remain relatively consistent throughout life. By preschool, boys display higher levels of physical aggression than girls. This divide becomes more pronounced through childhood and adolescence, and is clearly demonstrated by the drastic gender difference in murder rates around the world. Research further shows that males are more likely than females to express aggression in order to ensure the sexual fidelity of their partners. For example, men often report higher levels of anxiety and dissatisfaction toward sexual infidelity than toward emotional infidelity (i.e., being in love with another person), whereas females show the opposite pattern. Females show higher levels of relational and indirect aggression than do males.

These gender differences highlight our evolutionary ties with aggression. A man can most effectively pass on his genes by making sure that a partner is carrying his child, and so he is able to use strength and power to suppress his mate's partners. A woman is most likely to pass on her genes by making sure that the man she mated with remains committed to her child, and so she uses indirect aggression to intimidate rival mates.

Age differences

Across cultures, aggressive behaviors appear very early in childhood. Infants display angry facial expressions by 4 months, and interpersonal aggressive behaviors develop quickly thereafter. The existence of aggressive behavior at such a young age suggests that there must be at least some inborn aggressive tendencies.

Research shows that toddlers 1–3 years old are the most aggressive group of humans on the planet. In daycare settings, about 25% of interactions among toddlers involve some kind of physical aggression (e.g., one child pushing another child down). No other group, not even violent youth gangs or hardened criminals, resorts to physical aggression 25% of the time. Fortunately, children cannot do much damage at that age!

After age 3, most people become less aggressive over time. However, a subset of people become more aggressive over time. The most dangerous years for this subset of individuals (and for society) are between ages 15 and 30, when violent crime rates are the highest.

Although these generalizations summarize the data accurately, exact developmental trends in general aggression are difficult to measure because aggressiveness manifests itself in different ways at different ages – for example, in taking things at age 4, fighting at age 8, telling lies about others at age 12, vandalism at age 16, and murder at age 27.

Personality traits

We all know that some people lash out aggressively at others at the slightest provocation, while other people hardly ever lash out. There is a 'dark triad' of personality that is linked to aggression, violence, and other antisocial behaviors: (1) psychopathy, (2) narcissism, and (3) Machiavellianism.

Psychopathy is a personality disorder marked by callous and unemotional affect and low empathy for others. Psychopaths often engage in antisocial behavior to gratify their own desires, and show little for their actions. They focus on immediate rewards rather than long-term consequences, and have difficulty learning from their past mistakes. The term narcissism comes from the mythical Greek character who fell in love with his own image reflected in water. Narcissists have a grandiose, inflated view of themselves, and a sense of entitlement. Narcissists lash out aggressively at others who criticize them. The term Machiavellianism comes from the Italian Renaissance diplomat Niccolò Machiavelli, who wrote *The Prince*, a guide for the prince to maintain his power and authority over subordinates by any means, including cunningness and force.

Biological factors

There are a variety of biological factors that appear to influence aggression. While most of them are insufficient to cause aggression and require some sort of situational trigger, they nonetheless increase the likelihood of aggression.

People with lower levels of arousal, such as blood pressure and heart rate, tend to exhibit more aggression than those with average (or higher) arousal ratings, perhaps because they seek to increase their arousal levels by engaging in antisocial behavior. In one experiment, men who responded very little physiologically to violent movie clips acted more aggressively than those who had a higher response.

Research has also established a strong link between low levels of the neurotransmitter serotonin and aggressive behavior. Serotonin is referred to as the 'feel good' chemical in our brains, and so when we lack a sufficient amount of it, we may be more inclined to behave aggressively. This relationship has been demonstrated causally using both animal and human participants. Moreover, the male sex hormone testosterone has been linked with increased aggression, but less consistently. Higher levels of plasma testosterone probably increase aggression slightly, but the outcome of winning and dominating affects testosterone levels just as much.

Overall executive functioning also has a significant impact on the likelihood of aggression. This type of higher-order cognitive functioning occurs toward the front of the brain just behind the forehead, called the prefrontal cortex. Damage to the prefrontal cortex has been shown to directly increase aggression levels. Prefrontal cortex damage can also create several problems that increase the likelihood of aggression, such as low IQ and the development of attention deficit hyperactivity disorder (ADHD).

Genetics

Although there is yet to be a conclusive demonstration of the heritability of aggressive inclinations in humans, research suggests that certain people have a genetic predisposition to behave aggressively. In one study, people with a particular variation of the gene that determines monoamine oxidase activity (MAOA) were at a significantly higher risk of becoming aggressive adults, but only if they had been abused in childhood. Abused children with lower MAOA became more aggressive adults than both nonabused children with MAOA depletion and abused children with normal MAOA. Another important

study showed that individuals who had a gene variation that lowered serotonin and dopamine activity were at a higher risk for antisocial behavior in adolescence.

Nurture

There is substantial support for the argument that aggression is, at least partly, determined by situational factors. For instance, although the sex differences discussed earlier may suggest that aggressive tendencies are innate, sex differences in aggression disappear under high levels of provocation. In fact, statistics show that female partners are actually more likely than their male counterparts to exhibit domestic physical aggression in heterosexual relationships (although males are likely to cause more physical injury or even death). Clearly, 'nature' cannot fully explain aggression.

Physical situation

Subtle unpleasant changes in our immediate surroundings often influence our levels of aggression. One salient correlate of aggression is heat. Research has consistently demonstrated a link between hot temperatures and aggression. Other nonsocial, unpleasant sensations such as noxious odors (e.g., smoke, pollution), and loud (particularly uncontrollable) noises have also been linked to aggression. Certain visual stimulation, including aggressive cues (e.g., weapons), can also trigger aggressive behavior.

It is also important to consider how the immediate situation influences aggression. For example, rates of aggression may increase among certain populations such as prisoners, not because those individuals are naturally more aggressive, but perhaps because the enclosed prison environment makes them more prone to aggressive behavior.

Social situation

Our social environment as well as our physical environment can contain unpleasant situational cues. Crowding, defined as the perception that there are too many people in the vicinity, can increase aggression.

When we are rejected by others in a social situation, we are also more prone to use aggression. For example, an analysis of school shooters found that 13 out of the 15 shooters had been rejected by a romantic partner prior to the shooting spree. The greater the degree of social rejection, such as in extreme cases like ostracism (being directly isolated or rejected by others), the more prone a person is to using aggression.

Aggressive arousal

Many factors that increase aggression (e.g., heat, violence in media) also increase physiological arousal. Thus, it is not surprising that arousal is linked to aggression. There are at least four reasons why arousal might increase aggression. First, high arousal might be interpreted as an aversive stimulus, which would trigger aggression in the same ways that other aversive stimuli have been shown to do. Second, arousal narrows attention. If aggressive cues are salient in the situation, then people will focus most of their attention on the aggressive cues. Third, arousal increases the dominant response, which is defined as the most common response in that situation. Thus, whatever people are normally inclined to do (including

behaving aggressively), they will be even more strongly inclined to do when they are physiologically aroused. Fourth, arousal from any source (e.g., exercise, coffee, an exciting movie) may be misinterpreted as feelings of hostility or aggression if people are later provoked, a process called excitation transfer. For example, a woman is accidentally bumped while walking to her car after a long workout at the gym. Her increased heart rate and perspiration from exercise might be mislabeled as anger at being bumped, if she yells at the person who bumped her.

Disinhibiting factors

All people have aggressive impulses, but most are able to inhibit these impulses. However, some situational factors can reduce aggressive inhibitions. One such factor is alcohol. To use an analogy, alcohol increases aggression by paralyzing the brakes, not by stepping on the gas. In murder cases, at least half of the perpetrators were intoxicated when they murdered the victims (often the victims were also intoxicated). Laboratory experiments have shown that alcohol seems to increase aggression in combination with other factors. Factors that normally increase aggression (e.g., frustration, provocation) have a stronger effect on intoxicated people than on sober people. If someone is insulted, his or her response will be more violent if he or she is drunk than when he or she is sober. When there is no provocation, however, the effect of alcohol on aggression may be negligible.

Similarly, anonymity has been consistently linked to increased aggression. When people are anonymous, they seem to lose their inhibitions against behaving aggressively. Perhaps this is why violent crimes are much higher at night than during the day time, and why bank robbers and members of the Ku Klux Klan wear masks when they commit violent crimes. Laboratory experiments show that aggressive behavior increases when people cannot be identified by name or appearance.

Environment

Apart from personality and situational influences, a person's overall environment can have quite a significant impact on aggression.

Family

Children from neglected or broken family backgrounds are more likely to become aggressive adults than children from stable families. Moreover, children are more likely to become aggressive adults if they witness a significant amount of domestic violence while growing up. Those who are physically abused at a young age are more likely to become physically abusive parents and romantic partners themselves.

Peers

As children grow, peer groups wield a greater influence on their behavior. Children who are rejected by their peers are more likely to behave aggressively later in life, and vice versa (aggressive children are likely to be rejected by their peers). Having antisocial peers is also a risk factor for aggression and violence.

Community

Beyond family and peers, a person's collective culture also influences aggression. Societal norms and expectations differ widely across cultures, and often impact on aggressive behavior. Violence and aggression are more acceptable in some cultures (e.g., cultures that place a large emphasis on honor) than in others. There are great regional differences in aggression in the United States, with violence levels being much higher in the South than in the North. Psychologists Richard Nisbett and Dov Cohen theorize that this discrepancy is a result of a southern culture of honor. Southern settlers typically came from herding families that relied on livestock to make a living, whereas Northern settlers relied on agriculture. Aggression is theoretically more practical and useful in protecting animals rather than crops, and so the idea of using aggression to preserve the honor and success of their family business became ingrained in individuals from the South. The overall condition of a particular community also affects aggression. Impoverished neighborhoods are often more conducive to crime and violent behavior. Similarly, communities that are characterized by high levels of racism, prejudice, or intolerance provide a breeding ground for aggression.

Media

Violence in the mass media can increase aggression and fear of victimization, and make people numb to the pain and suffering of others. Experimental studies have shown that violence in the mass media causes aggression, and longitudinal studies have shown that the effects can persist for decades. In fact, in 1972, the US Surgeon General issued a warning about the harmful effects of violence in TV programs and films. Violent video games, which were developed after the Surgeon General had issued his warning, may be even more harmful than violence in TV programs or films, for at least three reasons. First, video game play is active, whereas watching TV is passive. People learn better when they are actively involved. Suppose you wanted to teach a person how to fly an airplane. What would be the best method to use: read a book, watch a TV program, or practice on a video game flight simulator?

Second, players of violent video games are more likely to identify with the violent characters therein. If the game is a first-person shooter, players have the same visual perspective as the killer. If the game is third person, the player controls the actions of the violent character from a more distant visual perspective. In either case, the player is linked to a violent character. In a TV program, viewers might or might not identify with a violent character. Third, violent games directly reward violent behavior by awarding points or allowing players to advance to the next game level. In some games, players are also rewarded through verbal praise, such as the words 'Nice shot!' or 'Impressive!' after killing an enemy. It is well known that rewarding behavior increases its frequency. In TV programs, reward is not directly tied to the viewer's behavior. A recent Dutch study by Hanneke Polman and her colleagues provided the first evidence that playing violent games produces stronger effects than simply observing violence. In this study, some participants played violent games, whereas other participants watched the games being played, and the effects of aggression were stronger on the players than the watchers.

What Reduces Aggression?

Although aggressive behavior may never be eliminated from society, various treatments have been developed to reduce aggression. In all cases, any method of reduction is most effective when applied in early childhood before aggressive behavior becomes crystallized. In general, two primary approaches have been used to reduce aggression: behavior modification and cognitive-behavioral therapy.

Behavior Modification

The main goal of behavior modification is to reduce aggression by reinforcing the learning of nonaggressive behaviors. This method is most effective when applied to instances of proactive aggression. People often aggress in subtle, indirect ways, such as talking behind the back of a coworker or inviting all friends but one to a party. Proactive aggression involves a certain degree of planning, patience, and cunning in order to achieve one's goals, for example, trying to malign the reputation of a detested peer. In order to reduce this type of aggression, behavior modification principles use a technique called the differential reinforcement of alternative behavior. Rather than simply rewarding someone for not using aggression, this approach seeks to actively reinforce prosocial behaviors. In this way, aggression is decreased because prosocial behaviors are increased. For example, an aggressive child could be given a candy bar every time he helps his sister. Furthermore, it is especially helpful to reinforce positive social skills such as engaging in 'small talk' so that the child learns effective ways to achieve a goal without using aggression (e.g., accommodating, negotiating). The overall effectiveness of these methods is increased by the presence of prosocial role models, such as parents or celebrities, who reinforce and model prosocial, nonaggressive behaviors.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy is commonly applied to treat reactive, hostile aggression. Given that these cases are characterized by feelings of anger and rage, cognitive-behavioral techniques attempt to reduce emotional responses to provocation. Techniques typically involve meditation, relaxation, and concentration on peaceful imagery. In addition, people are trained to mentally prepare for future provocation by learning to interpret provocative events in a more benign manner. For example, in self-instructional training, people memorize nonaggressive thoughts like 'I know how to control my anger,' 'I will not lose control,' and 'Just continue to relax.' Individuals are trained to manage their aggressive thoughts by imagining a potential conflict and visualizing a calm, peaceful solution. When behavioral techniques like meditation and relaxation are combined with the rehearsal of nonaggressive cognition, reactive aggression is most effectively reduced.

Conclusion

Aggression is a complex and multifaceted behavior, and has been used by living species for millions of years to attain

desirable goals and resources. Aggression researchers have attempted to delineate the origins, causes, and defining characteristics of aggression. Over time, aggression and violence levels have declined. We hope that aggression research will help this trend to continue.

Glossary

Classical conditioning A form of learning that pairs a neutral stimulus to a conditioned stimulus in order to invoke a similar behavioral response when the neutral stimulus is present that is invoked by the conditioned stimulus.

Cognition A psychological function referring to the act of processing and manipulating information, including such processes as awareness, perception, reasoning, and learning.

Declarative memory Memory for facts or information that can be consciously stated or declared.

Executive function A broad term describing the higher order cognitive processes which are responsible for the most complex human functions. Within the brain, the frontal lobe is the brain region associated with executive functions.

Inhibition The cognitive ability that enables an individual to refrain from expressing a behavioral response.

Nondeclarative memory Memory for skills or procedures that does not necessarily require conscious awareness.

Priming The phenomenon that occurs when the presentation of a stimulus influences the response to a subsequently presented stimulus, usually occurring outside of an individual's immediate awareness.

Processing speed A measure of the time required to respond to and/or process information in one's environment.

Risky decision-making The decisional cognitive processes involved in the choice to engage in unsafe or risky behaviors.

Set-shifting A cognitive process that refers to the ability to shift one's attention back and forth between two tasks or two lines of thought.

Working memory The ability to temporarily store and manipulate information in one's mind for immediate use.

Introduction

Literally, thousands of studies now exist showing that various aspects of cognition change with age. Age-related declines in cognitive abilities such as learning, memory, attention, executive function, decision-making, and problem-solving have been detected using both cross-sectional and longitudinal designs. One controversy that has arisen when comparing results from these two types of designs is when cognition first starts to decline. Longitudinal studies generally place the beginning of decline later than cross-sectional studies. Earlier views tended to place the beginning of cognitive decline in the sixties or later with only a few studies suggesting that decline might begin as early as in the fifties. There is now compelling evidence that many aspects of cognition begin to decline in middle age and that a significant portion of individuals over 70 years of age living independently can be classified as having a significant cognitive impairment. In fact, 10–30% of individuals over 60 years of age have been found to have a diagnosable cognitive impairment as a result of various pathologies associated with aging. Similarly, ~22% of individuals over 71 years of age in the United States have been estimated as having a significant cognitive impairment without dementia. The prevalence of cognitive impairment without dementia is greater in men, older individuals, and individuals with a lower educational level.

In this article, changes in cognition will be examined from a lifespan perspective reviewing the available data on cognitive changes from early adulthood to old age. Until very recently, few studies examined cognition in middle-aged individuals. It is now recognized that it is important to know when change in cognition begins because if we wait until old age, precipitating or mediating causes may have disappeared or changed.

We will begin with the area of cognition that has received the most attention, memory.

Declarative Memory

Memory has been divided into the domains of declarative and nondeclarative memory systems, also frequently referred to as explicit and implicit memory, respectively. Declarative memories are facts that can be consciously stated, or declared. For example, the recollection that I drove to work yesterday would be a declarative memory. The skills and procedures required for the drive would be classified as nondeclarative memories. Many daily tasks, such as riding a bike, engaging in games or sports, or typing a paper at the computer, fall within the domain of nondeclarative memory. Performance on these procedural tasks, in which past experiences serve as an aid, do not necessarily require conscious awareness. In contrast, declarative memory occurs with conscious awareness. In the laboratory, declines in performance on both declarative and nondeclarative tasks have been observed in older individuals.

Tests of verbal and visuospatial material have been used to assess declarative memory across the lifespan. In an investigation of memory performance, children and older adults were found to exhibit poor recall on multitrial tests of both verbal and spatial information. For the verbal test, participants were administered five immediate trials of the Rey Auditory Verbal Learning Test (RAVLT). In this test, participants hear 15 concrete nouns on each trial, but in a different order. After each presentation, participants are instructed to recall as many words as they can remember. The number of words recalled on each trial is the measure of performance. For the spatial test, participants were administered a version of the game of

Memory Cards (also referred to as Concentration). Twenty-four cards are in a 4×6 matrix on the computer screen and participants are instructed to turn over two cards at a time for matches and attempt to get as few mismatches as possible. Five immediate trials are administered with the spatial location of the 12 matching pairs always in the same location. The percentage of matches out of all attempts is the measure of performance.

Latent growth curve analyses were used to examine performance across trials on both the RAVLT ($N=2124$) and Memory Cards ($N=1579$) tests for five age groups (5–12, 13–18, 19–39, 40–59, 60–92). In this analysis, the intercept (initial start of the learning curve), slope (rate of learning), and shape (change in rate of learning) were examined. Significant differences were detected for both tasks on the first trial (intercept), but not on the rate of learning on subsequent trials (slope). The spatial and verbal learning parameters were not significantly correlated. Thus, we propose that there is not a single general learning ability underlying these different task modalities.

An earlier version of this data set was used to show changes on the first trial of these two tasks for participants 15–89 years of age (age groups: 15–19, 20s, 30s, 40s, 50s, 60s, 70s, 80s). **Figure 1** shows age changes for performance on these two tasks with a sample size that has virtually doubled in size since the original report. An analysis of performance on the first trial of the RAVLT detected significantly poorer recall in individuals 50 years of age and older, while the 80-year-old individuals showed significantly poorer verbal recall than all younger age groups. A similar significant decline occurred for the Memory Cards task. That is, individuals 50 years of age and older

demonstrated poorer performance than individuals 15–29 years of age, and individuals in their 80s showed poorer spatial memory than all younger age groups. The decline of both spatial and verbal declarative memory by 50 years of age is consistent with other reports of significant declarative memory decline in middle-aged humans for both verbal and spatial information. Similar declines in midlife have been reported for declarative memory in rodents and nonhuman primates.

Nondeclarative Memory

Findings from classical conditioning studies of the eye-blink response and word-stem priming task will be described as both paradigms have been used to examine nondeclarative memory changes across the adult lifespan. Briefly, to exemplify the eye-blink procedure used in research studies, a conditioning stimulus tone is activated for 500 ms with onset of a mild puff of air to the eye as the unconditioned stimulus at 400 ms. A conditioned response is scored if the eye-blink occurs prior to delivery of the puff of air. That is, a conditional response occurs on a trial if there is an eye-blink between 29 and 400 ms after tone onset. A deficit in acquisition of the classical conditioned eye-blink response has been detectable in the 40–50-year-old subjects in previous research investigations. Similarly, declines in classical conditioning of the eye-blink response have been reported in rabbits and cats at ages equivalent to middle age in humans.

Word-stem priming has received the most attention in studies examining nondeclarative memory in older individuals. Priming is said to occur when the presentation of a

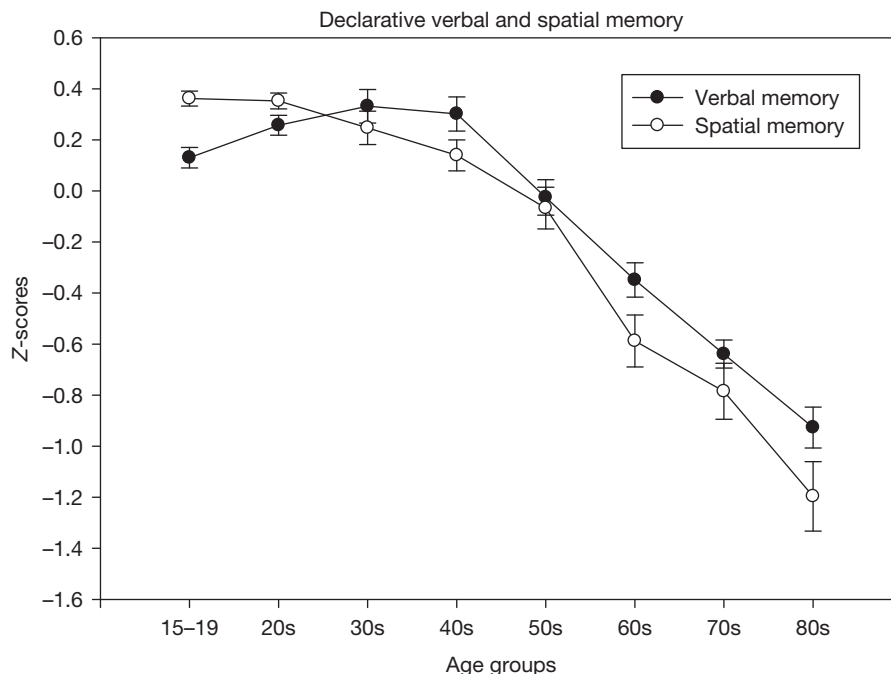

Figure 1 Standard Z-scores for performance on the first trails of the RAVLT and Memory Card task for participants from 15 to 89 years of age (RAVLT $N=2266$; Memory Cards $N=1518$). Adapted from Foster SM, Cornwell RE, Kisley MA, and Davis HP (2008) Cognitive changes across the life span. In: Qualls SH and Smyer MA (eds.) *Changes in Decision Making Capacity in Older Adults: Assessment and Intervention*, pp. 25–60. Hoboken NJ: Wiley.

stimulus influences the response to a subsequently presented stimulus. For example, when a person provides pleasantness ratings to a list of words that includes the word *motel*, and is later asked to complete the word stem *mot*, the probability that the subject answers *motel* is higher than for word stems that were not primed by the pleasantness rating (e.g., completing the baseline control stem *acc* with the nonpresented word *accord*). In one study, word-stem priming in each decade of life from the 20s through the 80s was assessed and individuals in their 70s and 80s scored significantly lower priming scores. No decline in priming was detected for younger age groups. However, priming scores for individuals in their 40s, 50s, and 60s tended to be intermediate between the younger and older age groups. The failure to detect a decline in priming by middle-aged individuals might have been due to the small group sizes. More recently and with larger age groups, impaired word-stem priming in a middle-age group (mid-30s to early 50s) as compared to a young adult group (late teens to mid-30s) was reported. Thus, significant nondeclarative memory deficits, like declarative memory deficits, are detectable in middle-age individuals with further decline occurring in the elderly (individuals in their 70s and 80s).

Executive Function

Executive function is a broad umbrella term that describes the higher-order cognitive processes which are responsible for the most complex of human functions and behaviors. Although there is much debate regarding the specific cognitive processes that should be defined as part of executive functioning, the literature seems to agree on the fact that executive control is necessary for goal-directed behavior, such as the formulation of a goal, devising strategies and plans to achieve the goal, and the execution and implementation of such plans. The underlying cognitive processes identified in the literature as executive functions include, but are not limited to, the following: focused and divided attention, inhibition, self-regulation, initiation of behaviors, working memory, planning, organization, problem-solving, information processing, and cognitive set-shifting.

Within the brain, the frontal lobes, specifically the prefrontal cortex, is the brain region associated with executive functioning. Executive functions are usually quite vulnerable to cognitive decline, as the frontal lobes are one of the initial brain regions to experience atrophy, or neuronal cell death, in response to natural age-related and pathological processes, including Alzheimer's disease and frontotemporal dementia. As a result, executive dysfunction can manifest itself in a myriad of cognitive and behavioral problems, including impulsivity, poor judgment and decision-making, perseveration, and an inability to switch back and forth between two lines of thought. Consequently, impairments in executive functioning can detrimentally affect older adults and their ability to live independently. Due to the multiple processes that underlie executive functioning, and the lack of agreement among researchers regarding the processes that should be defined as part of executive control, this section will focus on understanding age-related declines in executive functions for the following areas: cognitive set-shifting, inhibition, working memory, and problem-solving.

Cognitive set-shifting, also referred to as task-switching or mental flexibility, is an individual's ability to shift their attention between two tasks or lines of thoughts. Set-shifting is often assessed by two popular neuropsychological measures: the Trail Making Test (TMT) and the Wisconsin Card Sorting Test (WCST). The TMT has two parts: Part A and Part B. Part A requires an individual to connect 25 numbers in sequence as quickly as possible. Part B requires an individual to shift back and forth between connecting number and letters in alphabetical and numerical order as quickly as possible. Part B of the TMT, therefore, can detect problems in an individual's ability to shift set. In a study with a sample size of 680 participants ranging in ages from 18 to 89, age-related changes in performance on the TMT were found. As the participants' age increased, their performance on Part A and Part B declined. Furthermore, the age-related effects were more prominent for Trial B than A; the trial that required shifting. The results of this study suggest greater difficulty for individuals in their ability to set-shift with increasing age.

The WCST, another prominent test of executive functioning, assesses individuals' ability to set-shift, as well as their inhibitory control and planning abilities. The test requires an individual to sort a target card by placing it under one of four stimulus cards, which differ by shape, number, and color. An individual must determine the *rule* for sorting the cards (i.e., sorting them by shape, number, or color), and is given feedback regarding the correctness of each of their choices. After ten trials, the *rule* is changed, and the individuals must alter their decisions accordingly. This test will be used to exemplify changes in both set-shifting and inhibitory control as it requires an individual to shift cognitive sets and inhibit old responses when adjusting to the new *rule*.

In an investigation to study the age-related changes on WCST performance, 48 younger adults (18–38 years) and 49 older adults (60–86 years) completed a computerized version of the WCST. The level of education and health status of participants were statistically controlled to avoid potential confounding variables. Overall, the older adult participants performed more poorly on the task as compared to the younger adults. Additionally, the older adults were more likely to make perseverative errors than the younger adults. Perseveration refers to the inability to cognitively shift focus away and inhibit a prior way of responding. In the WCST, perseverative errors refer to the mistake of sorting cards by an old *rule* instead of the new *rule*. The results of this study further exemplify that individuals show deficits in their ability to set-shift, as well as in inhibition, as they age.

Inhibitory control is another cognitive process part of executive functioning that has been demonstrated to decline with age. Inhibition is often measured by the well-known Stroop task. The Stroop task requires participants to look at a card with four color names printed on it in conflicting colored ink. Instead of reading the words, individuals are asked to quickly name the color of the ink each word is printed in and their response is timed. Therefore, the test requires individuals to inhibit an overlearned response (i.e., reading the words) to respond in a novel way (i.e., stating the color of ink).

To investigate age-related changes in inhibition, a research investigation was conducted using a version of the Stroop task in a sample of 80 adult males of various ages across the

lifespan. Participants were given four trials. In trial 1, participants simply read a card with four color words on it as quickly as possible. In trial 2, participants saw four colors and were asked to name the color of the ink. In trial 3, participants read a card with four color words on it, but printed in conflicting colored ink. In trial 4, the inhibition condition, participants were asked to name the color of the ink the words were printed in and were told not to read the words. The results demonstrated that the older adult participants did not differ from the younger group on the simple reading task, yet were significantly slower during the inhibition condition, suggesting a deficit in inhibitory control. Other investigators have reported similar findings on the age-related changes on the Stroop test, but argue that this deficit is related to a general slowing of cognitive processing. However, differences among ages on the inhibition condition, but not the reading conditions, reveal that performance is affected by another process other than slowed reaction time. Regardless of the underlying cause, suggested as due to slowed information processing or natural age-related changes in the brain, the cognitive and behavioral manifestations of age-related changes produce deficits in the ability to shift cognitive sets and apply inhibitory control. Furthermore, as in the realm of memory, deficits in executive function are first detectable in middle age.

The Tower of Hanoi (TOH) and Tower of London (TOL) are two popular problem-solving tasks that have been used in hundreds of studies with young adult college students, various patient populations, and age groups varying from childhood to old age. The TOH has attracted the interest of cognitive psychologists because of its application to the development of solution strategies in problem-solving. It is a transformation puzzle that requires a repetitive strategy for the achievement of an optimal solution. The task consists of three pegs with a number of rings varying in size. Typically, at the start, the rings are stacked on the left peg with the largest disk on the bottom and the smallest on the top. The research subject is instructed to achieve the same disk arrangement on the right peg by moving one disk at a time and never placing a larger disk on a smaller disk. The minimal moves for an optimal solution are $2^n - 1$ where n represents the number of disks.

To explore problem-solving, individuals between the ages of 15–89 were tested on both a 3- and 4-ring puzzle ($N = 755$). [Figure 2](#) shows age changes for performance on the 3- and 4-ring TOH. On the 3-ring TOH puzzle, a significant increase in the number of moves to solve the puzzle was detectable in the 60s. On the 4-ring TOH, a significant decline in performance of individuals in their fifties was found. Thus, like memory, there is a decline in problem-solving by at least the 50s.

The TOL was developed to assess planning in individuals who sustained damage to the frontal lobes. The TOL is similar to the TOH in that one must move a set of objects (balls of differing colors) from a start arrangement on three or more pegs to a goal position in as few moves as possible with the constraints that balls cannot be stacked above the peg and only one ball at a time can be moved. [Figure 2](#) shows age changes for performance from 15 to 89 years of age on the TOL. A significant impairment was detected in individuals in their 60s and older. In addition, TOL performance in 300-plus individuals between 21 and 79 years of age was examined on the CANTAB test battery. Within this study, individuals in

the oldest age group (74–79 years) required more moves to successfully complete TOL problems.

Working memory refers to a cognitive process that involves the active manipulation of information while maintaining it in consciousness. For example, multiplying 16×18 in your head requires the active manipulation and holding of information in awareness. To assess this ability, performance on both a verbal and spatial n -back task for ~400 individuals was investigated. In the n -back task, participants are shown a series of stimuli and asked to indicate for each stimulus if it is identical to the stimulus n -back in the series (e.g., Is the present stimulus identical to the stimulus presented two presentations back?). Changes across the lifespan on a 3-back visuospatial and verbal task are present in [Figure 3](#). Individuals in their 60s and older demonstrated significantly poorer working memory performance than younger individuals. Similar results have been reported on several working memory tasks with significant deficits detectable in the 40s.

Decision-Making

As we age, we are faced with making decisions that can dramatically impact our quality of life. For example, ‘which Medicare supplement will provide the most benefit?’, or ‘what form of care will be best for my ailing spouse?’ are typical challenging decisions made by older individuals. A laboratory analog of risky decision-making is the Iowa Gambling Task. For this task, research participants are presented four decks of cards on a computer screen and asked to select from any deck. The goal of the game is to select cards that result in winning money and avoid losing money. Participants are told some decks are better than other decks and they can avoid losing if they stay away from the worst decks. The two bad decks have high rewards, but even higher loss. The two good decks have low rewards, but even lower loss. Participants play 100 trials. The results of this test for the last 25 trials of the Iowa Gambling task for 872 individuals between 15 and 89 years of age are displayed in [Figure 3](#). The individuals in their 80s made significantly poorer choices than young adults, which demonstrates a decline in decision-making abilities with age.

Processing Speed

Processing speed is a measure of the time required to respond to and/or process information in one’s environment. With increasing age, processing speed has been shown to slow dramatically. Thus, older individuals require more time to complete a cognitive task when compared to younger adults. Additionally, a speed of processing theory has been formulated within the cognitive aging literature that accounts for some of the age-related changes that occur in cognition. A large number of studies demonstrate that along with a common factor of age-related decline, processing speed is at least a partial mediator of age-related performance deficits in a variety of cognitive tasks. Thus, the slowing of individuals’ ability to process information inevitably impacts their memory, decision-making, and other cognitive functions.

This reduced, or slowed, speed of processing has been found to account for poorer performance by older adults on

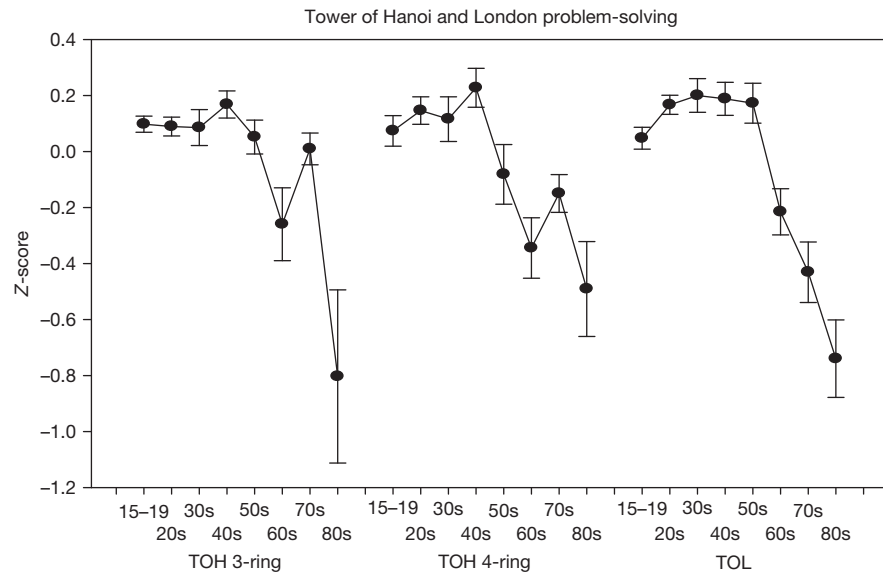

Figure 2 Standard Z-scores for performance on the average of five trials for the 3- and 4-ring Tower of Hanoi and moves on 21 trials on the Tower of London for participants between 20 and 89 years (Tower of Hanoi $N = 1293$; Tower of London $N = 2036$). Adapted from Foster SM, Cornwell RE, Kisley MA, and Davis HP (2008) Cognitive changes across the life span. Figure 3 Standard Z-scores for number of category shifts in the Wisconsin Card Sorting Test (WCST), the percent correct responses on a verbal and visuospatial n -back task, and the number of choices from good decks minus bad decks in the Iowa Gambling Task for participants from 15 to 89 years of age (WCST $N = 1874$; n -back verbal and spatial $N = 745$; Iowa Gambling Task – Risky Decision $N = 872$). Adapted from Foster SM, Cornwell RE, Kisley MA, and Davis HP (2008) Cognitive changes across the life span. In: Qualls SH and Smyer MA (eds.) *Changes in Decision Making Capacity in Older Adults: Assessment and Intervention*, pp. 25–60. Hoboken NJ: Wiley.

a complex decision-making task. For example, an investigation compared young and elderly adults on three risky decision-making tasks (Iowa Gambling Task, Cambridge Gambling Task, and Balloon Analogue Risk Task). One goal of this

study was to determine if a participant's age directly influenced their performance, or if the effect was indirect via age-related changes in processing speed and/or memory. A path analysis found that speed of processing fully mediated performance on

the Cambridge Gambling Task and the Balloon Analogue Risk Task, and that memory acted as a full mediator of performance on the Iowa Gambling Task. These findings were the first demonstration that age effects on decision-making can be fully mediated by cognitive factors such as processing speed or memory. This path analysis approach provides a promising avenue for examining the possibility that age-related deficits on other tasks will be either fully mediated (age effect disappears) or partially mediated (age effect significantly reduced) by processing speed or other cognitive variables.

The Relationship Among Cognitive Functions

The examination of cognition across the adult lifespan reveals normal age-related declines in almost all areas, including memory, executive functioning, decision-making, and processing speed. Although each of these cognitive functions are discussed as separate entities, declines in one area of cognition are highly correlated to declines across other cognitive domains as a factor of natural aging processes. In other words, the various areas of cognition are thought to be related to each other. This suggests that changes in several areas of cognitive functioning may be accounted for by changes in one area of cognition, such as speed of processing or fluid intelligence. Although most areas of cognition do decline with age, an individual's ability to retain general knowledge or information acquired over time remains intact. The amount of acquired knowledge, known as crystallized intelligence, has been found to not only remain stable over time, but also may continue to increase with age.

Cognitive Rehabilitation: Behavioral Interventions and Their Impact on Cognition

Natural aging processes can negatively impact our cognitive functioning as the literature suggests. As a result, these changes in cognition manifest themselves in the ability of older adults to function in everyday life, which can not only influence their quality of life but also their ability to live independently. Aside from natural aging, older adults are at a high risk for the development of dementia, including Alzheimer's disease and vascular dementia. Despite the high rate of individuals developing dementia-related cognitive impairment annually, little is known about the cause of these fatal neurodegenerative diseases. However, in recent years, much research has been focused on finding preventative measures to reduce the risk of cognitive decline among the older adult population.

Certain behaviors, such as solving daily crossword puzzles or playing strategic board games, have long been suggested as having a positive effect on cognition and may thwart age-related cognitive decline. Empirical research has begun to explore the impact of behavioral interventions on cognitive functioning, which has been referred to as cognitive enrichment. According to the cognitive-enrichment hypothesis, engaging in certain behaviors, such as intellectually stimulating activities, physical exercise, and socialization, can advantageously affect cognitive functioning in older adulthood. Despite the mainstream popularity of the 'use it or lose it' mentality, which is encompassed by the cognitive-enrichment hypothesis, much controversy and

debate surrounds this theory. Therefore, the empirical evidence for and against this hypothesis will be reviewed.

Training the brain through mental exercise has been compared to training the physical body through physical exercise. Conceptualizing the brain and mental activity in this manner has produced multiple lines of research aimed at determining if mental training can improve mental functioning and decrease the rate of cognitive decline. Due to the plasticity of the human brain, or its ability to alter and change functionally and physically, researchers speculate that the brain is capable of learning and changing over one's entire lifespan. Based on this idea, a research study investigated the effects of a brain training program on normal age-related memory loss in older adults. For this study, a large sample of older adults was recruited and randomly assigned to one of three experimental conditions: an experimental training group, an age-matched control group, and a no-contact control group. Participants in the experimental training condition used a cognitively demanding computer program for 1 h a day over a period of 8–10 weeks, which required them to engage in intense auditory and language exercises. At the end of the study period, all participants were compared on a battery of neuropsychological tests to determine if the brain training generalized to other broad measures of memory. The results showed that the participants who received the daily training exercises had made significant improvements in their global auditory memory score as compared to participants in the control groups. After a 3-month follow-up, the participants in the experimental condition continued to outperform the control group participants on a digit span forward test. Upon completion of this study, the researchers concluded that a plasticity-based training program can improve memory functioning among seniors.

Other research studies have reported similar findings regarding the benefit of training interventions on cognitive functioning. For instance, over 2500 older adult participants were recruited to determine if a cognitive training procedure would improve their overall cognition. Participants were assigned to either an experimental condition in which they received cognitive training in memory, reasoning, or visual search, or they were assigned to a control group. The results demonstrated that participants who received training in a particular domain (i.e., memory training) also demonstrated improvement in a 2-year follow-up in the same domain they received training as compared to the control group. Overall, the study demonstrated that this type of intervention does have benefits to the specific domain targeted by training, but may not generalize to other cognitive domains. A similar, large-scale study which investigated the generalizability of the effects of brain training on a sample of over 11 000 adults found that although the training resulted in improvement on the specific cognitive tasks, the effects did not generalize to tasks that were not used during training.

Based on the available literature, cognitive training has been found to benefit an older adult's cognitive functioning albeit, in most cases, limited to the cognitive domain receiving the training. In addition to cognitive training, the effects of engaging in mentally stimulating activity on cognition in older adulthood have also been studied. According to the cognitive-enrichment hypothesis, individuals who have greater rates of engagement in cognitively demanding activities should have a reduced risk for cognitive decline compared to those who do

not actively engage in these types of activities. In order to investigate this phenomenon, the methodologies within these studies rely on the use of self-report measures of cognitive activity. The researchers conducting these studies also vary in their interpretation of stimulating or intellectually demanding cognitive activity, such as reading a book or playing chess. Regardless, the empirical evidence within the literature strongly supports the cognitive-enrichment hypothesis; higher rates of engaging in stimulating cognitive activity among older adults has been associated with a reduced risk of cognitive decline.

Although there is strong supporting evidence for the cognitive-enrichment hypothesis, others question the reliability and the generalization of these findings. Two major limitations have been reported within the cognitive training studies that have tested the enrichment hypothesis. First, the effects of the training are narrow and often do not generalize to other areas of cognition. For instance, memory training exercises may not benefit reasoning or decision-making, they benefit only memory. Second, the majority of cognitive training studies do not monitor or investigate long-term effects. Therefore, it is difficult to determine the long-lasting effects of these interventions or whether or not the improvements continue at a steady rate over a period of time. Third, the research methodology investigating the effect of engagement in stimulating mental activity on cognition has been questioned. Self-report measures, for example, can be unreliable due to inaccurate estimations of one's own mental activity level. Also, a desire to maintain a positive self-image, also known as a desirability bias, can distort an individual's portrayal and report of their actual level of activity. An additional limitation within this body of research is the variability among researchers regarding the conceptualization of mental activity and mental exercise. Researchers have defined it as anything from attending lectures to watching television, while making arbitrary inferences to the level of cognitive demand each activity requires.

Other major criticisms regarding the research finding a relationship between level of mental activity and cognitive functioning is that it is correlational, making it impossible to determine the direction of causality within these studies. An opposing hypothesis to the conclusions drawn by the cognitive-enrichment research is that a reduction in the level of stimulating mental activity in older adults can be an early indication of a dementing process. In other words, the disease process is driving the level of mental activity, not that the mental activity is driving the lack of or presence of a disease process. Additionally, another rival explanation to the findings of the cognitive-enrichment studies explains that older adults who report high levels of mental activity may have always engaged in intellectually demanding activity and may, therefore, have had a higher socioeconomic status than their counterpart. Thus, having the advantage of a higher economic status may have afforded them a higher quality health care, better nutrition, better educational opportunities, or other unknown variables that could have influenced their cognitive functioning in old age.

The influence of educational attainment and other early environmental factors on late life cognition has been referred to as the cognitive reserve hypothesis. Models of cognitive reserve have been discussed as both passive and active processes; active processes refer to the brain's attempt to repair or

cope with damage, whereas passive models refer to the brain's capacity to withstand damage or atrophy. A common passive model of cognitive reserve is the threshold model which indicates that all individuals experience cognitive decline as they age; however, individuals who have higher levels of cognitive functioning in their young adulthood will decline, but their cognitive performance may never drop to clinically significant degrees of impairment. For example, in a longitudinal study of cognitive performance over time, individuals of varying degrees of education and knowledge demonstrated decline in cognitive performance at similar rates. Therefore, this finding is more conducive to understanding cognitive reserve through a threshold paradigm. In other words, individuals with greater educational attainment and higher cognitive abilities in their youth will experience similar rates of cognitive decline as those who have less education and cognitive abilities. However, due to the fact that their premorbid level of functioning was higher, the time it takes for these individuals to reach functional levels of impairment may be longer than the average individual. Thus, they are typically able to function independently without problems despite some degree of cognitive decline.

Besides the literature on cognitive fitness, the cognitive-enrichment hypothesis also extends to the use of other behavioral interventions that may reduce the risk of cognitive decline, including exercise. A substantial body of research has been dedicated toward exploring the effects of physical exercise on cognitive functioning. One particular study aimed to determine the effects of an aerobic fitness program on older adults' cognition. A total of 124 older adults were placed into two groups: an aerobic exercise group and a nonaerobic exercise group. Before completing the exercise training, all participants were tested on a variety of cognitive measures to obtain baseline measures. The participants in the aerobic group walked for a period of 1 h three times per week over 6 months, whereas the nonaerobic group simply engaged in stretching and toning exercises over the same period. At the end of the testing period, the participants in the aerobic fitness group had demonstrated specific improvements on several cognitive measures compared to the participants in the nonaerobic group.

Likewise, a meta-analysis reviewing the relevant research that investigated the implementation of an aerobic exercise program on older adults' cognition was conducted. After analyzing 18 relevant research articles, the authors of the meta-analysis reported a large effect size of 0.48. The data was consistent with the view that an aerobic exercise training program can have an advantageous effect on an older adult's cognitive functioning. Overall, the research in this area suggests that engagement in aerobic exercise may thwart cognitive decline or reduce the risk of dementia among older adults.

The research testing the cognitive-enrichment hypothesis suggests that certain behaviors and interventions, specifically cognitive training fitness programs, mental activity, and aerobic exercise, can help an older adult's cognitive functioning. In addition to the behaviors examined in this brief review, the cognitive-enrichment hypothesis also extends to and explores other behaviors and their relation to cognitive functioning among older adults, including socialization and mental health practices. Despite the findings supporting cognitive enrichment, much debate exists on the validity and the interpretation of this body of research. Although this area of research remains

new, the preliminary findings are encouraging regarding the possibility of delaying and reducing normal age-related cognitive decline in older adulthood. Interpretations of the cognitive-enrichment hypothesis, however, should be done with caution due to the fact that these behaviors may only delay normal age-related decline and may not influence the outcome of a pathological dementing process. However, future studies should continue to explore and examine the cognitive-enrichment hypothesis in an effort to validate and understand its implications.

Glossary

Calcium hypothesis of aging The hypothesis that cognitive and memory deficits associated with aging are due to dysfunction of mechanisms for regulating levels of calcium in neurons.

Cholinergic hypothesis of aging Pathological aspects of aging, such as Alzheimer's disease and cognitive impairments, are due to the selective loss of neurons in the basal forebrain that produce the neurotransmitter acetylcholine.

Dementia with lewy bodies (DLB) The second leading cause of dementia behind Alzheimer's disease. The primary

characteristic of DLB is the presence of Lewy bodies which are small clumps of protein that are found within the intracellular fluid of cells in the brain.

Nonsteroidal anti-inflammatory drugs (NSAIDs)

NSAIDs, such as ibuprofen, aspirin, and naproxen, are nonnarcotic analgesics that have anti-inflammatory effects that may be beneficial in coping with harmful effects of aging.

Oxidative stress Cellular damage resulting from the accumulation of reactive oxygen species – molecules produced by the mitochondria in cells as a byproduct of energy metabolism.

For much of the history of modern brain science, it has been widely held that the mammalian brain undergoes significant developmental changes early in life, followed by a steady, and occasionally precipitous, decline across the life span. At the heart of this thinking is the assumption that plasticity – the ability to change structure and function – is a feature of the developing brain but not of the adult brain. This and other long-held assumptions have been challenged in recent decades, and we are coming to a new understanding of the brain's amazing ability to remain plastic and to change across the life span. For example, the common belief that we lose significant numbers of neurons as we age has been reconsidered. Indeed, it is now well established that the adult brain retains the ability to produce new neurons. In this article, we first examine prominent theories of brain aging at the cellular level of analysis. These include the cholinergic hypothesis, oxidative stress, the calcium hypothesis, and genetic models of aging. Then, we discuss some of the age-associated changes in the vascular system and neuron numbers in the various systems of the brain. Next, common age-associated neuropathological conditions and therapeutic interventions are explained (excluding Alzheimer's disease which is addressed in a separate article). We conclude with some rather encouraging evidence that it may be possible to maintain a healthy brain well into advanced age.

Major Neuronal Theories of Brain Aging

Cholinergic Hypothesis of Aging

The cholinergic hypothesis of aging states that loss of function among cholinergic neurons is a primary contributor to Alzheimer's disease and loss of cognitive function as we age. Neurons of the basal forebrain are the primary source of the neurotransmitter acetylcholine, and they extend processes throughout the brain to regions that include the limbic system and the neocortex. The cholinergic hypothesis is supported by reports of relationships between the integrity of basal forebrain

cholinergic neurons and the degree of age-related impairment in both animal and human subjects. These correlational results, however, do not establish the contribution of age-related changes in the basal forebrain cholinergic system to cognitive impairments. Evidence that supports a functional link comes from two main sources: treatments targeted at improving cholinergic function relieve impairment in aged subjects, and sensitivity to anticholinergic agents increases with aging. Evidence that is not consistent with the cholinergic hypothesis includes reports that selective removal of cholinergic neurons in the basal forebrain of a rodent model of aging fails to reproduce impairments commonly found in aged subjects. Moreover, therapeutic interventions that target the cholinergic system, which included until recently all drugs approved by the Food and Drug Administration for use for the treatment of Alzheimer's disease, produce modest effects, at best. Thus, while the cholinergic hypothesis has generated considerable research and revealed targets for therapeutic intervention, it is now widely held that other types of neurons, in addition to cholinergic neurons, are likely to contribute to age-associated deficits. In the next section, we consider some of the theories that describe why and how other types of neurons might become dysfunctional or die off as we age.

Oxidative Stress

In this section, we discuss a series of hypotheses on the causes of brain aging that are all centered on the theme of oxidative stress. Oxidative stress is the gradual accumulation of reactive oxygen species (ROS) within the cells of the body as we age (ROS is a subset of 'free radicals'). ROS are biological compounds such as superoxide anion radical (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl ions (OH^-). These molecules are produced in mitochondria, which are energy-producing components found inside the cells of the body. If not kept in check, ROS can lead to the oxidation of lipids, proteins, and DNA that can cause their destruction, malfunction, or mutation. Accordingly, the body has a host of systems designed to

watch over ROS. These usually take the form of enzymes (such as superoxide dismutases) and metabolites (such as vitamin C). The body has two main pathways with regard to ROS: one that produces ROS and one that breaks ROS down. The oxidative stress theory proposes that some process or combination of processes causes an imbalance in these two pathways, which leads to an increase in oxidative damage and what we know as aging. ROS are utilized by various leukocytes, also known as white blood cells, in the body to mount an immune response when faced with pathogens. The production of ROS by mitochondria and the antagonistic response by the immune system represent two distinct pathways, and also two distinct aspects of the oxidative stress theory of aging that we discuss next.

Inflammation is a natural part of the body's defenses against invading pathogens and injury. The brain contains a collection of cell types, including microglia, that are ready to respond to potential threats. When a pathogen is detected, microglia are activated and proinflammatory cytokines – proteins secreted by cells of the immune system to carry signals between cells – such as tumor necrosis factor α , interleukin-1, and interleukin-6 are released. These in turn activate more microglia, which attack invading cells, destroy debris, and call in cellular reinforcements. Once the threat is eliminated, they then return to an inactive state until they are called upon again. There is mounting evidence that, as we age, microglia tend to remain in the active state and do not return to their inactive state. This may lead to a prolonged or increased immune response and consequently, an increase in oxidative stress. The respiratory burst system is an important immune response in the brain in which activated microglia use an enzyme known as NADPH oxidase to rapidly produce large amounts of the ROS superoxide, which is used to kill the intruding cells via oxidative damage. In addition to an increase in ROS production, activated microglia can also damage the body in the form of autoimmune attacks. Activated microglia have been implicated in the neuronal death associated with Alzheimer's and Parkinson's diseases among others. Given the link between inflammation and degenerative disease, it is easy to see why researchers would want to investigate the use of anti-inflammatory medication to treat these symptoms as we discuss later in this section.

The mitochondrial DNA theory of aging proposes that an accumulation of mutations and deletions in mitochondrial DNA contributes to aging processes. Mitochondrial DNA is the DNA found in the mitochondria – a structure in cells that generates adenosine triphosphate (ATP), which provides a source of chemical energy for cells. Mitochondrial DNA is involved in functions such as cellular metabolism, calcium storage, and oxidative phosphorylation – a metabolic process that uses energy released by the oxidation of nutrients to produce ATP. Oxidative phosphorylation results in reactive oxygen species (ROS), which can be damaging to cells as described previously. Because of their role in oxidative phosphorylation, mitochondrial DNA uses oxygen at a very high rate and thus produces the majority of reactive oxygen species in a cell. The accumulation of ROS can have harmful effects on the brain's neurons, leading to oxidative damage and cell death. There is evidence that aged animals have higher levels of ROS in comparison with younger animals, suggesting again that aging is a consequence of the damage done by the accumulation of free radicals in cells.

In addition to promoting free radical production, mitochondrial DNA is more susceptible to mutations than DNA found in the nucleus of cells, and has lower DNA repair. Mitochondrial DNA is not fully protected by histones – the proteins that package DNA – and this makes the DNA more susceptible to free radicals and mutations. One current theory suggests a cyclic mechanism for mitochondrial DNA mutations and cell death due to ROS. Because mitochondrial DNA is highly susceptible to mutations, the accumulated mutations are thought to impair cellular oxidative phosphorylation, leading to increased levels of ROS. Increased ROS, in turn, leads to further mutations and the cycle continues. Mutations in mitochondrial DNA have been shown to increase with age as well as in the presence of neurodegenerative disorders. In addition, mice with point mutations in mitochondrial DNA as well as full deletions showed reduced life span and early onset of age-related characteristics. Also, human studies show that mitochondrial DNA deletions increase with age and some research indicates that these deletions occur in cells with higher levels of oxidative damage. ROS are not the only molecules implicated in the aging process. In the next section, we see what role calcium is believed to play in the aging process.

Calcium Hypothesis

While it is well known that calcium helps promote healthy bone structure, it also plays an important role within neurons. Calcium molecules often serve as 'second messengers' within neurons by helping to pass along messages received from other neurons via receptors. One way in which they pass messages is through a type of channel in the neuron's membrane that opens in response to signals sent from neighboring neurons. This channel allows calcium ions to enter the cell. The calcium ions that enter the cell are highly regulated as only a minute amount will activate a host of cellular processes. As one might expect, if the cell is particularly sensitive to calcium, then dysregulation of calcium ions may be responsible for what we call aging. This line of investigation is referred to as 'the calcium hypothesis.' As we get older, there is an increase in the concentration of L-type voltage-gated calcium channels and more calcium tends to enter the cell each time the calcium channels are opened. The age-associated increase in calcium channels is correlated with decreased cognitive function in aged animals whereas blocking these channels improves animals' memory.

In addition to the dysregulation of extracellular sources of calcium, aging may also be due to dysfunction of intracellular calcium release. Each cell contains an organelle that is called the endoplasmic reticulum, and one of its many functions is to store calcium reserves until needed. When called upon, the endoplasmic reticulum can release the calcium by way of either ryanodine receptors or IP₃ receptors. Chronic elevation of intracellular calcium is related to excitotoxicity – a form of cell death – in tissue cultures. The ryanodine receptors mediate a process known as calcium-induced calcium release in which calcium from the endoplasmic reticulum is released when the receptor detects calcium. When ryanodine is administered to the ryanodine receptors, it binds in the place of calcium and this has been shown to help maintain calcium levels.

Understanding the roles of cellular and molecular mechanisms of aging may eventually prove useful in combating their

negative effects. In order to investigate how specific molecular changes influence development across the life span, scientists have come up with several different kinds of genetic models; we now look at those models that focus on aging.

Genetic Models

Certain strains of mice are often inbred to create a population of animals with similar characteristics so that a specific phenomenon or characteristic can be studied in a controlled manner. The senescence accelerated mouse (SAM) model of aging provides a rodent model of aging and aging-related disorders and is comprised of two main strains: accelerated senescence-prone (SAM-P) and accelerated senescence-resistant (SAM-R) mice. They were developed in 1973 when Dr. Toshio Takeda and his research group noticed that, while maintaining a colony of a specific strain of mice, some litters would show accelerated characteristics of aging and had a shorter life span. When compared to their SAM-R counterparts, the SAM-P mice have shorter life span, hearing impairments, brain atrophy, learning and memory impairments, cataracts, osteoporosis, and immune system impairments. SAM-P mice also have higher levels of ROS. Some researchers attribute this fact to functional impairments in mitochondrial DNA, resulting in increased output of ROS. As stated previously, increased levels of ROS are one potential mechanism by which age-related neurodegeneration and cell death can occur. SAM-P mice also show accelerated age-related decline in some important cellular functions such as cell survival and proliferation. This impairment of cellular function can lead to degeneration of tissues.

SAM models provide a useful research tool for aging studies. One strain of SAM-P (SAMP-8) shows learning and memory deficits from early in development. This particular strain shows higher levels of ROS early on and is of particular interest to researchers in the dementia field because SAMP-8 mice show early onset of development of β -amyloid plaques, which are implicated in Alzheimer's disease and other forms of dementia. SAM-P strains can be useful in the development of drug therapies and treatments for age-related disorders because of their varying diversity. For example, while one strain may show a deficit in learning and memory, another strain may show osteoporosis, while yet another strain would demonstrate frontal lobe atrophy. Given the variety of age-related disorders present in strains of the SAM-P mice, they are a useful and effective tool for aging research. Now that we have covered some prevailing ideas about aging on a cellular-molecular level, we discuss aging-related changes at a broader neuroanatomical view in the paragraphs that follow.

Systems-Level Anatomical Changes in the Brain with Age

Vascular Changes

The brain needs a constant supply of blood to carry oxygen and essential nutrients to the neurons in the brain in order for them to function properly. The carotid arteries are the two main arteries that carry blood to the brain, while other arteries within the brain carry the blood to specific regions. If blood

supply to a region of the brain is cut off, then surrounding neurons will begin to die and the area will become damaged in what is commonly known as a stroke. Stroke can cause permanent damage to brain regions, leading to serious disabilities or death. Given that the incidence of stroke increases with age, it is important to be well informed about the associated risk factors for a stroke.

The vast majority of strokes are classified as ischemic strokes. These occur when blood flow in the brain becomes blocked. This blockage is usually made up of a fatty deposit known as an atheroma or a plaque. The plaque builds up in arteries, causing the blood vessel walls to harden and shrink in size, which is a condition known as atherosclerosis. The buildup becomes larger as more blood platelets aggregate together in the area, contributing to the formation of a blood clot. An ischemic stroke can be further classified as either a thrombotic or an embolic stroke, depending on where the clot initially forms. If the clot forms inside the blood vessels of the brain, then it is classified as a thrombosis; if it forms elsewhere in the body before traveling to the brain, then it is considered an embolism. An intracerebral hemorrhagic stroke is a less common type of stroke in which a weak spot on a blood vessel known as an aneurysm enlarges and bursts. Blood spills out into the brain when the aneurysm ruptures, causing an increase in pressure and extensive damage to surrounding areas. A subarachnoid hemorrhage is similar to an intracerebral hemorrhage, but the blood vessel bursts near the brain's surface and the blood spills out into the region between the skull and the brain known as the subarachnoid space.

Several risk factors can increase the likelihood of having a stroke, one of which is age. Even though a stroke can occur at any age, the majority of strokes happen after middle age and the incidence increases the older one gets. High blood pressure puts a person at greater risk of having a stroke because it causes stress on the heart and blood vessels that can lead to atherosclerosis or rupturing of an aneurysm over time. High blood pressure and high cholesterol are very unhealthy for the cardiovascular system. Maintaining a healthy cardiovascular and circulatory system can greatly reduce the chance of having a stroke. High blood pressure and high cholesterol can be treated through exercise, weight loss, regulation of diet, and with medication if necessary. Having a condition known as atrial fibrillation increases the risk of stroke. An atrial fibrillation occurs when the top two chambers of the heart (the atria) beat irregularly, causing blood to pool in the heart and clots to form. This can result in an embolic stroke if one of the clots moves to the brain. Diabetics are at greater risk for having a stroke because they tend to have high blood pressure; furthermore, the damage to the brain during a stroke is greater when blood sugar is very high. Smoking dramatically increases the chance of a stroke, since smoking reduces oxygen levels in the blood and causes the heart to work harder. A transient ischemic attack (TIA) or 'mini-stroke' is caused by temporary blockage of the blood vessels. It does not cause permanent damage but should be recognized as a warning sign of a future stroke.

Diagnostic tests need to be run before administering treatment to a person who has had a stroke. Blood thinners are an effective treatment for ischemic stroke but if the stroke is hemorrhagic, then administering blood thinners would increase bleeding and damage. Most physicians use X-ray and

brain imaging techniques such as CT (computed tomography) and MRI (magnetic resonance imaging) to find the blockage or area of bleeding. An angiogram is an X-ray technique in which dye is injected into arteries to more accurately locate obstructions and aneurysms. An angiogram can be used as a screening tool to look for abnormal blood vessels. Once a diagnosis is made, treatment can begin. For ischemic strokes, the primary medical treatments are administering a clot-dissolving tissue plasminogen activator (tPA), anticoagulant drugs, antiplatelet drugs, and low dose aspirin. The main surgical treatments used for ischemic strokes are a carotid endarterectomy (removing the blockage from the artery), performing an angioplasty to reduce plaque buildup, and setting up a stent to improve blood flow in the vessel. The primary treatment for hemorrhagic strokes is through surgical interventions to stop the bleeding and repair the damaged blood vessels.

Neuron Loss

As reviewed in the previous sections, most theories of brain aging are built around the notion that the most likely cause of age-associated cognitive decline is the widespread loss of neurons. This view is changing rapidly due to development of new techniques for assessing neuron numbers and better methods for early diagnosis of pathological conditions. Two regions of the brain have come under close scrutiny – the neocortex, which is responsible for higher order cognition, and the hippocampus, which is implicated in long-term memory. It has been known since the 1950s that the hippocampus is important for memory, and memory impairments associated with aging are similar to those caused by damage to the hippocampus. However, it is now known that there is no significant age-associated loss of neurons in the hippocampus, even among aged subjects with severe memory impairments. This fact was supported by a rodent model of aging and a newly developed technique for unbiased counts of neuron numbers. These findings have since been confirmed among both nonhuman and human primates.

The assumption that neurons are lost in the cerebral cortex as we age is also coming under increasing challenge. When pathological conditions such as Alzheimer's disease are controlled for, it appears that there is little loss of cortical neurons in a variety of regions including visual and motor cortex, and the prefrontal cortex, which is an area important for using experience to guide choices about current situations. This finding is encouraging as it suggests that there may be a useful distinction between 'successful' and 'pathological' aging. In addition, instead of focusing exclusively on age-associated neuron loss, investigators are beginning to test hypotheses about how changes in connectivity between neurons may account for deficits associated with aging, particularly in the prefrontal cortex, an area strongly implicated in age-associated cognitive decline. In specific, recent evidence suggests that there is a decrease in both excitatory and inhibitory synapses, the points of communication among neurons, in certain regions of the prefrontal cortex. In addition, there is evidence that the vesicles that contain neurotransmitters at certain synapses may change with age and this may be related to cognitive status among the elderly. These and other functional changes in communication among neurons will continue to be a promising focus of investigation.

Age-Associated Neurological Disorders

Parkinson's Disease

Parkinson's disease is a chronic, progressive, degenerative disorder of the central nervous system. Common symptoms of the disorder include muscle rigidity, tremor, bradykinesia (slowing of movement), postural instability, and cognitive problems. The primary symptoms of Parkinson's disease are a result of decreased stimulation of the motor cortex by the basal ganglia, a group of nuclei in the forebrain associated with motor control as well as motor and cognitive habits. The decreased signal from the basal ganglia is due to degeneration of neurons in the substantia nigra, a nucleus of cells in the midbrain that release the neurotransmitter dopamine. Dopamine is a catecholamine neurotransmitter that plays an important role in sleep, cognition, motivation, learning, attention, and movement. Within the basal ganglia, there is a direct pathway that provides an excitatory signal to the cortex and facilitates voluntary movement and an indirect pathway that provides an inhibitory signal to the cortex and inhibits movement. The ultimate result of neuronal damage in Parkinson's disease is inhibition of the direct pathway and excitation of the indirect pathway, both leading to the classic symptoms of tremor, muscle rigidity, slow movement, and postural instability.

The cause of cell loss in the substantia nigra is unknown, and Parkinson's disease is considered to be idiopathic (having no known cause). However, in recent years, theories have emerged as to the etiology of neuronal degeneration. One proposed mechanism of cell death in Parkinson's results from the accumulation of a protein common to neural tissues, α -synuclein, as a complex which forms what are known as Lewy bodies (described in the next section). Another proposed mechanism of cell death involves the oxidative stress model of aging which we described previously. In this case, cell death is a result of iron accumulation in the substantia nigra. Cells in the substantia nigra have a large amount of melanin, resulting in the dark color that gives the structure its name ('black substance'). The iron binds to neuromelanin and ultimately results in accumulation of reactive oxygen species (ROS) which are toxic to cells and can result in cell death.

There is currently no cure for Parkinson's disease, although treatments can be effective at managing symptoms. The most widely used treatment is levodopa (L-Dopa), which is the biological precursor to dopamine and increases the levels of dopamine in the brain. L-Dopa is often given in conjunction with dopa-decarboxylase inhibitors. Dopa-decarboxylase is the mechanism by which L-Dopa is metabolized into dopamine, and the inhibitors help to prevent it from being metabolized elsewhere in the body before it reaches the brain. Even with dopa-decarboxylase inhibitors as a part of treatment, only about 1–5% of L-Dopa reaches dopaminergic neurons. Although L-Dopa is the most commonly used line of treatment, other therapies are available such as agents that act by stimulating dopamine receptors. In addition, there are drugs available that inhibit the breakdown of dopamine, such as monoamine oxidase-B inhibitors. These drugs interfere with the naturally occurring enzyme that breaks down excess dopamine in the brain, effectively increasing levels of dopamine in the brain.

In addition to therapies that pharmacologically enhance the dopaminergic system, there are also surgical treatments. The most widely used surgical treatment of Parkinson's disease is deep brain stimulation, or DBS. DBS involves the surgical implantation of what has been likened to a 'brain pacemaker' that sends electrical pulses to specifically targeted areas of the brain including the internal capsule and the subthalamic nucleus. The direct effect of DBS on neurotransmitter release and overall brain physiology is not fully known or understood, but it can provide relief from major Parkinson's symptoms. However, DBS is only used in the most extreme cases, typically after other lines of therapy have failed. Other surgical therapies that are not widely used but have shown some promise as potential treatments are lesions of the subthalamic nucleus and the globus pallidus. Though other options exist, DBS remains the most commonly used surgical therapy for Parkinson's disease.

Lewy-Body Dementia

Dementia with Lewy bodies (DLB), often referred to as Lewy body dementia, is the second leading cause of dementia behind Alzheimer's disease. The primary characteristic of DLB is the presence of Lewy bodies in the brain, named after Dr. Friederich Lewy in 1912. Lewy bodies are small clumps of protein that are found within the intracellular fluid of cells in the brain. The primary protein that makes up these Lewy bodies is known as α -synuclein, which is a naturally occurring protein believed to be used in the formation of vesicles, which help store neurotransmitters used for cellular communication. It is not currently known exactly what causes the α -synuclein protein to go rogue, but one theory is that the body can start to overproduce α -synuclein. Another is that some malfunction eventually makes the protein insoluble and more able to clump together. One theory even proposes that Lewy bodies might actually be 'good,' and are made by the body to inactivate rogue α -synucleins that have not been properly eliminated.

In addition to the production of Lewy bodies, DLB also leads to a decrease in certain neurotransmitter systems such as acetylcholine and dopamine. Similar to Parkinson's disease, a dysfunction of these chemical messengers can lead to symptoms such as slow movement, rigidity, and a shuffling gait. Along with Parkinson-like symptoms, people with DLB typically exhibit a fluctuating level of cognitive impairment. One day the patient may seem alert and active but the next day will be sluggish and easily confused. Another common symptom of those with DLB is frequent hallucinations, which are thought to be related to the formation of Lewy bodies in the temporal lobe. Unfortunately, there is currently no known cure for DLB. One commonly prescribed treatment is a group of drugs known as cholinesterase inhibitors, which stop the breakdown of acetylcholine, allowing it to remain active longer. Caution must be used when medicating DLB patients with neuroleptics (antipsychotics) because they have been shown to be sensitized to these treatments and may develop the aptly named neuroleptic malignant syndrome. This syndrome is characterized by various homeostatic imbalances such as muscle rigidity, fever, and autonomic dysfunction.

Interventions

One potential intervention for age-related functional decline is caloric restriction. Caloric restriction involves reducing the amount of calories consumed, either by reducing overall food intake or by reducing the caloric content of the food without altering overall consumption. Reducing a nutritious diet by 20–50% can result in beneficial effects such as: increased life span, increased protection from harmful effects of stress, and slowed onset of many age-related diseases. Additionally, reduced calorie diets show lowered risk for disorders such as Parkinson's disease and Alzheimer's disease. Caloric restriction has been shown in animal models to be an effective strategy for combating age-related cognitive decline. Mouse models of Alzheimer's disease show slowed progression of the disease when the caloric intake is reduced 30–40%. Also, squirrel monkeys put on a reduced calorie diet have fewer β -amyloid plaques, a congregation of misfolded proteins and amino acids widely thought to be a main contributor to Alzheimer's disease. Additionally, long-term studies of rhesus monkeys show that animals kept on a restricted diet chronically (about 30% of control animals) show better health overall when compared on measures such as rate of aging and incidence of disease.

Though caloric restriction has been shown to be a promising potential intervention for age-related health decline, in practice, it proves slightly more difficult. For example, issues with implementation may come about as it can be difficult to maintain a chronically restricted diet. Additionally, quality of life can be affected by such a change in one's dietary intake. To combat these issues, research is now focused on areas of caloric restriction mimetics. This area of research is aimed at development of compounds, such as resveratrol, that can mimic caloric restriction by targeting both stress and metabolic pathways.

Caloric Restriction Mimetics

Resveratrol is a polyphenolic phytoalexin produced in plants and is primarily found in the skin of grapes, which is a constituent of red wine. It is also found in blueberries, peanuts, pistachios, and groundnuts in lower concentrations. It has been investigated extensively for its cardio-protective, cancer preventive, estrogenic, anti-inflammatory, and antioxidant effects. Resveratrol has been implicated as a possible antiaging drug because of its similarities with caloric restriction in improving overall health. Resveratrol circulating in the blood stream is rapidly metabolized by the body and has a short half-life of decay. The chemical products of resveratrol's metabolism have a much longer half-life than resveratrol in its unconjugated form. Accordingly, it is difficult to tell how much resveratrol is actually accumulating in the tissues of the body before being broken down. Resveratrol has been shown to lower the risk of cardiovascular disease by increasing vasodilation and reducing the aggregation of platelets in blood vessels. Since resveratrol selectively inhibits COX1 (see section on the role of cox1), it decreases the likelihood of restricted blood flow due to blockage. Resveratrol also promotes vasodilation by improving nitric oxide signaling, which is an important mechanism for protecting against ischemic damage. Since resveratrol can cross the blood brain barrier, it promotes vascular

protection in the brain from cerebral ischemias, which are a major cause of stroke. Research with rodents has demonstrated that resveratrol can decrease motor damage and the amount of tissue death following a stroke.

In addition to regulating vascular homeostasis, COX enzymes play an important role in the body's inflammatory and immune response. Resveratrol has been shown to decrease inflammation by selective COX inhibition and by decreasing superoxide formation in rats. Resveratrol has also been shown to reduce reactive oxygen species (ROS) damage as well as promote antioxidant effects and reduce inflammation. The exact mechanisms by which resveratrol reduces oxidative stress are not fully understood and are still under investigation.

In aging research, resveratrol has been described as a possible mimetic for caloric restriction. Early research yielded exciting results indicating that the life span of lower organisms could be extended by manipulations of the gene for silent information regulator 2 (Sir2). However, these increased longevity results were not replicated in rodent models. Sir2 is part of a class of proteins called sirtuins that are histone deacetylases. Extra copies of Sir2 have been correlated with increased life span in yeast, worms, and flies. Mammals have seven sirtuins and SIRT1 is the mammalian homolog of Sir2. Resveratrol has been shown to activate SIRT1 in mammals, but this has not been shown to extend life span in rats. Resveratrol has numerous protective qualities that are beneficial to maintain good health and mimic metabolic changes associated with caloric restriction.

Nonsteroidal Anti-Inflammatory Drugs

In addition to caloric restriction, nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, aspirin, and naproxen, can be beneficial in coping with harmful effects of aging. These drugs are nonnarcotic analgesics that have anti-inflammatory effects and fever-reducing abilities. NSAIDs block the synthesis of prostaglandins, which cause inflammation at the site of an injury to protect from infection and cause increased pain sensitivity. Nonselective NSAIDs prevent the release of prostaglandins by directly inhibiting the enzymes Cyclooxygenase 1 (COX1) and Cyclooxygenase 2 (COX2). These enzymes play an important role in the body's inflammatory response as well as in regulating vascular homeostasis. COX1 synthesizes thromboxane A2, which promotes clot formation through increasing platelet aggregation. In addition, thromboxane A2 constricts blood vessels in order to raise blood pressure and retain heat. Prostacyclins are synthesized by COX2 to prevent platelet aggregation and dilate the blood vessels. Together, the inhibition of these compounds reduces inflammation and associated pain. In high doses, nonselective NSAIDs have negative side effects on the upper and lower gastrointestinal (GI) tract that can result in painful ulcers. The inhibition of COX1 with NSAIDs diminishes the protection of the GI tract's mucosa lining. Selective NSAIDs called COX2 inhibitors were created in an attempt to reduce inflammation and pain without damaging the mucosa lining of the GI tract. Early clinical trials demonstrated that COX2 inhibitors significantly decreased gastrointestinal problems associated with NSAIDs. However, the results of these clinical trials also demonstrated an increased risk of cardiovascular problems. The strongest

COX2 inhibitors, such as rofecoxib, were significantly correlated with cardiovascular complications when compared with placebos and nonselective NSAIDs. Currently, celecoxib is the only COX2 inhibitor available in the United States and FDA changed its label to include warning about possible cardiovascular problems.

The majority of individuals taking high doses of NSAIDs are those suffering from arthritis, which causes inflammation in the joints and considerable pain. The incidence of osteoarthritis is correlated with age, so it is important to understand the risks and benefits of using high doses of NSAIDs. Low dose aspirin has been shown to possess cardio-protective effects and it is highly recommended that the elderly and those individuals at high risk for heart attack and stroke take low dose aspirin. Aspirin irreversibly inhibits the ability of individual platelets to produce thromboxane A2, and therefore decreases the likelihood of dangerous clots forming in the blood vessels. Ibuprofen has been shown to interfere with the irreversible binding of aspirin to platelets, resulting in reduced platelet aggregation. Therefore, it is important to be knowledgeable about possible drug interactions when taking low dose aspirin.

Another type of inflammation, called neuroinflammation, is a pathological characteristic of Alzheimer's disease (AD) in affected brain regions where damage is sustained. Misfolded proteins called β -amyloid plaques and neurofibrillary tangles develop in the brain of individuals with AD. These plaques and tangles prevent the communication between neurons and eventually lead to neuronal cell death. Neuroinflammation is concentrated around these β -amyloid plaques and neurofibrillary fibers. This finding supported the hypothesis that anti-inflammatory drugs may aid in the prevention or treatment of AD. Epidemiological evidence demonstrated a lower incidence of AD in individuals with arthritis who were currently taking high doses of NSAIDs. Subsequent clinical trials, however, did not support this hypothesis and some trials were suspended due to health concerns over using high doses of NSAIDs. It is too early to recommend the use of NSAIDs for AD prevention based on current research, but scientists are still investigating the relationship between neuroinflammation and AD.

Maintaining a Healthy Brain

Successful Aging

There are many things one can do to help prevent or prolong the onset of age-related deficits. One of the most effective methods observed thus far is readily accessible and inexpensive: exercise. Cardiovascular health can be a strong predictor of mental health as we age, and several studies have shown a link between increased blood pressure in mid-life and diminished cognitive functions in later life. Studies have also linked antihypertensive treatment with reduced cognitive decline in people with hypertension compared to those who remain untreated. Another major cardiovascular concern linked to cognitive decline is dyslipidemia, an abnormality in the amount of lipids (such as cholesterol) in the blood. Studies have shown a relationship between cognitive decline and high levels of cholesterol for both high-density and low-density cholesterol. There is not yet strong evidence to support the

use of statins to treat cognitive decline related to dyslipidemia. Type 2 diabetes has been implicated in a more rapid cognitive decline when compared to nondiabetics. The duration of diabetes has also been shown to correlate with increased risk of cognitive decline. There has been modest success thus far with the use of antidiabetic medication to ameliorate the symptoms. Finally, a link has also been shown between hyperinsulinemia, or excessive levels of insulin in the blood, and cognitive decline.

Exercise does more than just improve the brain through cardiovascular health. Exercise has also been shown to increase the levels of a protein in the brain known as brain-derived neurotrophic factor, or BDNF. BDNF is one of many chemicals known as neurotrophins that encourage the growth and survival of neurons within the brain. In rats, lack of exercise can decrease the expression of BDNF whereas as little as a week's exposure to exercise has been shown to greatly increase BDNF levels. Not only does exercise increase BDNF but it also increases the production of new neurons in the hippocampus, a brain structure associated with learning and memory. Exercise has also been shown to facilitate the induction and maintenance of long-term potentiation, a phenomenon in which two cells are better able to communicate with one another as the result of activation. On a more practical level, exercise has also been shown to improve rats' performances on the Morris water maze in which they are tasked with finding a platform that is hidden below the surface of the water. The improvement seen in the Morris water maze and other such memory tasks can be abolished if the animal has its BDNF signaling blocked, implicating BDNF as a likely component of this pathway.

Many studies have shown that our ability with language and verbal manipulation is also implicated in aging. One study, sometimes referred to as the 'Nun Study,' included several members of the convent of the School Sisters of Notre Dame in a long-term study of their cognitive abilities, and the nuns agreed to donate their brains for examination upon their deaths. One benefit of conducting an aging study among a convent of nuns is that from the time they entered (with the average age being 22) each nun has lived a relatively similar life and thus from then on, most nonbiological differences between them were kept to a minimum. Before taking their vows, each nun was required to write an autobiography of their life up to that point. When the brains were analyzed, there was a strong correlation between those nuns that aged successfully and idea density scores (the ability to express a large amount of ideas in a small amount of words) and grammatical complexity in their autobiographies written several decades earlier. One evaluation of the data even suggests that those nuns that had a more positive outlook on life were healthier and lived longer.

In this article, we have discussed many of the important mechanisms of aging and age-related decline in brain function, as well as potential therapies for combating these negative aspects of aging. There is still much debate about whether what we consider aging is a pathological condition or if there are simply various degrees of severity to the declines and deficits associated with the aging process. While aging is often viewed with emphasis on the degenerative diseases (Alzheimer's disease, Parkinson's disease, dementia with Lewy bodies), several of the theories presented here involve a more gradual accumulation of damage as part of a general aging process. At the cellular level, aging is currently thought to be largely due to accumulation of ROS and their harmful effects on cells. In addition to ROS, calcium dysregulation may play a significant role in the age-associated cognitive deficits. Research in the field of aging has led to the development of major theories of brain aging centered on the cholinergic system, oxidative stress, mitochondrial DNA, and calcium dysregulation. To combat the consequences of aging, researchers have studied genetic models like the senescence accelerated mouse (SAM) model of aging as well as possible interventions that include caloric restriction, resveratrol, and NSAIDs. Current research has provided us with many ways to intervene and potentially stave off the aging process, but there is still much to be explored. As the average life span and the number of aged individuals increases (especially with a looming, aging 'baby boomer' generation), our efforts to understand the mechanisms of brain aging are increasingly coming to the forefront of scientific research.

Glossary

Focal deficit This expression indicates a symptom that depends on a circumscribed (opposite to diffuse) brain damage.

Modularity In neuropsychology, the term modularity refers to the idea that cognition and consciousness have a composed structure made up of relatively independent and domain-specific processing components.

Neuropsychology It is a multidisciplinary scientific approach to the study of cognitive brain functions in normal and brain-damaged subjects through paradigms derived from Psychology and Neurology.

Presemantic memory It is the collection of visual-structural knowledge about stimuli in the absence of knowledge about their identity and function.

Processing stage It is the result of a transformation of the information entering a biological or nonbiological system from one status to another.

Semantic memory It is the collection of knowledge, meaning, and concepts that have been acquired over the course of the life span.

Vestibular reflex The vestibuloocular reflex is elicited by irrigating cold or warm water into the external auditory canal. This maneuver evokes reflex eye movements, and it is commonly used to evaluate the function in the peripheral vestibular system or, together with other tests, to evaluate brain stem death. More recently, it has been employed for temporally reactivating brain circuits partially affected by a brain damage.

Visual Agnosia: Overview

Visual agnosia refers to the general impairment of stimulus recognition in the visual modality in the absence of perceptual deficits, memory problems, and general intellectual impairment. Individuals with visual agnosia demonstrate normal recognition of objects through modalities other than vision (touch, audition, and verbal description of objects function). Agnosia does not necessarily impair the recognition of all visual stimuli, but can selectively affect certain categories of percepts (objects, faces, colors, written words, body parts, environmental scenes), leaving others intact. Patients are well aware of their predicament. In 1889, Freund, a German neurologist of Breslau, described a case of visual recognition deficit that he named optic aphasia and he interpreted as a consequence of the disconnection of visual from language areas. A year later (1890), Lissauer, a colleague of Freund, published a paper where he clearly distinguished two different forms of agnosia: apperceptive agnosia, or inability to construct a good perceptual representation from the visual input, and associative agnosia, or inability to access the stored knowledge related to the percept. Despite these two authors being the first to report documented cases of agnosia, the term *agnosia* was coined by Freud in 1891 to describe object recognition problems in some individuals. Although it is a relatively rare neurological symptom, with some 100 cases published between 1890 and 1990, its study has greatly contributed to our understanding of how the process of visual recognition is organized in the human brain. As already mentioned, the most common form of agnosia is agnosia for objects, but forms of agnosia specific for a category of objects are also possible (e.g., agnosia for faces (prosopagnosia), agnosia for colors (color agnosia), agnosia for words (pure alexia or agnosic alexia), agnosia for scenes). Here, we briefly review these different forms of agnosia.

Object Agnosia

Although there is no standard taxonomy of object agnosias, most neuropsychologists agree on Lissauer's original distinction between apperceptive and associative agnosia, depending on the processing stage of visual information affected by the brain lesion. Because this account has continued to be employed in the neuropsychological literature to the present day, we will use it as a general framework for our present purpose. As we will see, however, this classical dichotomy captures well the cases at one end and the other of the agnosia spectrum, but not the variants falling in between.

Apperceptive Agnosia

This kind of agnosia is evident when patients are unable to recognize objects because they cannot see them properly, in the absence of elementary visual deficits. This type of agnosia is thought to arise from a breakdown at relatively early stages of visual processing, where the elementary features of the stimulus are processed. Object recognition through verbal description by the examiner is preserved, instead. These patients have relatively good visual fields, visual acuity, brightness discrimination, color vision, depth, and motion perception. Despite this, shape perception is abnormal in such a way that patients cannot recognize or copy pictures, letters, and even simple geometric shapes. Some authors consider a prerequisite for differentiating these patients from those showing deficits in the early stages of perception that they are normal on figure-ground discrimination tests but fail on Efron's test (judge whether two pairs of simple geometrical figures are same or different). If tested, identification of object orientation in space may become pathological, despite the preserved visuomotor ability to mimic object orientation based on the same visual information (this finding has been taken as evidence

supporting a dual stream model of visual perception, which attributes to the occipitotemporal ventral pathway ('what' pathway) object identification and to the occipitofrontal pathway ('how' pathway) object-directed action control). Recognition of real objects appears to be better than recognition of geometric shapes, possibly because of the availability of cues such as size and surface properties such as color, texture, and specularity rather than object shape. In most cases of apperceptive agnosia, the brain damage is diffuse, often caused by carbon monoxide poisoning. In the rare cases with circumscribed brain lesions, the damage primarily affected the ventral occipitotemporal cortex bilaterally. According to a widely accepted interpretation, apperceptive agnosia can be considered a deficit of shape perception resulting from defective perceptual grouping of object local features into a global percept. However, clinical findings show that apperceptive agnosia covers a wide spectrum of disorders, some of which fall in between apperceptive and associative agnosia. Hence, two neuropsychologists, Riddoch and Humphreys, proposed to differentiate between distinct subtypes of apperceptive agnosia, each corresponding to a defective processing stage along the hierarchically organized stream of visual information processing leading to conscious object perception (according to Marr's computational model of vision): *Shape agnosia* and *integrative agnosia*, which are 'closer' to the apperceptive type; *transformational agnosia* and *agnosia due to impairment of internal object representation*, which are 'closer' to the associative type. *Shape agnosia* results from a deficit of the initial processing stage of visual recognition and consists in the inability to organize the sensory input into a unified percept: these patients complain of blurred or unclear vision and are unable to discriminate stimulus boundaries from the background or other contiguous or overlapping shapes, as well as its orientation and size. *Integrative agnosia* consists of the inability to integrate single object features into a global shape, in the presence of the ability to identify single object details. This deficit is more severe when object shape is defined by high frequency details or when overlapping figures must be identified, but is reduced when silhouettes of objects with reduced internal details are used for discrimination. *Transformational agnosia* is a deficit of perceptual categorization (first described in 1982 by E. Warrington), which occurs when patients can recognize objects presented in a canonical view, but fail when they are presented in noncanonical views. What is lost is the ability to manipulate the mental representation of the object to match it with its perceptual image. *Agnosia due to impairment of internal representations of objects* occurs when a structural description of the object is formed normally, but its internal representation stored in presemantic memory cannot be accessed through a given route to match on-line descriptions encoded by the visual system.

Associative Agnosia

This type of agnosia occurs when patients can form a structural description of the visual object (object copy is preserved), yet being unable to recognize it. Associative agnosic patients cannot identify objects even by nonverbal means (e.g., by pantomiming their use or grouping together dissimilar objects from the same semantic category); however, recognition is preserved

in the tactile modality (by touching the object) or from a spoken definition. It is still debated whether cases of relatively pure associative agnosia are possible, that is, without a concomitant apperceptive deficit. Intrahemispheric location of the lesion is generally occipitotemporal, unilateral (with the prevalence of left hemispheric lesions), or bilateral. Following a left-sided lesion, associative agnosia can be present in both visual hemifields, probably because the semantic role played by this hemisphere is greater than that of the right hemisphere. Associative agnosia has been explained as a deficit of arousal of the semantic associations related to the visual percept: patients, despite being able to form a normal visual representation of the stimulus, are unable to grasp its meaning and therefore cannot name it. In visual naming tasks, errors tend to be semantic (e.g., 'knife' for 'fork') or totally unrelated to the stimulus (e.g., 'horse' for 'chair') or consist of the identification of the superordinate ('flower' for 'daisy'). Miming the use of a visually presented object is also impaired, whereas it is not if it follows a verbal description of the object. Patients also fail in semantic categorization and association tasks, as well as in the description of the semantic attributes of an object. According to one view, associative agnosia is the consequence of a disconnection between visual areas and other brain centers responsible for language or memory. This hypothesis, however, does not account for the inability of agnosic patients to convey information nonverbally and to access old knowledge through vision. A different interpretation, perhaps the most widely accepted, assumes that stored visual memory representations have been damaged in such a way that the newly formed visual percepts cannot be matched against them and therefore recognition is impossible. Associative agnosia must be differentiated from optic aphasia and semantic amnesia. In the former, a visual stimulus is recognized but cannot elicit naming, whereas in the latter, semantic knowledge and naming of the stimulus are inaccessible, irrespective of the sensory modality which conveys the information.

Face Agnosia (Prosopagnosia)

The term *prosopagnosia* (from the Greek *prosopon*, meaning face, and *agnosia*, meaning ignorance) refers to the inability to recognize familiar faces. The symptom was first reported by the Italian ophthalmologist Quaglino in 1867, but the term prosopagnosia was adopted only in 1947 by the German neurologist Joachim Bodamer. The deficit is confined to the identification of physiognomic traits, as shown by the fact that identification is preserved through nonphysiognomic cues such as voice, a particular item of clothing, a scar, and gait. In the most severe cases, patients cannot recognize their own faces at the mirror or that of closest relatives. In the milder forms, the deficit may be limited to friends, acquaintances, and to famous people. Perceptual categorization of the stimuli is preserved (patients know that a face is a face) as well as the ability to differentiate faces by sex, race, age, and emotional expressions. What is lost is the ability to identify a face as a known face. Psychophysical and neuropsychological studies on face recognition abilities in normal and brain-damaged patients have revealed that *familiar and unfamiliar face* processing follow dedicated routes in the left and right hemisphere, respectively. Nonrecognition of familiar

faces is more likely to occur after a left brain lesion, whereas nonrecognition of unfamiliar faces is more likely to occur after a right brain lesion. This distinction led the neuropsychologist A.L. Benton (1980) to differentiate between two independent face processing deficits produced by brain damage: *apperceptive prosopagnosia*, which refers to a defective perceptual processing of face information and is brought out by unfamiliar face tasks, and *associative prosopagnosia*, which involves an additional mnemonic component and is elicited by familiar face tasks. Recent fMRI data have located a specific area of the fusiform gyrus in the ventral part of the inferior temporal cortex called the fusiform face area (FFA), which is activated more strongly in response to face stimuli than other stimulus categories. Lesion-producing prosopagnosia often involve the FFA and are more frequent in the right side of the brain or are bilateral. The degree of domain specificity of FFA for face processing is currently object of debate.

Apperceptive and Associative Prosopagnosia

According to the model of visual recognition proposed by Bruce and Young (1986), the identification of a face is the final stage of a sequence of operations made by distinct, hierarchically organized, information processing modules distributed along the occipitotemporal ventral pathway of the brain. At the earlier stages, perceptual face processing results in the construction of an object-centered, tridimensional *structural description of the face*. If this processing level is damaged, patients are unable to recognize familiar faces (*apperceptive prosopagnosia*) as well as other categories of familiar stimuli. At later processing stages, the structural description of the face activates an abstract representation of it stored in *recognition units* responsible for the feeling of familiarity. Then, the information gains access to the semantic memory sectors (*identity nodes*) containing biographical, relational, and other information about the familiar face. From the identity nodes, information finally has access to the modules containing the person's *name*. The anatomofunctional independence of the names module is confirmed by the existence of anomia for proper names following left brain damage and by the frequent inability experienced by normal subjects to retrieve the name of an otherwise well-known person. *Associative prosopagnosia* is normally consequent upon an impairment either at the level of recognition units or of identity nodes, or both: patients pass the tests involving face identification, but fail recognition of familiar faces, though they show good semantic knowledge of the persons to whom the faces refer. Prosopagnosia must be distinguished from the impairment of retrieving from semantic memory any type of information related to an individual and/or an entity (loss of semantic knowledge for individual entities).

Specificity of the Face Deficit

A recurrent issue of debate in the neuropsychological literature is whether prosopagnosia is specific to faces or extends to other categories of objects. This latter view is supported by documented cases of prosopagnosic patients who also had difficulties in discriminating among the members of other stimulus categories, for example, a chair from an armchair, car makes, and

mammals of similar shapes. Moreover, there have been cases of farmers who had found it difficult to differentiate among their own cows, and an ornithologist who had lost the ability to discriminate birds of different species. However, there have been an equivalent number of reports of prosopagnosics with a preserved ability of differentiating exemplars of the same category when they are not faces. So, the question is whether faces are special stimuli with special features requiring a dedicated brain-processing module, or it is the nature of the processing they undergo which differs from that applied to other classes of stimuli (e.g., words and objects). Authors supporting this latter view – for example, Farah – claim that faces require an holistic processing mode to be identified for which would be responsible the right hemisphere, whereas words require an analytical processing mode, for which would be responsible the left hemisphere, and objects share both processing modalities. So, depending on the severity of the deficit, the global mode, the analytical mode, or both can be impaired, resulting in different patterns of recognition deficit involving mostly faces (mild deficit of global perception), words (mild deficit of analytical perception), and objects (more severe deficit of global and/or local perception). This theory, however, has been challenged by the reports of patients with agnosia for faces and words but not for objects, and agnosia for objects without impairment of either faces or words. Further support of the theory that faces are a special class of stimuli comes from neurophysiological recordings in the monkey and fMRI data in man. The former revealed the existence in the inferior temporal cortex of the monkey brain of neurons selectively activated by familiar faces or by face details; the latter has shown the existence in the human fusiform gyrus of the inferior temporal cortex of one area predominantly activated by face stimuli (fusiform face area (FFA)), and a different area, located in the parahippocampal region, predominantly activated by scenes depicting places or buildings, called parahippocampal place area (PPA), and unresponsive to faces. Lesions to this area can give rise to a different form of agnosia for landmarks and the environment called *topographic agnosia* (see section 'Agnosia for Landmarks and Environment (Topographic Agnosia)').

Unconscious Face Recognition

This behavior consists in the fact that some prosopagnosic patients react differently to famous faces that they deny recognizing and to unfamiliar faces, thus showing some degree of implicit knowledge of the famous faces. Implicit identification of explicitly nonrecognized familiar faces can be evidenced by psychophysiological and neurophysiological measures, such as electrodermal skin conductance, pupillometry, event-related brain potentials, and by psychological paradigms, such as forced choice, reaction times, and priming (the improvement in performance, which occurs in a decision task when a target stimulus is preceded by a nontarget semantically related to the target). When implicit recognition is probed by these means, it is possible to see an increment in these indirect measures of recognition when familiar faces stimuli are presented relative to when unfamiliar ones are presented. Perhaps the most convincing interpretation of this phenomenon is that conscious recognition requires a higher activation threshold from the visual input than implicit recognition. According to this

view, if the lesion producing prosopagnosia completely impairs the function of recognition units, both implicit and explicit recognition will be impossible. If the impairment is only partial, instead, the output from recognition units will be sufficient for unconscious recognition but insufficient for overt recognition.

Color Agnosia

Color agnosia describes a deficit in color naming and/or color-object associations that cannot be accounted for by aphasia or dyschromatopsia (impaired color discrimination). Such patients perceive colors correctly, but are unable to name them, to retrieve their name when given the name of an object of a given color, to match a color with an object, or to sort colors according to their hue. Some patients are agnosics for colors only when they have to make a visuoverbal match (naming a visually presented color and pointing to a color named by the examiner); others are agnosics only when are asked to retrieve colors from semantic memory (e.g., what color is a banana?, coloring in a drawing of an apple). This dissociation has been related to two different forms of color agnosia: *color anomia* or *aphasia* and *color amnesia*, respectively. *Color anomia* is considered a visuoverbal disconnection deficit. Patients are unable to match verbal with visual color information, but are capable to retrieve color information from semantic memory. The interpretation of this behavior is framed in anatomical terms: patients have a left occipital lesion which causes right hemianopia and, hence, confines accessible visual information in the left hemifield/right visual areas. Color naming requires callosal transfer of information to the left hemisphere, which is interrupted by the lesion of the fibers connecting the visual areas of the right hemisphere with the language areas of the left hemisphere where the names of colors are stored. *Color amnesia* is shown by patients who not only are unable to name colors, but are also unable to retrieve color information from semantic memory (e.g., when they have to name the color of an object from memory (what color is a panther?) or color in the drawing of the same object). The disconnection hypothesis cannot account for this behavior, which is more correctly described as a defective access to, or degradation of, the semantic memory sector where associations between objects and colors are formed. The brain damage responsible for color amnesia is in the territory of the temporo-occipital branch of the left posterior cerebral artery, or is bilateral.

Tactile Agnosia

Tactile agnosia is the inability to recognize objects through palpation in the absence of elementary sensory deficits such as ahylognosia (inability to identify substance features) and amorphognosia (failure to recognize shape haptically). Recognition through the visual modality is preserved. The locus of the lesion involves the posterior-inferior portion of the parietal lobe and can be unilateral or bilateral. When the lesion involves the right hemisphere, only the contralateral hand is agnostic, whereas both hands can be affected when the lesion

involves the left hemisphere. This latter condition parallels that described in the visual modality for associative agnosia following a left hemispheric lesion, and can be ascribed to the apparently dominant semantic role of the left hemisphere. The prevalence of tactile agnosia is much lower than the prevalence of visual agnosia, but the difference may be more apparent than real because of the features of cortical vascularization of the parietal lobe. The available evidence does not permit to differentiate between apperceptive and associative forms of tactile agnosia. The deficit is interpreted as a failure of the associative-semantic system to match the tactile features identifying an object with its meaning. Tactile agnosia must be differentiated from *tactile aphasia*, which is shown by patients who cannot name objects they are handling but can show that they have recognized them either by miming their use or by passing association or categorization tests. Tactile aphasia can be considered a disconnection deficit between tactile information about an object and its name, and is observed in patients with callosal resection and in those with damage to the left parietal lobe.

Agnosia for Words

Agnosia for words is also known as pure alexia, perceptual word-form agnosia or pure word-form blindness and is usually discussed in the context of language impairments. However, given that these patients present a language impairment limited to visually presented words (e.g., reading), but not to auditory presented stimuli, it can also be treated as an agnostic symptom. These patients may be able to spell words out loud and to write well, but fail in reading their own handwriting of the same words. Their reading is typically extremely slow and characterized by the processing of one letter at a time ('letter by letter reading'). This deficit has also been called ventral simultanagnosia, to indicate the failure in reading multiple letters simultaneously. It remains controversial whether this form of agnosia is limited to words or extends to other classes of visual objects. The lesion site in these patients is typically in the ventral occipitotemporal cortex.

Agnosia for Landmarks and Environment (Topographic Agnosia)

This type of agnosia refers to the inability to recognize familiar landmarks, scenes, and/or buildings, and can be differentiated from other disorders affecting spatial orientation. These patients, unsurprisingly, get easily lost and are unable to learn new routes, despite being able to read and draw maps, describe familiar routes, and provide directions. The lesions giving rise to topographical agnosia usually follow bilateral or right posterior artery infarction and may implicate the parahippocampal place area in the parahippocampal gyrus.

Anosognosia

'Is there anything wrong with you?' 'No, I am fine.' 'So why are you in the hospital?' 'I felt unwell.' 'Is there anything wrong

with your left arm or leg?’ ‘No, they are all right.’ This might seem a normal conversation between a doctor and a patient, but it has, in fact, an extraordinary feature which affects the significance of the patient’s answer: despite her claim, the patient was completely plegic on one side of the body. A stroke caused a permanent damage to the right side of the brain and the motor abilities reliant on the integrity of that hemisphere were impaired. As a consequence, the patient was not able to move the part of the body contralateral to the affected side of the brain. The striking thing was that the patient claimed that there was nothing wrong with her, and if she was asked more stringent questions about the affected limbs, she firmly denied her motor problem. This remarkable, well-known phenomenon, first described in scientific papers by Austrian, German, and Swiss neurologists at the turn of the nineteenth century, was named anosognosia in 1914 by the French neurologist Joseph Babinski. The term, derived from Greek, means ‘lack of knowledge for the illness,’ and since then it is used to indicate the behavior of patients who firmly deny their pathological conditions. Anosognosia can be observed in association with different brain diseases, ranging from denial of complex mental and neurodegenerative disorders, such as schizophrenia and Alzheimer disease, to the denial of more focal neurological and neuropsychological deficits such as motor, sensory, and cognitive disorders. Interestingly, patients affected by anosognosia can show different degrees of knowledge of their neurological deficits, ranging from a resolute denial of the disease, even when overtly faced with the negative consequences of their symptoms, to attenuated forms of awareness where the patients’ behavior suggests that some ‘dim knowledge’ of their status is present but not directly available for explicit report. Another important aspect of anosognosia, both theoretically and clinically, is its specificity. When a patient, following a brain damage, has many co-occurrent neurological impairments, the lack of knowledge is, in most cases, segregated to only one pathological domain. For instance, if a right hemisphere stroke has caused left hemiplegia, left hemianesthesia, and cognitive impairments, the lack of knowledge is often related to only one of these symptoms, with the patients denying a specific impairment, but admitting the others.

Selective-Specific Form of Anosognosia: The Case of Anosognosia for Hemiplegia

One of the most studied forms of impaired knowledge for the disease is anosognosia for hemiplegia (AHP) where, as indicated earlier, patients deny their contralesional motor problems. This disturbance is frequent after damage to the right hemisphere, with a prevalence ranging from 20% to 50% of hemiplegic patients, depending on the studies, the differences being related to the time of evaluation (acute vs. chronic phase of the illness) and selection criteria. We take this form of anosognosia as paradigmatic to indicate the selective and specific aspect of denial of illness. Other forms of anosognosia will be briefly discussed after the description of AHP. AHP patients, if inquired about their potential capability of performing actions either with the right or with the left hand, or even bimanual actions, claim that they can perform any kind of movement equally well. Patients’ false belief of still being able to move remains unchanged even when, having been

requested to actually perform different kinds of actions, sensory and visual evidence from the affected motionless side should suggest that no movement has been performed. To better grasp the manifold aspects of AHP, a collage of a conversation with a patient showing an intractable denial is reported subsequently. The patient typically suffered from a right hemisphere stroke and, as a consequence, she was left with contralesional complete hemiplegia. The patient was evaluated approximately 1 month after the brain infarct.

E: Where are we?
P: In the Hospital
E: Which hospital?
The patient answered correctly.
E: Why are you in the hospital?
P: Because I had a stroke.
E: What is a stroke?
P: I do not know.
E: How is your left arm?
P: Fine.
E: Can you move it?
P: Yes.
E: Would you be able to raise your left arm up in the air?
P: Yes, I would.
E: Would you be able to lift the telephone receiver with your left hand?
P: Yes, I would.
E: Would you be able to open a bottle, using both hands?
P: Yes, I would.
E: Would you be able to brush your hair handling the hairbrush with your left hand?
P: Yes, I would.
E: Would you be able to wash your face using both your hands?
P: Yes, I would.
(The patient was then asked to actually perform some movements.)
E: Could you touch my hand with your right hand?
P: (The patient does it without any problem.)
E: Could you touch my hand with your left hand?
P: (Although she seems to try the movements, she cannot raise the arm and reach the examiner’s hand. Nonetheless, after a while she says ‘Done.’)
E: Have you done it?
P: Yes, I think so.
E: Could you touch your left hand with your right hand?
P: (She does it without any problem, thus showing that she knows what and where is the left plegic limb).
E: Could you open this bottle for me, please?
P: (The patient attempts to do it using only the right hand.)
E: Can you manage?
P: No.
E: Why?
P: Because it does not open.
E: How do you open a bottle?
P: With one hand I hold the bottle, with the other I unscrew the cap.
E: Are you doing it?
P: Yes.
E: Can you put your left hand on your left shoulder?
P: Yes, I can.
E: Then please do it.
P: (the patient seems to try the movement: she also overtly looks at the left motionless arm and at the shoulder. After that, she looks at the examiner as if she had finished performing the requested action).
E: Have you done it?
P: Yes, I think so.
(The patient, on the wheelchair, is taken to the bathroom and placed in front of the basin.)
E: Could you wash your face using both hands, please?

P: (The patient takes the bottle of the liquid soap with the right hand and attempts to soap her left hand as if the left hand was actually over the basin, near the midline. However, the left hand was not there because it was lying on her lap. After having soaped the 'ghostly' hand, she started to move the right arm/hand forward and backward as if she was washing the two hands, one against the other. Finally, she washed the face using the right hand.)

E: Are you washing both your hands?

P: Yes, I am.

E: Are you washing your face?

P: Yes, I am.

E: With both hands?

P: Yes, I think so.

(Then the patient was asked to brush her hair handling the hairbrush with the left hand. The hairbrush was on the table and the left hand was lying motionless on the table as well. She took the hairbrush with the right hand and forced it below the left hand. While 'holding' the hairbrush with the left hand, she moved the head as if she was actually brushing the hair. After a while, she looked at the examiner and seemed satisfied with her performance.)

E: Have you done it?

P: Yes, I have, but only on the left side (!).

Possible Interpretation

Although anosognosia was first reported by neurologists who tried to interpret the impairment as a direct consequence of the brain damage, in the second half of the last century, one of the most accepted interpretations of anosognosia was based on a motivational account according to which denial was considered a defensive mechanism against the stress caused by the illness. This caused a lack of studies investigating the cognitive process affected in AHP, because the motivational interpretation considered the disorder not directly due to the brain lesion, and therefore as the direct effect of a damage to a specific cognitive system, but as the consequence of the activation of a normal psychodynamic reaction. At the end of the last century, however, this interpretation was questioned on the basis of many clinical observations which were not predicted by a pure motivational/psychodynamic account. As already mentioned, anosognosia is often selective in patients with multiple pathologies who may deny one deficit, but spontaneously report another. Also, the time course of AHP is at odds with the idea of a psychodynamic reaction. Indeed, anosognosia tends to ameliorate with time, and it is observed much more frequently in the first period after the stroke than during the chronic phase. A defense mechanism would, again, predict the opposite temporal pattern, insofar as time is needed for establishing a psychodynamic reaction. Interestingly, during the amytal testing (a diagnostic tool that, through a pharmacologic intervention – the injection in the brain circulation of a barbituric – produces a temporary functional suppression of the activity of one hemisphere, also causing a temporary hemiplegia contralateral to the injected hemisphere), anosognosia appears immediately after the amytal injection and mainly when it is the right hemisphere that is knocked down. Another striking, opposite effect of a physiological manipulation is seen when the injection of cold water into the left ear of the AHP patient provokes an instantaneous, although temporary, remission of the denial. This effect, triggered by a vestibular reflex, lasts a few minutes during which a left side nystagmus (left side reflexed ocular movement) is observed. In such cases,

the patients astonishingly admit their paralysis but again 'forget' it when the effect of the stimulation is over. Again, a psychodynamic reaction should not be influenced by a physiological manipulation. These and many other clinical and experimental data suggested that AHP might be better explained within a neuropsychological framework that would consider the denial not as a normal functional reaction triggered by the emotional strain, but as a specific cognitive deficit caused by the brain damage. New approaches to the interpretation of AHP explain the denial behavior by referring to a cognitive model of motor production and motor control. In these models, a comparator system has to match the congruity between the intended movement and the sensory consequences of the actually executed movement. When an intended movement is not performed, the comparator should detect the mismatch between the movement/no-movement conditions. Within this context, two different proposals have been put forward. According to some views, the comparator does not work because the patient, as a consequence of the brain damage, has lost the intention to move and therefore cannot discover that he/she is plegic. On the basis of anatomoclinical correlations, other views consider anosognosia as a failure of the comparator that, directly damaged by the brain lesion, does not detect the mismatch between a desired action and the actual status of the sensorimotor system (leading to altered motor awareness), in the face of an intact capacity of programming movements and forming sensorimotor predictions. This hypothesis would imply that the brain activity leading to the construction of a conscious intention of action is normal. Moreover, it can also explain the neural base of the 'false belief' of being still able to move. In this view, the false belief would not be a mere confabulation but would express the patient's feeling of action related to the 'normal' or quasinormal activation of the intention programming system. Although more studies are needed for verifying the 'motor' hypothesis of AHP, this approach to the study and interpretation of AHP was very innovative because, for the first time, anosognosia was not considered as a secondary disorder due to the presence of other neurological/neuropsychological symptoms, but instead a specific disorder of motor consciousness. The study of the anatomical localization of the lesion has shown that patients with AHP, compared to patients with hemiplegia without anosognosia, show damage in frontal premotor areas, suggesting that motor production and motor control share common anatomical substrates. These findings are directly relevant for models of motor control and, more generally, for accounts of consciousness. Indeed, the involvement of premotor areas in self-monitoring of action implies that, at least for motor functions, monitoring is neither the prerogative of some kind of central executive system, hierarchically superimposed on sensory-motor and cognitive functions, nor a function that is physiologically and anatomically separated from the primary process that has to be monitored. Instead, the anatomical correlates of anosognosia show that monitoring can be implemented in the same neural network responsible for the process that has to be controlled. It is worth noting that recently the idea that AHP might be somehow related to a motivational reaction has been again proposed on the evidence that anosognosic patients may show some sort of implicit knowledge of being plegic. This might imply that the anosognosic behavior is the result of a

repression mechanism. However, although the demonstration of an implicit knowledge is necessary for admitting a psychodynamic account of the disorders, its presence is not sufficient for establishing a direct causal relation. For instance, it is plausible that the impaired operation is not completely abolished but instead damaged to a degree that allows an implicit but not an explicit processing of the information that therefore would not reach a sufficient strength for an overt recognition of the disease. Although a motivated defense reaction may contribute to some cases of denial of illness and may shape the severity and the way in which anosognosia manifests itself, more research is needed to better understand the involvement of defense mechanisms in AHP and the possible interaction between motivational repression and conscious control of action.

Other Specific Forms of Anosognosia

As already pointed out, selective anosognosia can be observed for other neurological/ neuropsychological conditions that further suggest its specific and selective nature. Interestingly, many reports of selective forms of anosognosia also point to the possibility that the disturbance can be considered a modular deficit of a monitoring/controlling system. Constructional apraxia (CA), for example, is a disorder often associated with right brain damage in which drawing, copying, and block construction are severely impaired. This disorder can be conceived as the motor expression of a more pervasive disorder in combinatory and organizing activity, and it has recently been associated with damage to the dorsolateral prefrontal cortex, extending to subcortical structures like the putamen, the insula, and the caudate nucleus. Interestingly, when the patients are profoundly anosognosic (i.e., they are totally satisfied with their abnormal constructional performance), lesion in Area 44 is additionally found. Area 44 is one of the premotor areas which, as reported previously, is also affected in hemiplegic anosognosic patients. The anatomoclinical correlation between anosognosia for CA and premotor lesion has been taken as further evidence that in the motor domain, patients' unawareness for their motor impasse can be the consequence of inefficiency in comparing intended and anticipated action to real action execution due to a lesion of a motor-monitoring system implemented in the same area of motor programming. Conceptually analogous findings have been reported for unawareness of a different sensory disturbance. Cerebral acromatopsia is a rare disorder of color vision caused by bilateral damage to the occipitotemporal cortex. Patients affected by this disorder see the world in black and white and are usually aware of their visual deficit. However, a fascinating single case of acromatopsia showed that patients can be anosognosic even for this very specific form of visual impairment; despite verbal and nonverbal/perceptual testing clearly demonstrating the presence of severe color blindness, the patient claimed that his color vision was completely normal, denying any problems even when faced with his errors in naming colors. Moreover, color vision improved with time and a parallel improvement in awareness was observed. The simultaneous occurrence of acromatopsia and anosognosia, their parallel recovery, and the lesion site in visual areas suggest that both deficits were due to dysfunction of the same brain region, implying that normal perception and normal monitoring share common anatomical

substrates. In the sensory domain, anosognosia has been reported also for tactile anesthesia, and even in this domain, the unawareness of the disorder seems to be related to lesion intrinsic to somatosensory areas. The notion that the conscious perception of the presence or absence of a sensorimotor experience depends on the same system involved in the processing of the primary function giving rise to that experience, can be seen as evidence in favor of a modular structure of consciousness.

Anosognosia for More Generalized Cognitive Impairment

As mentioned earlier, unawareness of dysfunctions can be observed for more complex neurocognitive disorders such as those characterizing Alzheimer deficits or schizophrenic symptoms. In these multicomponential pathologies, is very hard to individuate a common core explaining the different denial behaviors. The fact that in many instances there is a severe intellectual impairment is of course a confounding factor. However, a shared feature in Anosognosia for Alzheimer (AA) and Anosognosia for Schizophrenic disorder (AS) is the damage to frontal lobe circuits. In AA, a significant association with brain areas, which are considered to be responsible for tracking the physiological state of the body (like the right hemisphere ventromedial prefrontal cortex) has been found. This would be generally consistent with the role of medial and orbital frontal structures in signaling the deviations from expected outcomes. In the case of AA, the deviation to be detected would be the divergence between one's own actual versus expected performance. This interpretation of AA prompts the idea of a comparator system whose dysfunction generates different degrees of unawareness for the patient's deficit. Therefore, similar to other more specific forms of anosognosia, AA might seem to be the result of the incapability of detecting a mismatch between a desired state and the actual status of the system. Other interpretations of AA point to the possibility that memory or executive dysfunctions, typical of this disease, may affect the immediate ability to update and judge cognitive performance in a domain-specific manner. Also, this interpretation seems to explain the possible different forms of anosognosia observed in Alzheimer disease as a result of an intramodular impairment.

As for schizophrenia, the presence of anosognosia is frequently associated with bilateral volume reduction in different areas of the frontal lobes. Awareness in these patients can be fractionated in awareness of illness and awareness of cognitive impairments and functioning, and some studies have shown that awareness of schizophrenic symptoms can be relatively poor while insight into cognitive deficits can be better or even preserved. It is interesting to note that memory functioning is a strong predictor of awareness of memory deficits in schizophrenic patients and that worse memory is associated with overestimation of function. This seems to be again consistent with the neuropsychological findings such as those discussed earlier that cortical systems underpinning awareness of a deficit are related and anatomically close to those underpinning the function whose deficit is studied. Whatever explanation will turn out to be true for explaining denial of illness, we would like to conclude this section with a quotation from George Prigatano: "Understanding the biological and neuropsychological mechanisms responsible for anosognosia in its various forms may reveal important insights into brain

organization and how human consciousness (subjective awareness of the self and the environment) is possible. The comparative study of anosognosia in patients with identifiable brain disorders in comparison to patients with psychiatric disorders may provide rich insight into the body-mind problem."

Glossary

Cognitive therapy A system of psychotherapy focused upon identifying and restructuring dysfunctional thoughts and schemas linked to psychopathology.

Exposure in vivo The structured treatment of anxiety disorders by systematic confrontation of feared external situations to reduce avoidance behavior and anxiety.

Exposure to somatic cues Extends the methods of exposure in vivo to those internal cues and bodily sensations associated with panic attacks.

Limited symptom attack An anxiety episode with a few subjective anxiety symptoms, insufficient in number to qualify as a panic attack.

Panic attack A discrete period of intense fear, not explained by a continuing organic factor, that arises rapidly with at least 4 anxiety symptoms from a 13-item list specified in the DSM-IV-TR.

Agoraphobia and panic disorder are anxiety disorders that are formally classified into three overlapping syndromes in the current psychiatric taxonomy: panic disorder without agoraphobia, panic disorder with agoraphobia, and agoraphobia without history of panic disorder.

Agoraphobia is characterized by marked fear of entering crowded, public places; of traveling away from home, especially by public transportation; of feeling trapped or confined; and of being separated from a place or person associated with safety. Sudden, brief episodes of extreme anxiety – panic attacks – are commonly associated with agoraphobia and may lead to avoidance of situations in which they occur. Often there is a ‘fear of fear’ pattern, in which the bodily sensations of mounting panic are themselves a source of anxiety. Generally more debilitating than specific or social phobias, agoraphobia causes some people to remain entirely housebound. As a syndrome of anxiety elements in physiological, behavioral, and subjective domains, agoraphobia represents a distinct disorder with a typical clinical presentation and course.

Panic disorder has been formally recognized since 1980 as an anxiety syndrome marked either by repeated, unexpected panic attacks that are associated with distress and behavioral impairment or by significant apprehension about having future panic attacks.

Since the 1970s, clinical researchers have developed effective pharmacological and psychological treatments to reduce or eliminate agoraphobic avoidance behavior and panic attacks.

Agoraphobia and Panic: Past and Present

The term agoraphobia was introduced by the German psychiatrist C.F.O. Westphal (1822–1890) in a classic monograph of 1871, *Die Agoraphobie*. The term derives from the Greek *agora*, referring to a marketplace or place of assembly. Westphal described the abnormal fears of a series of three men who experienced anxiety episodes when walking alone in public places. Feared situations included city squares, concert halls, churches, open streets and fields, crowded rooms, and traveling by carriage, bus, or train; typical anxiety symptoms were

trembling, heart palpitations, and ‘an immediate breakout of intense anxiety.’

The development of behavior therapy in the 1950s by Joseph Wolpe and others was closely connected with the study of phobias and other anxiety disorders. Interest in agoraphobia revived with American and British research on systematic desensitization and related methods in the 1960s, and with the publication of Isaac Marks’ *Fears and Phobias* in 1969. Systematic desensitization produced disappointing outcomes with agoraphobia, but treatment based on exposure to relevant situations was successful in reducing avoidance behavior and anticipatory anxiety.

Progress in psychological and pharmacological treatment of agoraphobia in the 1970s influenced the diagnostic classification itself in the United States, so that in 1980, agoraphobia appeared for the first time as a distinct category. Further developments gave prominence to the panic attack as the central feature of agoraphobia in panic disorder with agoraphobia; panic disorder without agoraphobia was the parallel syndrome not marked by phobic avoidance of situations.

In recent years, psychological treatment of the agoraphobia and panic disorder syndromes has focused on therapeutic exposure to panic sensations, on encouraging patients to make more realistic and benign ascriptions as to the source of their anxiety, and on helping them to question their essential premise that thoughts or concerns about emotional distress must necessarily engage one’s attention and activate affective arousal. Exposure to somatic cues, breathing retraining, systematic confrontation of feared external situations, and cognitive therapy have become the leading psychological interventions.

Descriptive Psychopathology, Diagnosis, and Epidemiology

Description of Agoraphobia

People with agoraphobia usually fear, and often avoid, situations in which it would be difficult or embarrassing to obtain help if overwhelmed by anxiety. Such situations include (1) traveling away from home, especially by bus, train, or car;

(2) crowded, public places, such as government buildings, supermarkets, concert halls, shopping malls, and places of worship; and (3) confined places, such as elevators, the dentist's or beautician's chair, and – when driving – passing through tunnels, over bridges, or along a limited-access highway. Agoraphobia is commonly associated with panic attacks that often arise in the situations typically feared and avoided. Some people with agoraphobia restrict their lives substantially, sometimes to the point of remaining housebound, to avoid the anxiety or panic aroused by entering public places.

Dysphoric mood, somatoform disorders, interpersonal conflict, or substance abuse may accompany agoraphobia. Untreated, agoraphobia tends to follow a chronic, fluctuating course. It is common for people with agoraphobia to experience daily variations in anxiety severity. For some, there may be weeks or months of near-normal functioning followed by a resurgence of the original symptoms. For others, gradual improvement leading to complete recovery may occur without professional intervention, but this is not typical.

Description of Panic Attacks

Panic attacks are recurrent, distinct episodes of extreme anxiety or distress, not explained by the presence of a continuing organic factor. Panic attacks include at least 4 of a 13-item list of typical anxiety symptoms, which are initially unexpected and not produced in response to stimuli associated with specific or social phobias. (Panic attacks are categorized as unexpected or uncued, situationally bound or cued, or situationally predisposed; only unexpected panic attacks are used in the diagnosis of panic disorder.) Because individuals who have unexpected panic attacks may also report situational attacks, clinicians are careful to discern the focus of anxiety – the panic attack itself or concerns about becoming embarrassed.

The list of typical symptoms in a panic attack includes shortness of breath, dizziness, heart palpitations or rapid heart rate, trembling or shaking, sweating, the sensation of choking, depersonalization or derealization, and fear of dying, losing control, or developing an acute mental illness. The anxiety symptoms in a panic attack arise suddenly and rapidly increase in intensity. An organic factor may have been influential in early panic attacks (e.g., the patient may have experienced dizziness as a result of a viral infection of the vestibular system, or depersonalization following ingestion of an illicit drug) but, by definition, the attacks will have continued despite successful treatment or removal of the initiating organic factor.

Diagnostic Classification: Historical Context

Before 1980, neither agoraphobia nor panic disorder was listed as a distinct disorder in the DSM classification. Agoraphobia could be found among lists of the Greek names for specific phobias in textbooks on psychiatry and abnormal psychology. It is now clear that agoraphobia is in no sense a specific phobia – its prevalence, its resistance to treatment by systematic desensitization, its distressing and disabling consequences, and the broad range and severity of its symptoms – most often including panic attacks – all clearly set it apart from such focal fears as phobias of heights, snakes, blood, or the number 13.

Patients with agoraphobia show various specific patterns of avoidance, and there is no standard list of situations that must be feared for the diagnostic criteria to be met. The current view is that what is chiefly feared in agoraphobia is the absence of safety signals, not the presence of disturbing objects. Most recently, the DSM-IV-TR has cited as a central feature of panic disorder with agoraphobia fear of situations from which it would be difficult to escape, or in which help may be unavailable, in the event of a panic attack, leading to avoidance or marked distress. Alternatively, in agoraphobia without history of panic disorder, patients fear limited symptom attacks or circumscribed anxiety episodes.

Anxiety restricted to social situations in which the person fears embarrassment or humiliation under the evaluative scrutiny of others is better construed as social phobia.

The DSM-IV-TR Classification

Agoraphobia appears twice in the DSM-IV-TR, as panic disorder with agoraphobia and as agoraphobia without history of panic disorder. Similarly, panic disorder appears twice, the second panic syndrome being panic disorder without agoraphobia. All three syndromes are listed as anxiety disorders. The DSM-IV-TR lists separate criteria sets, not diagnostic categories in themselves, for panic attack and for agoraphobia.

Panic disorder with agoraphobia

The essential elements of this diagnosis are the presence of panic attacks and agoraphobia, as defined in the criteria sets.

Agoraphobia without history of panic disorder

A person with this disorder has never had problems that meet criteria for panic disorder. Instead, he or she fears, and may avoid, situations in which it would be difficult or embarrassing to leave in the event of the sudden onset of anxiety, which may represent a 'limited symptom attack' that would not include the range of symptoms associated with a panic attack.

Panic disorder without agoraphobia

Patterns meeting criteria for panic disorder but not agoraphobia are classified as panic disorder without agoraphobia.

Epidemiology

Appropriate methodology requires assessing the prevalence and correlates of the syndromes in the general community as well as in clinic samples (which tend to be unrepresentative). Because of changes in the taxonomy, allowance has to be made for the different terms and criteria in studies conducted in different decades. The most informative studies use accurate community survey techniques.

In community studies, about half of the respondents with agoraphobia are also classified as having panic disorder. In clinical samples of agoraphobia, as many as 95% have the combined syndrome panic disorder with agoraphobia. In the Epidemiological Catchment Area study reported in the 1980s, the ratio of women to men with agoraphobia was 2.7:1.

Estimates of the prevalence of agoraphobia have been consistent across countries and cultures in studies using the same instrument and careful sampling procedures, but more recent

studies give lower prevalence estimates. The lifetime prevalence of agoraphobia, with or without panic, was cited as about 5% in the late 1980s and as about 2.5% in the 1990s.

Agoraphobia is associated with more severe impairment than other phobias and is strongly associated with dysphoric mood. Comorbidity rates for major depressive disorder in patients with a panic disorder syndrome range from 10% to 65%, and in about a third of the cases, depression precedes the development of panic attacks. In the other two-thirds of cases, major depressive disorder occurs concurrently with or subsequent to the development of panic disorder.

In the agoraphobia syndromes substance abuse, hypochondriasis, somatization disorder, and personality disorders are often present. The usual course is chronic. The age at onset in agoraphobia varies but is usually in the 20s or 30s with a mean of about 28 years. There is no general agreement on an association between agoraphobia and specific childhood experiences. Maternal overprotection has been studied, but findings are mixed.

Lifetime prevalence estimates for panic disorder increased from 3.5% in the mid-1990s to about 4.7% in 2005. The rate for panic disorder without agoraphobia is cited in the National Comorbidity Survey Replication as 3.7%, and for panic disorder with agoraphobia as 1.1%. The lifetime prevalence rates for isolated panic attacks without agoraphobia are much higher at 28%.

The typical age of patients at the onset of panic disorder is 24 years. Women are 3 times more likely to be diagnosed with panic disorder with agoraphobia than men, and twice as likely with panic disorder without agoraphobia. Although few theories or models address gender issues, recent research has focused on gender-specific stressors (e.g., premenstrual distress, sexist events) for women that may account for more severe symptoms.

The estimated morbidity risk of anxiety disorders in the first-degree relatives of patients with agoraphobia is 32%. Concordance rates for either of the panic syndromes are significantly higher in monozygotic than in dizygotic twins; a Norwegian study showed 31% concordance in 32 monozygotic twins but 0% in 53 dizygotic twins. Such results have been taken to indicate some genetic predisposition for agoraphobia and panic disorder.

Theories of Etiology and Maintenance

Biological Theories

The observations that anxiety syndromes run in families and that pharmacological treatment can be helpful have led to considerable interest in possible biological mechanisms – though it has to be noted that successful pharmacotherapy would not logically confirm a biological etiology. Attention has been paid to the heritability of agoraphobia and to possible physical vulnerability factors.

A predisposition toward agoraphobia and panic may be inherited, but it is not possible to predict who will develop a disorder even among people with a number of close relatives with agoraphobia or panic syndromes. Those syndromes probably conform to a diathesis–stress model in which an inherited vulnerability is necessary, but not sufficient, for the eventual

appearance of a disorder, which would require the additional operation of certain environmental factors.

Physiological variables distinguishing agoraphobia from normal functioning, and from less pervasive anxiety disorders like specific phobia, include resting heart rate and forearm blood flow (both higher in agoraphobia) and skin conductance (higher and more variable in agoraphobia). However, such findings have not produced clear conclusions with implications for etiology or treatment.

Inherited vulnerability factors include personality traits such as neuroticism, which is thought to result from lability of the limbic system, of the autonomic nervous system, or of specific neurotransmitter processes. One study showed that rats bred for emotionality had more brain benzodiazepine receptors than rats bred normally. Malcolm Lader noted that many of the data on panic may be explained by an instability or hypersensitivity of central noradrenergic mechanisms centering on locus coeruleus function. Yet, few definite conclusions may be drawn from the many physiological and endocrine studies. The best-supported generalization is that patients with agoraphobia and related anxiety disorders have chronically overaroused central nervous systems and are slow to habituate to noxious stimuli.

Several physiological processes and physical disorders produce symptoms like those of panic, arousing interest in possible mechanisms for the disorders. These include hyperventilation, asthma, limbic seizures, abnormal thyroid function, heart disease, hypoglycemia, and mitral valve prolapse. Of interest has been the provocation of panic by sodium lactate infusions; people with a history of panic disorder, but not those without prior experience of panic, tend to react to the infusion with panic. Furthermore, pharmacological treatment by means of imipramine can abolish the lactate provocation of panic. Although such observations may appear to confirm a biological basis for panic disorder, the mechanism is a subtle one that interacts with environmental and cognitive factors, given that the lactate provocation of panic can also be blocked by psychological treatment.

Other biological challenges that typically produce panic-like symptoms include the inhalation of air containing greater than normal proportions of carbon dioxide. Recent research indicates that healthy women during the premenstrual phase are more likely to report panic-like symptoms in reaction to a CO₂ challenge than healthy women in the follicular phase.

No particular biological variant explains all of the features of agoraphobia. An inherited predisposition probably interacts with behavioral and cognitive mechanisms to produce panic and agoraphobic syndromes. David Barlow has pointed out that “The fact that language and meaning structures are the most common stimuli for anxiety in humans requires a complex neurobiological system.”

Social, Interpersonal, and Personality Factors

From a psychodynamic viewpoint, patients’ inner representations of other people are especially relevant to agoraphobia. Disturbed ‘object relations’ make the person vulnerable to insecurity and anxiety.

From an experimental perspective, Susan Mineka and others have shown that in humans and animals, early separation from parents can be linked to agoraphobia-like behavior.

An integrative theory put forward by Alan Goldstein and Dianne Chambless in 1978 sought to explain many of the phenomena of agoraphobia and panic, including typical personality factors and interpersonal styles. Goldstein and Chambless argued that the person with agoraphobia (1) fears panic attacks rather than particular places; (2) has difficulties with self-sufficiency, independence, and assertiveness; (3) is unable to trace the antecedents of emotional feelings when they arise; and (4) develops the initial symptoms of agoraphobia in a climate of interpersonal conflict. The interaction of these factors produces agoraphobia. This theory is consistent with the observations that some agoraphobia clients have assertiveness difficulties and troubled marital relationships. It also gave prominence to panic attacks in what was termed the complex agoraphobia syndrome.

Similar points have been made recently by Steven Hayes and others in the context of developing acceptance and commitment therapy (ACT), which recasts older conditioning terminology, such as stimulus generalization, into the language of stimulus equivalence and the verbal classes to which anxiety-relevant situations belong. Hayes illustrated this by describing a client with agoraphobia who had initially felt trapped at a checkout counter at the mall, and later started to worry about being trapped in an unsatisfactory marriage and an unfulfilling job. Hayes cited evidence that clients who were especially likely to avoid rather than confront challenging situations developed additional anxiety symptoms later. Behavioral avoidance and attempts to suppress dysphoric private experiences led to increased, not decreased, distress.

Behavioral and Cognitive Theories

Conditioning theories

Early behavioral theories of the etiology of agoraphobia called attention to classical conditioning as a possible mechanism, and treatments designed to replicate extinction procedures have been notably successful. Exposure in vivo, in which one learns to confront agoraphobic situations without leaving at the onset of anxiety, helps patients overcome a pattern of avoidance of situations and can attenuate panic attacks. However, the success of such treatments cannot confirm that conditioning experiences cause agoraphobia.

Panic attacks could result at least partly from conditioning processes. A panic attack may be viewed as the result of a vicious circle or upward spiral in which, at each point, internal stimuli associated with anxiety, such as those produced by increases in heart rate, elicit conditioned anxiety responses themselves in a process known as interoceptive conditioning. It follows from this view that it will be helpful therapeutically for the patient to confront anxiety sensations specifically rather than simply the external situations in which they arise. The exposure principle predicts that systematic confrontation of sensations such as breathlessness will ultimately diminish their power to evoke anxiety.

If any arousal of anxiety leads inexorably to a vicious circle that culminates in a panic attack, then people with panic disorder would never experience limited episodes of mild or moderate anxiety. However, it is usual for panic disorder patients to display moderate levels of generalized anxiety between their panic attacks. Unadorned conditioning theories

do not easily explain why mild anxiety does not always escalate into panic attacks. The cognitive therapy approach attempts to address this problem.

Cognitive theories

Aaron Beck's cognitive therapy rests upon theoretical assumptions that center upon the individual's appraisal of events. Such appraisals range from fleeting automatic thoughts in the form of accessible, though covert, verbalizations (e.g., "Oh, no. I knew I'd get anxious if I came to the mall, and I feel slightly dizzy already!") to deeper and more enduring cognitive schemas, not necessarily verbalized, reflecting a more fundamental attitude (e.g., strange feelings could indicate an impending medical crisis).

Central to the application of cognitive therapy to panic attacks is the patient's appraisal of the bodily sensations or somatic cues connected with mounting anxiety. David Clark has argued that people with panic disorder have developed cognitive schemas concerning vulnerability to medical catastrophes, and he and others have demonstrated that people with panic disorder show cognitive biases in that direction. This model complements the conditioning of somatic cues model by indicating who is vulnerable to panic and why not all anxiety episodes culminate in panic. Variations in cognitive appraisals between and within individuals may account for the unpredictability of panic attacks. In Clark's model, patients make catastrophic misinterpretations of bodily sensations related to anxiety, viewing them as signals of a medical disaster such as a heart attack. The misinterpretation itself arouses increased anxiety, and the vicious circle continues when further alarming appraisals are made.

One of our clients associated a sense of warmth, especially in her face, with the onset of a panic attack. On entering an overheated consulting room she said: "Oh no! Is it hot in here?" When the therapist remarked that it was, stiflingly so, the client was relieved. She said: "Thank goodness! I thought I was having a panic attack!" The therapist reflected that simply stating that the room was hot was enough to forestall a panic attack for this client, which led immediately into a fruitful discussion of the rationale for cognitive therapy.

Experimentation in the tradition of cognitive psychology has produced intriguing findings about the attentional and interpretive biases that are associated with, and may play a role in maintaining, anxiety syndromes. Two experimental procedures in which potentially disturbing words, such as 'choking' or 'fainting,' are presented to research participants on computer screens – the emotional Stroop task and the dot-probe task have been used most frequently to assess visual attentional biases toward threatening information. The Stroop task calls for naming the color in which a word is printed, and the dot-probe task calls for signaling when a symbol on the screen replaces a significant word; delays in color naming, and rapid responses to a probe, indicate that the word is emotionally poignant for the respondent. Studies employing these two tasks provide evidence that individuals with panic disorder exhibit selective attentional biases for panic-relevant stimuli. Research has demonstrated that individuals with panic disorder have a tendency to interpret ambiguous bodily sensations and external (environmental) stimuli as threatening. Similarly, they tend to overestimate aversive consequences following

panic-relevant stimuli; that is, they exhibit a covariation bias. Furthermore, individuals with panic disorder tend to remember panic-related situations and panic-related words especially well compared to healthy controls.

It is important to note, however, that most studies have relied solely on self-report, and the findings, thus, are vulnerable to experimental demand and response bias. To overcome these limitations, researchers have recently started to employ online, indirect indicators of cognitive biases. One study, for example, used the contingent negative variation (CNV), a neurophysiological measure of expectancy, to examine covariation bias in panic disorder. The late CNV component was higher for panic-relevant pictures compared to both phobic-relevant (but panic-irrelevant) and neutral pictures in individuals with panic disorder; this, however, was not the case in healthy controls. A recent functional magnetic resonance imaging (fMRI) study replicated previous findings that individuals with panic disorder exhibit longer latencies to name the color of panic-related words. More importantly, this study demonstrated that the latency to color name panic-related words correlated with increased activation of the right amygdala, hippocampus, and prefrontal areas. Thus, neuropsychological evidence seems to corroborate the self-report findings that individuals with panic disorder tend to engage in biased processing of panic-relevant stimuli.

A comprehensive model

David Barlow's comprehensive theory suggests that panic results from activation of an ancient alarm system, and represents the basic emotion of fear, while anxiety is a more general cognitive-affective structure. Panic occurs in response to true alarms (panic attacks elicited by genuine danger), false alarms (panic attacks in the absence of objective danger that result from a genetically determined predisposition in interaction with an accumulation of general stress), and learned alarms (panic attacks that are triggered by external or internal cues). False and learned alarms are relevant to the panic and agoraphobia syndromes. Anxious apprehension also plays a part; a cognitive schema containing propositions concerning anxiety elicits negative affect when triggered, resulting in directing attention to internal self-evaluations, increased arousal, narrowing of attention, and hypervigilance concerning sources of apprehension.

Barlow's model of agoraphobia is his model of panic disorder with the addition of the development of agoraphobic avoidance. Biological vulnerability interacts with objective stress to produce an initial uncued panic attack, or false alarm. The connection of the panic attack with interoceptive cues leads to the development of cued learned alarms. As a result, there is a psychological vulnerability characterized by anxious apprehension about future panic attacks. Next, panic attacks are triggered unpredictably by a combination of autonomic and cognitive symptoms of anxiety with additional somatic cues. Avoidance behavior may develop, giving rise to the panic disorder with agoraphobia syndrome.

Clinical Assessment

In assessing clients with the agoraphobia and panic syndromes, the first step involves establishing the appropriate

diagnosis. Second, identifying the specifics of a patient's levels of distress and impairment allows development of an individualized treatment plan. Third, evaluating concomitant problems permits employment of adjunct treatments or influences the sequence in which treatments are provided. Fourth, monitoring the patient's progress throughout the course of therapy is essential in determining response to treatment and alerting the clinician to needed procedural changes.

Diagnosis

People with agoraphobia and panic disorder syndromes may self-refer for treatment, having made a self-diagnosis after reading a magazine article or viewing a television presentation. Patients may be referred to a mental health professional by emergency room staff after one or more visits for urgent treatment during panic attacks. Because many people with agoraphobia are either entirely housebound or have a limited range of travel, clinicians working with this disorder become accustomed to making home visits, at least in the early stages of assessment and treatment.

Because there are several physical conditions that give rise to symptoms like those of agoraphobia and panic, it is important that patients receive a physical examination before mental health interventions begin. If anxiety persists despite successful treatment of a precipitating or complicating physical condition, then treatment of the anxiety disorder proceeds.

Assessment is needed to identify comorbid psychiatric disorders. Also relevant for assessment are issues like marital conflict, social skills deficits, and difficulty with personal autonomy that may not require a formal diagnosis but may yet be important foci for intervention. Not all people who experience anxiety when in public places or who have had panic attacks show patterns that meet diagnostic criteria for agoraphobia or panic syndromes.

Assessing the Range and Extent of Anxiety and Avoidance Behavior

Simply applying the appropriate diagnostic label is insufficient to guide treatment. The clinician seeks to know the patient as a unique individual, and accordingly conducts the usual psychosocial history and mental status examination. Beyond that, the nature and extent of the anxiety problems will need to be charted in sufficient detail to allow formulation of an appropriate individual treatment plan and continued evaluation of progress toward treatment goals.

Developed by David Barlow and his colleagues, the Anxiety Disorders Interview Schedule-IV (ADIS-IV) allows detailed and accurate characterization of the person's anxiety problems and permits authoritative diagnosis in DSM-IV-TR terms. The instrument is primarily employed in research trials to ensure uniformity of diagnostic practices. Although the complete protocol is too lengthy for routine clinical use, subsets of the ADIS-IV may be used appropriately and conveniently in most clinical settings.

Clients are asked to self-monitor general anxiety, panic attacks, and agoraphobic avoidance daily. Individualized forms may be used so that details of the specifics of the patient's situation may be accommodated. For example, daily ratings

may be made of avoidance of, fear in, and self-efficacy concerning each item in a customized graded hierarchy of feared situations. Daily ratings of the frequency and intensity of panic attacks allow the patient to record the circumstances surrounding each episode – situational, cognitive, and interpersonal.

A hierarchically ordered behavioral test may be designed for patients with agoraphobic avoidance patterns. This takes the form of an unaccompanied journey – walking, driving, or using public transportation – to take in as many situations relevant to the patient's fear and avoidance as is feasible. The clinician asks the patient to proceed as far as possible, and takes the distance actually traveled as a helpful datum in sampling current levels of agoraphobic avoidance.

Physiological monitoring has been a customary component of research trials designed to provide generalizable information on treatment effectiveness, but is far less common in routine clinical practice. Typically, measures of anxiety in the different domains – self-report, behavioral observation, and psychophysiological – do not covary as might be predicted. When all such measures are available, it is recommended that treatment proceed until clear reductions have been seen in each measurement modality.

Treatment

Pharmacological Treatment

Pharmacological treatment has several advantages for the patient, and significant progress has been made in this area since 1970, improving the general outlook for agoraphobia and panic disorder. Medication is readily available and convenient to use. However, concerns arise from medication side effects, from high relapse rates when the medication regimen is discontinued, and – in the case of minor tranquilizers – from the possibility of substance dependence.

Antidepressants

Medications initially developed to treat depression can also be helpful in the management of anxiety disorders. The term antidepressants may be misleading in this context because there is controversy about their role in treating agoraphobia and panic syndromes (do they attenuate dysphoric mood, facilitating other treatments, or do they act specifically to block panic attacks?).

Antidepressants often used to treat panic disorder include selective serotonin reuptake inhibitors such as fluoxetine (Prozac), sertraline (Zoloft), escitalopram (Lexapro), and citalopram (Celexa). Tricyclic antidepressants such as imipramine (Tofranil) continue to be helpful. Early studies showed that imipramine reduced panic attacks, but patients continued to avoid agoraphobic situations. Later studies demonstrated imipramine's superiority to placebo medication and indicated that it brought additional benefit when added to behavioral treatment. However, this was not attributable to the blockade of panic. When imipramine is used in conjunction with the antitherapeutic recommendation to avoid confronting feared situations, improvement in mood, but not in agoraphobia, is the result. Imipramine plus exposure therapy seems more effective than either treatment alone. Inconsistencies in

research findings with imipramine may result from marked differences in dosage across studies.

Monoamine oxidase inhibitors such as phenelzine (Nardil) are also used. Whereas some studies have shown little if any difference between phenelzine and placebo in application to agoraphobia, another has shown that phenelzine reduces general disability and avoidance behavior. In that study, phenelzine was more effective than imipramine. For reasons that are unclear, phenelzine appears to potentiate self-initiated exposure.

Benzodiazepines

The benzodiazepines are minor tranquilizers that have been extensively prescribed for various forms of anxiety and stress reactions, clinical and subclinical, for decades. Donald Klein's initial work on imipramine had suggested that it is specific for blocking panic, whereas the benzodiazepines are effective only with generalized or anticipatory anxiety. Later work suggests that high doses of benzodiazepines may be effective in treating panic attacks. The development of high-potency benzodiazepines like alprazolam (Xanax) and lorazepam (Ativan) has brought clear benefit in the treatment of agoraphobia and panic. Alprazolam has been the subject of a multicenter worldwide double-blind study of people with panic disorder (with and without agoraphobia). Fifty percent of the alprazolam patients and 30% of placebo patients were panic-free 3 weeks after the start of the trial.

Strong withdrawal reactions after discontinuance of alprazolam pose a significant problem, as does the phenomenon of rebound panic in which a minority of patients may experience even worse panic attacks after withdrawal from medication than before treatment.

Summary

Antidepressants and benzodiazepines are helpful in the treatment of agoraphobia and panic. Concerns include side effects, rebound panic after withdrawal from the drug, and chemical dependency. Since the late 1990s, the selective serotonin reuptake inhibitors and other new medications have been widely prescribed for people with agoraphobia, and there is a ferment of pharmacological research activity. The mechanisms underlying successful pharmacological treatment are unclear.

Psychological Treatment

Psychodynamic approaches to agoraphobia and panic have received far less attention than biological, behavioral, and cognitive approaches in recent decades, and there is no corpus of empirical research on psychodynamic formulations of etiology or on the results of psychodynamic treatment. Behavior therapists have progressed from desensitizing anxiety to treating avoidance behavior and panic attacks.

Treatment of agoraphobic avoidance behavior

Despite initial enthusiasm for Joseph Wolpe's technique of systematic desensitization as a therapeutic breakthrough for phobias, its application to agoraphobia in controlled clinical trials in the 1960s brought disappointing results. Developments in the 1970s established flooding in fantasy and graded practice in real life as effective treatments. Researchers in

Vermont led by Stewart Agras and Harold Leitenberg showed that graded practice – with or without praise for specific accomplishments – could quickly reduce agoraphobic patients' avoidance of unaccompanied journeys away from the clinic. This work converged with that of Isaac Marks, Andrew Mathews, and others in the United Kingdom to identify exposure in vivo as the central ingredient of psychological treatment for agoraphobic avoidance.

Procedural variations such as brief or prolonged exposure duration, massing or spacing of treatment sessions, and terminating exposure at the point of increasing or decreasing anxiety were examined assiduously by clinical researchers, but the consensus is that these technical details are less important than the general recommendation to confront, rather than avoid, feared situations. This exposure principle is as well founded as any in the entire field of mental health work.

Treatment of panic

The essential technique in the psychological treatment of panic is exposure to somatic cues, or reproduction of and confrontation by the bodily symptoms that the patient associates with panic attacks. The patient is asked to create sensations of panic deliberately during and between treatment sessions. Running in place, voluntary hyperventilation, and spinning around in a swivel chair are examples of procedures for creating such sensations. Clinicians match particular procedures to patients' most troublesome symptoms; someone who is most alarmed by dizziness will practice spinning around, while someone disturbed by the sensations of a rapid heart rate will run up and down the stairs.

In early trials, this approach brought the most impressive results yet seen in the treatment of panic and agoraphobia, the success rates approaching 100% in some studies. Advances in methodology that have allowed the daily monitoring of panic attacks have permitted accurate tracking of panic attack frequency. 'Percentage of patients panic free' has become a standard datum to report in contemporary treatment trials.

The efficacy of exposure to somatic cues has been attributed to various theoretical processes. These include the exposure principle, possibly resting upon the extinction or habituation of conditioned anxiety responses to panic sensations, or upon the development of coping skills by the patient. The success of the method is consistent with the specific hypothesis that chronic hyperventilation underlies panic disorder. It is also consistent with the cognitive therapy view that the patient makes catastrophic misinterpretations of the bodily sensations of panic, ascribing to them morbid significance as harbingers of a medical emergency.

Parallel to exposure to somatic cues is cognitive therapy in the contemporary treatment approach to panic. Consistent with David Clark's model of an interaction of sensitivity to somatic cues and the catastrophic misinterpretation thereof, patients are engaged in a cognitive treatment process of collaborative empiricism in which implicit schemas construing panic sensations as signals of dire illness are carefully assessed, gently challenged, and empirically tested. Cognitive therapy involves exploring, in a sympathetic and accepting way, the specific idiosyncratic cognitions that are assumed to underlie emotional distress. Real-life 'experiments' are undertaken in attempting to challenge unrealistic assumptions. There is no standard,

structured format that must be applied systematically to all patients; rather, the principles of cognitive therapy guide a creative treatment approach with each individual. The results of preliminary trials of cognitive therapy have been as encouraging as those of exposure to somatic cues, and the combination of these treatments has brought the best outcomes.

Guidelines by the National Institute for Health and Clinical Excellence in the United Kingdom state that cognitive-behavior therapy is now accepted as, and should be employed as, the treatment of choice for panic disorder. Structured treatment protocols for the comprehensive treatment of anxiety and panic have been developed and researched by Michelle Craske and David Barlow. Therapist guides and client workbooks are available.

Comprehensive treatment of agoraphobia

In addition to the central psychological treatment approaches of exposure in vivo, exposure to somatic cues, and cognitive therapy, relaxation training, and breathing retraining have been found helpful in the treatment of agoraphobia and are recommended as optional components of a treatment plan. There is a consensus that in the typical case of panic disorder with agoraphobia, treatment should proceed employing all of these techniques in sequence, beginning with self-paced exposure in vivo. Experts argue that, because it is not associated with deleterious side effects or complications from withdrawal, psychological treatment should be used first, and pharmacological treatment brought in as necessary subsequently.

Alternatively, using short-acting anxiolytic medication to help patients with severe agoraphobia embark upon an in vivo exposure venture, and then prolonging the exposure while the effects of the medication wane, has been validated in controlled studies by Marks and his associates as an ideal method for combining the advantages of both treatments rationally in a carefully structured treatment program.

Conclusions and Prospects

Although agoraphobia is fragmented by the current nomenclature into two distinct disorders, it is a coherent syndrome with a range of symptomatology extending far beyond the limited compass of specific phobias. Panic disorder, which overlaps with agoraphobia in one of the syndromes, is associated with a degree of distress similar to that seen in the mood disorders. Agoraphobia and panic disorder have yielded in recent years to effective pharmacological, behavioral, and cognitive treatments.

Currently in need of further attention by clinicians and researchers are the following. Whereas pharmacological treatment is readily available, it is difficult for many patients to gain access to specialized psychological treatment, especially in rural areas. Innovations in service delivery are needed, and studies should address the viability of psychological treatment of agoraphobia from remote sites by means of the latest communications technology. Many communities are underserved by mental health professionals, and individuals who are housebound by agoraphobia have even greater difficulties than most people in gaining access to needed psychological services. Encouraging developments in this context include the recent finding in the United Kingdom that brief training for

primary care therapists in cognitive therapy for panic disorder produced significantly better outcomes than treatment as usual. Self-directed treatment with limited therapist contact has been shown to be effective for clients in rural areas with sparse professional resources.

Glossary

Cognitive architecture The component processes and their interconnections that make up a more complex mechanism involved in a task like reading single words aloud or writing words to dictation.

Grapheme The smallest combination of letters associated with an elementary sound unit. Graphemes can be as small as a single letter. For example, the letter P corresponds to the pronunciation 'puh' while the letter pair PH (a bigram) corresponds to 'fuh.'

Hemifield One half of the field of view defined according to retinal coordinates.

Hemispatial neglect A neuropsychological condition that affects attention, exploration, and awareness of the hemispace opposite the damaged hemisphere. Clinical manifestations of neglect include bumping into objects and walls, ignoring objects, persons, and sounds coming from the affected side, forgetting to shave (or applying make-up) to one part of the face, etc.

Modular Refers to the idea of separable cognitive components working together to carry out a task. For example, the orthographic lexicon is a component that is modularly distinct from the phonological lexicon. Modularly distinct components can be independently affected by neurological damage.

Orthographic lexicon The stored representation of the spelled form of words in the reader's vocabulary. The orthographic lexicon maintains each word as a sequence of abstract letter identities.

Phonological lexicon The stored representation of the pronunciation of the words in a speaker's vocabulary.

Retinocentric A spatial coordinate system centered on the retina.

Syndrome In cognitive neuropsychology, the term refers to a cluster of impairments on a number of different tasks, and the co-occurrence of symptoms reflects a theoretically important principle. The term is not applied to impairments that co-occur simply because neurological damage has fortuitously affected a number of unrelated processes.

The advent of the visual word as a means of communicating ideas and preserving knowledge is of fundamental importance to human development. Because of the crucial role played by written language in so many domains it is no surprise that learning how to fluently read and spell occupies much of our initial efforts at school. As a general rule, good readers are also good spellers, while bad readers have a harder time producing the correct form of written words. This correlation suggests that these two tasks share common substrates. But given the demands specific to each task, reading and writing cannot depend on exactly the same underlying mental processes. For example, the rapid identification of a letter string depends on certain mechanisms unique to vision, whereas the retrieval and execution of letter shapes require motor processes specific to handwriting.

The main goal of this chapter is to describe and understand how certain neurological lesions can induce deficits in reading and writing (i.e., alexias and agraphias). What these different pathologies can tell us about the organization of the mental processes responsible for reading and writing in normal individuals will also be addressed. Neurological damage can selectively affect the peripheral components of word processing (e.g., the perception or production of letters) or its central components (e.g., the relationship between the orthographic form of a word and its sound or meaning). Generally speaking, the more peripheral the damage, the more likely the impairment will be specific to either reading or writing. Throughout this article, the reading and writing system will be deconstructed into different components, and the disorders associated with

their impairment will be described. First, the neuropsychological disorders related to the uptake of visual information will be presented. Next, deficits resulting from damage to more central mechanisms will be explained. These central mechanisms relate to orthographic, phonological and semantic knowledge, and often affect both reading and writing simultaneously. Lastly, the deficits that follow damage to orthographic output or, more specifically, to letter production, will be described.

Peripheral Dyslexias

Skilled reading demands accurate and rapid visual access to the symbols displayed on a page or computer screen. The quality of the visual information perceived is in part determined by the capacity to efficiently direct one's gaze and/or attention toward the text on the page (e.g., find the first paragraph). At the same time, in order for reading to be rapid and efficient, one must quickly recognize the letters in each word while maintaining their relative positions (e.g., LISTEN is not the same word as SILENT). In brain-lesioned patients who suffer from reading disorders as a result of damage to peripheral systems, the visual information perceived is inadequate to support accurate or fluent reading. Although these lesions will frequently have major repercussions on reading abilities, they will not affect spelling. Three types of peripheral alexias will be described in this section: pure alexia, attentional dyslexia, and neglect dyslexia. Note that we will use the term 'alexia' for some varieties of reading disorder and 'dyslexia' for others. 'Alexia' has

generally been the term that denotes reading disorders acquired as a result of neurological injury, while 'dyslexia' has more commonly been used to refer to developmental disorders of reading. However, the term 'dyslexia' has also been applied to certain forms of acquired reading disorder (e.g., deep dyslexia, attentional dyslexia, and neglect dyslexia) as has the term 'dysgraphia' to certain acquired writing/spelling disorders. We have varied our labeling, therefore, so as to be consistent with the published nomenclature.

Pure Alexia (Alexia Without Agraphia)

A dramatic example of a reading disorder that occurs without corresponding difficulties in spelling or writing is pure alexia (or alexia without agraphia). Jules Dejerine first described this syndrome over a hundred years ago at the Biological Society in Paris. In this seminal work, Dejerine documented the remarkable case of 'Monsieur C' both behaviorally and anatomically. Monsieur C, a highly educated businessman who had suffered a left hemisphere stroke, showed preserved writing and spoken language skills. He wrote fluently both spontaneously and to dictation but showed severe word blindness; that is, Monsieur C could not even read sentences he himself had written once the memory of the text had faded.

From neuroanatomical and behavioral observations, Dejerine concluded that pure alexia is a deficit caused by a disconnection between vision and language-based areas of the brain, a theory that Geschwind also resurrected in the mid-twentieth century. The disconnection theory Geschwind proposed entails that at least two lesions are necessary to isolate words from visual input, resulting in pure alexia: one in the left occipital lobe and the other in the splenium of the corpus callosum. Although it is a possible explanation for some of the cases reported over the years, current research suggests a more parsimonious neuroanatomical explanation. Most patients with pure alexia show a lesion of a small section of the cortex in the left mid-fusiform gyrus. This region is the only visible damage in at least one documented case of pure alexia. However, the specific role of this brain region and its importance for efficient reading remains a matter of intense debate.

The majority of cases showing alexia without agraphia are not as severely impaired as Monsieur C, who was unable to identify even single letters, treating them as unfamiliar shapes (e.g., he indicated that the letter A looked something like an artist's easel and S like a snake). The majority of pure alexics are able to identify individual letters but are forced to adopt a laborious approach to decipher even short familiar words. As a result, pure alexic readers (or letter-by-letter dyslexics as the syndrome is now often called) show very slow word identification (e.g., more than 2.5 s on average for even short, familiar words). A defining feature of letter-by-letter reading is the so-called word-length effect; that is, a linear relationship between the number of constituent letters and the time taken to read a word. The abnormally large word-length effect in this reading disorder is in striking contrast with the reading profile of normal readers, who show no word-length effect in naming latencies for words of less than seven letters.

The effect of length on performance suggests that patients with this form of reading disorder are limited to deciphering

words by analyzing each letter in sequence, so that the longer the word, the slower the reading speed (hence the term letter-by-letter dyslexia). Interestingly, though, this surface feature of the disorder is misleading. Good evidence indicates that it is generally not the number of constituent letters that impacts the reading of many letter-by-letter dyslexics but the extent to which the word contains letters that are perceptually confusable with other letters of the alphabet. This confusability index tends to be greater for longer words, simply because the longer the word, the more letters there are to be identified that are potentially confusable with other letters. It is possible to vary length while holding constant the summed confusability scores of the letters making up the word. When word-confusability scores are controlled in this way, letter-by-letter readers continue to read slowly, but their performance is generally not slower for longer than for shorter words. Thus, reading in this syndrome, despite the modern label for the disorder, does not seem to be invariably confined to a sequential analysis of letter identities. Rather, simultaneous analysis of multiple letters generates perceptual noise that delays recognition, and the degree of perceptual noise is determined by the overall confusability of the letters in a word.

Pure alexia offers a rich window into the visual mechanisms dedicated to word recognition. How specific is the disorder to reading? There are two alternative views on this question. The first attributes the reading disorder to damage of a specialized system for the visual analysis of alphabetic stimuli (i.e., words and letters). This account is based on the hypothesis that visual experience and expertise with words is sufficient to create area(s) of visual cortex responsive uniquely to visual words. Theories postulating that only alphabetic stimuli are impaired in pure alexia are examples of this specific account. The second account proposes that no brain part is uniquely devoted to visual word recognition per se but that some neural mechanisms that determine efficient perception of words are less crucial for other kinds of objects (e.g., faces, animals, man-made three-dimensional objects, etc.). This last account predicts that pure alexia is not a deficit specific to alphabetic material but rather includes an impairment in any task where the necessary visual resources coincide with those needed for reading. For example, one account proposes that visual word recognition requires simultaneous integration of multiple letters and that this integration mechanism is not specific to reading.

All thoroughly tested patients with pure alexia show some form of visual processing impairment not specific to alphabetic stimuli. Hence, the hypothesis of a general visual deficit is actually plausible. But the nature of the perceptual mechanisms, so important for reading yet of much less significance in other visual tasks, remains to be determined.

Attentional Dyslexia

Attentional dyslexia is a rare form of reading disorder that occurs after a brain lesion to the left parietal cortex. The main behavioral symptom is a failure to correctly perceive one item of a given category (e.g., the letter A) when this item is presented simultaneously with other items of the same category (e.g., BDGAH). A typical patient is able to read isolated words or letters with relative ease but his performance declines when

he is asked to identify those same items in a sentence or a letter string – because many items are visible at the same time. These patients also make many errors when they are asked to identify a single digit flanked by other digits but the error rate decreases significantly when the target is a set of dots to be counted. This behavioral observation implies that naming (in this instance, of numbers) is not accountable for the deficit. The main deficit in attentional dyslexia is a lack of control of a filtering mechanism that suppresses visual processing of unattended items in the visual field. Thus, these patients are unable to direct their attentional spotlight to a specific region of interest. As a result, more input than expected falls within the attentional spotlight and the wrong features are integrated together leading to perceptual errors. Within this framework, error rates are larger when the surrounding stimuli are from the same category.

Neglect Dyslexia

Although it is frequently associated with hemispatial neglect and right hemisphere damage, neglect dyslexia can also be observed in isolation. In fact, at least one patient has been known to have a right-side hemispatial neglect following a left hemisphere lesion in conjunction with left-side neglect dyslexia following right hemisphere damage. This exceptional patient undoubtedly proved the existence of a double dissociation between nonverbal neglect and neglect dyslexia. In this form of peripheral dyslexia, reading is impaired because the patients tend to omit or misread the left side of a page or the first letters of letter strings or words of a sentence. At the word level, visual errors made by left neglect dyslexics can be additions of letters at the beginning of words ('love' read as 'glove'), omissions ('cowboy' read as 'boy') or substitutions ('mother' read as 'bother'). In right neglect dyslexia, these errors occur at the end of the word. By itself, the existence of neglect dyslexia suggests that spatial attention plays an important role in normal reading. However, neglect dyslexia is quite variable between patients and different attentional mechanisms have been proposed to explain this variability.

It has been argued that at least three spatial frames of reference are necessary for understanding visual attention in words. The first frame is retinocentric; spatial information is represented by means of a coordinate system centered on the retina. When this form of spatial attention is impaired in neglect dyslexia, omissions and errors tend to be on the letter strings that appear in one hemifield, generally the left in patients with right hemisphere damage. Indeed, a word written on the left side of a sheet will be ignored or misread while it will be read correctly if it is presented on the right, no matter the word's orientation (right to left, left to right, vertically, etc.).

The next frame of reference is a stimulus-based one. When this frame is impaired for reading, words' spatial representations are altered. The left side of the word as a string of letters is misread, regardless of whether the orientation demands a left-to-right or right-to-left perusal. A word such as 'marble' might be read 'cable' if presented from left to right but as 'march' if demanding a right-to-left analysis of letters (i.e., 'elbram'). In contrast to retinocentric impairment, damage to the second frame of reference leads to the same error rates no matter where the letters string is presented in the visual field.

The third and last frame of reference implicates cognitive, higher-level representations of known words, and the processing is no longer at the visual extraction level. When this reference frame is impaired for reading, a word such as 'bible' could be read as 'cable' even if presented from left-to-right or right-to-left. Interestingly, this kind of patient tends to commit similar errors in writing or spelling, thus suggesting that at this level, attention is applied to more central orthographic representations, akin to the reading and spelling errors in central alexias and agraphias.

Central Dyslexias and Dysgraphias

Central dyslexia and dysgraphia are the result of a disruption to the linguistic mechanisms (i.e., orthographic, semantic, or phonological) that mediate reading and spelling, respectively. Neuropsychological studies of brain-damaged patients have contributed substantially to the development of a model specifying the cognitive processes and their interconnections that determine reading and spelling (see Figure 1). The structure of the model – its cognitive architecture – is founded on the assumption that separate routines from print to sound (or in the case of writing, from sound to print) are recruited for familiar and novel words. A familiar word contacts its stored visual form and meaning, and these representations are then available for reading aloud and writing. If a novel word is encountered (or in a task devised for experimental purposes, a pseudoword), no stored form or meaning is available. Reading aloud or writing to dictation is then based on subword graphemic units assigned to corresponding phonemic segments; for example, the written sequence FENT is pronounced

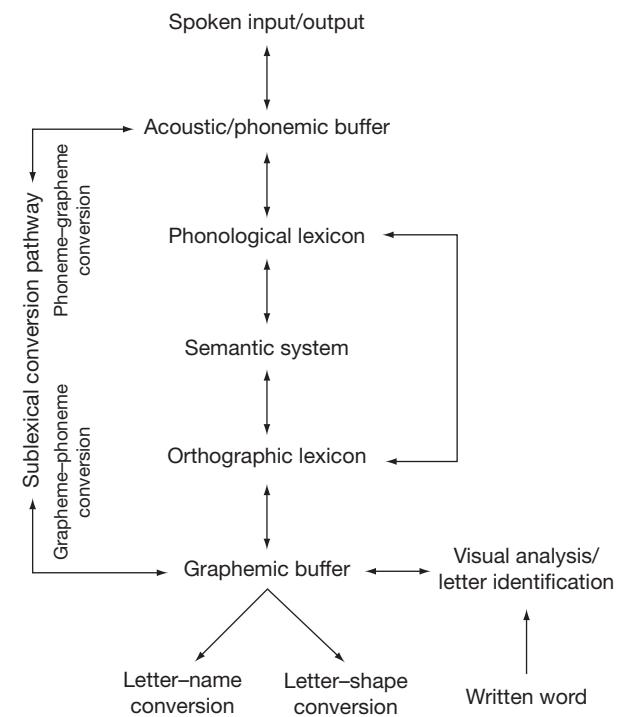

Figure 1 Modular architecture of reading and writing.

by knowing the sound associated with the letter F, and the typical rendering of the segment ENT. The framework offers an account of certain aspects of normal as well as pathological performance but is not without controversy. An alternative connectionist architecture rejects the view of two independent procedures for transcoding familiar and novel words. This rival approach has three sets of simple processing units, and so is referred to as the 'triangle model': grapheme units, representing orthography, phoneme units representing sound, and an array of semantic units for meaning. A spelling pattern generates recurrent activity over the grapheme units which then propagates through the network, resulting in a pronunciation for reading aloud (writing would entail a similar propagation of activity but from phoneme-to-grapheme units).

The triangle model, like its rival, includes two pathways between print and sound; a direct mapping between graphemes and their corresponding pronunciation, and a second pathway from print to sound via semantic units. Nevertheless, there are important differences between connectionist approaches and the more traditional dual-route model depicted in [Figure 1](#), the most basic of which is that the same processing mechanism is applied to the way familiar and unfamiliar words are mapped between spelling and sound. For expository purposes, we will follow the logic of the traditional model to describe central reading and spelling disorders. We will therefore begin our discussion on the central deficits of reading and writing with a short portrayal of the main components of this model.

In order to read, children must learn to assign a pronunciation to spelling units (e.g., the pronunciation of a sequence like INE). For writing, a similar mechanism is required but operating in reverse, to convert a pronunciation into a valid graphemic pattern. Note that the cognitive constraints on spelling-to-sound and sound-to-spelling conversion procedures are rather different. For example, the letter string HAIR has only one possible correct pronunciation but the spoken sequence/hɛər/has at least two corresponding orthographic forms (e.g., HARE, HAIR).

As reading and spelling develop, children learn to access or retrieve familiar words by directly contacting their stored visual forms. The ability to read or spell by using whole words rather than subword units implies three processing components for a word, one for its orthography, the second for meaning, and the last for pronunciation. This lexical-semantic route has some similarity with a dictionary: the orthographic lexicon contains the word's spelling (e.g., A-P-P-L-E), the semantic system containing its definition (e.g., the fleshy usually rounded red, yellow, or green edible fruit) and the phonological lexicon containing its pronunciation (e.g., /'a-pəl/). Theoretically speaking, the orthographic lexicon contains representations of all the words that a normal subject has learned to recognize in a single glance or to spell with high efficiency. The semantic system is responsible for storing the meanings of words. It is shared by other language mechanisms such as oral or sign language. The phonological lexicon is a system involved in the retrieval of spoken words in speech production. It plays an essential role in the spoken component of reading.

We will see that each of these processing routes and sub-systems can be damaged independently and cause different patterns of dyslexia and dysgraphia.

Phonological Dyslexia and Dysgraphia

In phonological dyslexia and dysgraphia, patients have difficulty in reading and spelling unknown words and pseudowords. Their performance, though, is clearly better or even in the normal range for known words, particularly for high-frequency words. Interestingly, most errors made by these patients are real words that are visually similar to the target word (this kind of error is termed a lexicalization; e.g., the nonsense word SIFE read as 'sift').

The cognitive architecture implies a division between the mechanisms responsible for known words and those responsible for unknown words and pseudowords. The fact that a cerebral lesion can affect reading and writing of pseudowords without affecting known words is consistent with the claim that distinct mechanisms are implied for processing these stimuli. In phonological dyslexia and dysgraphia, the lexical route is preserved, enabling the reading and spelling of familiar words, while the nonlexical route is impaired, affecting performance on spelling patterns that have no representation as real words.

Surface Dyslexia and Dysgraphia

At this point in our description of central deficits, the assumption that a distinction exists between a lexical and a sublexical pathway is not the only plausible interpretation of phonological dyslexia and dysgraphia. It is possible that pseudowords are simply harder to read and write than known words and that neurological damage only exacerbates this difference. The fact that normal subjects are slower and less accurate when reading and writing pseudowords versus real words is consistent with this possibility.

The finding of patients with the opposite behavioral profile – that is a deficit for words but no deficit for pseudowords – would eliminate this alternative possibility, however. Marshall and Newcomb were the first to describe such a patient in 1973. They documented what we now call surface dyslexia, that is, an acquired reading deficit in which the reader has difficulty reading 'exception' words (i.e., words with an irregular spelling-to-sound mapping; e.g., colonel) but makes fewer errors when asked to read regular words (e.g., fairy) and pseudowords (e.g., peratine). The initial cases described were less clear than expected given the assumption of a categorical distinction between whole-word and subword procedures for translating spelling to sound. Surface dyslexics often produced errors that indicated impairment of both procedures. This led to some doubt about the validity of the distinction, until a number of unambiguous cases were documented. From the perspective of the model, the reading impairment in surface dyslexia results from damage to the lexical route. Since this processing route is unavailable, surface dyslexic patients attempt to read and spell by the sublexical (i.e., grapheme-to-phoneme and phoneme-to-grapheme conversion) processing systems. Put differently, surface dyslexic patients often treat irregular words as if they were regular words or pseudowords. For example, they will pronounce COLONEL as /'kouləneɪl/ instead of /'kɜːnl/. Such errors are called regularizations and constitute the diagnostic pattern of surface alexia. Importantly,

these errors are more likely to occur for less common exception words (e.g., MOTHER might be read and spelled correctly but not LEOPARD).

Similar symptoms have been described for writing and spelling. In this case, patients make a large quantity of spelling errors for irregular words all the while correctly spelling regular words and pseudowords. The error rate in general is actually higher for this form of dysgraphia than for the corresponding surface dyslexia. In writing, the number of words with unpredictable phoneme-to-grapheme correspondences is quite high (e.g., the pronunciation 'boat' can be spelled in at least two ways, if we simply apply general principles of spelling-to-sound translation, including BOTE). Of course, some words, for example, DOG or CAT, have highly predictable sound-to-spelling correspondences. These words can be correctly spelled using the nonlexical conversion module. But many words have an unpredictable orthography, and the lexical route is needed for these to be correctly spelled.

It seems reasonable that surface dysgraphia should be seen together with surface dyslexia; both reading and writing errors can be attributed to a failure to contact a central representation of the word's orthographic form, and responses are based on more generic procedures that yield regularization errors. In very rare cases, though, surface dysgraphia occurs selectively (i.e., reading via word-specific procedures is demonstrably intact) or in association with another form of central dyslexia (e.g., phonological dyslexia). What do these unusual dissociations imply about the orthographic representations accessed for reading and spelling? One possibility is that different word-specific representations are available for input (reading) and output (spelling). The alternative is that the representations are indeed unitary but that distinct access and retrieval procedures exist that can be separately damaged to yield the dissociations seen in rare cases. The fact that such dissociations are so infrequent, though, indicates that the neuroanatomical substrates underlying any functional distinction between word-specific representations involved in reading and spelling must be so organized that they are mostly affected together.

Surface dyslexic and dysgraphic errors are the result of a failure to retrieve a word's pronunciation based on its stored orthographic form, and an overreliance on more general correspondences between spelling and sound units. We turn now to a very different phenomenon, involving reading or spelling impairment that ensues when the meaning of the word remains the only point of translation between its visual form and pronunciation, because all other routes have been destroyed.

Deep Dyslexia and Dysgraphia

In any cognitive neuropsychological task, the occurrence of semantic errors is probably one of the most spectacular kinds of error. In word reading, semantic errors are the main diagnostic behavior of deep dyslexic patients. For example, the typical patient could produce 'freedom' when confronted with the word 'LIBERTY' or 'knight' in response to 'CASTLE.' The first case of deep dyslexia was described in 1931 but the burgeoning interest in this reading disorder began in the late

1960s with the report of Marshall and Newcombe. In writing, the first case was described by one of us (D.B.) in the early 1980s. The limits on the performance of patients with deep dyslexia or dysgraphia are rather similar to the constraints suffered by patients with a phonological alexia or agraphia. In both types of disorder, performance for nonsense or unfamiliar words is affected while words yield better accuracy. However, deep dyslexic or dysgraphic patients are unable to cope with even a short nonsense word made up of a single syllable, thus suggesting a total destruction of the sublexical pathway. Of course, the syndrome is also associated with semantic errors produced by familiar words.

A comparatively large amount of research has been conducted on deep dyslexia. The reading pattern is probably the most complex and dramatic of all acquired reading impairments. Although semantic errors are the most frequent and diagnostic of errors in deep dyslexia, this kind of mistake is only one of the many characteristics of the syndrome. The most prominent features are (1) semantic errors, (2) visual errors (e.g., SYMPHONY read as 'sympathy'), (3) function-word substitutions (e.g., BUT read as 'and'), (4) derivational errors (e.g., MARRIAGE is read 'married'), (5) a complete failure to read pseudowords, (6) some classes of words found to be harder than others in reading aloud (function words > (i.e., harder than) verbs > adjectives > nouns), (7) strong concreteness (i.e., imageability) effect (TABLE easier than FATE).

To explain deep dyslexia, the dual-route model needs to postulate a number of deficits caused by independent damage to different functional components. Damage to the sublexical print-to-sound translation pathway is needed to explain the striking impairment in pseudoword reading. The presence of semantic errors as well as the concreteness effect suggests impairment to the semantic system itself. Destruction of the direct pathway between the stored visual form of the word and its pronunciation is also necessary since this procedure is clearly not available in deep dyslexia. If it was, the semantic errors would not occur because the pronunciation of the word could be retrieved without requiring that its meaning be contacted. Finally, visual errors suggest damage to the structural analysis of words; a possible source of these errors would be faulty processing within the orthographic lexicon. This unlikely coincidence of deficits observed in most deep dyslexic has led some researchers to argue that deep dyslexia is of no relevance for comprehension of normal reading mechanisms. Indeed, these researchers propose that deep dyslexics' left hemisphere lesion is so extensive that it is no longer available for reading. In this extreme case, reading would be mediated by a weakly literate right hemisphere. The attractiveness of this hypothesis comes from the reading similarities observed between deep dyslexics and patients with an isolated right hemisphere. However, the idea seems less plausible given evidence from a single case demonstrating many deep dyslexic characteristics, but whose reading was abolished after a second left hemisphere stroke.

The question remains, then. Why does the complex of symptoms characteristic of deep dyslexia occur, assuming that the pattern reflects the performance of a partially damaged left hemisphere reading system and not the normal reading capabilities of a linguistically restricted right hemisphere. Some progress on the issue has been made by researchers

constructing and analyzing connectionist models of reading that map the meaning of a visual word to its pronunciation. The relevant architecture consists of a primary layer of grapheme units representing the visual form of words, connected via intermediate units to 'sememe' units. The only function of intermediate units is to learn the pattern of associations that map specific letter patterns to a particular meaning, while sememe units represent the meaning of a word in terms of a limited set of semantic features like 'can be eaten,' or 'made of wood.' Sememe units connect to phoneme units via an additional set of intermediate mapping units.

This type of architecture has trouble learning to associate visually similar words with distinct semantic representations; however, the inclusion of a layer of 'clean-up' units that interacts with the sememe layer dramatically improves the mapping between the orthographic form of words and its meaning, by minimizing the confusion between visually similar words. Of great interest is the fact that damage to a percentage of clean-up units (by randomly altering a subset of weights) yields a number of the symptoms of deep dyslexia: visual errors occur as well as semantic errors, because the clean-up units no longer can differentiate between the patterns of activation generated by visually or semantically similar words. In addition, both deep dyslexic cases and the damaged connectionist model produce more complex errors, involving a semantic error driven by a visual substitution (SYMPATHY read as 'orchestra,' via the visual confusion 'symphony'). A concrete word like BOOK resists damage to the network more than an abstract word like FATE, because the former has many more semantic features than the latter. The clean-up units have greater redundancy to work with and so converge on the right meaning even after significant damage. Finally, because correct recognition of concrete words depends heavily on clean-up units, severe enough damage to this layer reproduces a striking reverse-concreteness effect also observed in one rare case of deep dyslexia; abstract words are read better than concrete words. Despite the undeniable value of these computational accounts, however, this approach has not yet produced a unified, coherent interpretation of the full symptom complex.

Deep dysgraphia is of considerable theoretical interest because the syndrome may sometimes occur in the absence of deep dyslexia, though the writing disturbance is invariably seen in association with some form of reading and language disorder. The dissociation between deep dyslexia and dysgraphia is evidence that procedures affording access to meaning from print may be partially distinct from procedures that operate in reverse to retrieve the spelled form of a word from its meaning. In addition, cases of deep dysgraphia show errors in their written performance indicating a failure to maintain letter identities in an output buffer holding active the graphemic representation of a word for sequential output. We discuss the reason for this surprising association of seemingly disparate effects when we consider writing disorders linked to impairment of the graphemic buffer.

Semantic Dyslexia and Dysgraphia

One possible outcome of severe damage to semantic representations is surface dyslexia, that is, a deficit in reading irregularly

spelled words. It seems reasonable to expect that words will be treated as nonsense words given severe enough damage to semantic representations. If the sublexical conversion pathway remains intact, orthographically irregular words will be regularized. Surprisingly, some patients – despite a severe semantic impairment – retain an ability to read and even spell both regular and irregular words. Semantic dyslexic cases suffer from Alzheimer's dementia or semantic dementia. They are able to read any kind of letter string (i.e., regular and irregular words as well as pseudowords), but they show no understanding of the words they can produce correctly. This kind of patient demonstrates that three processing routines are available to access pronunciation from print: the spelling-to-sound conversion procedure, the lexical-semantic pathway and a lexical nonsemantic pathway directly mapping word-specific orthographic forms to a pronunciation. It is this route that is used in semantic dyslexia to read irregular words correctly. Notably though, semantic impairment often does lead to surface dyslexia rather than semantic dyslexia. Why the different outcome in different cases? An interesting answer is that there are substantial individual differences in the utilization of semantic representations for reading. Some readers may need to rely more on semantic access to read irregular words whereas other readers are less dependent on word meaning.

Graphemic Buffer Impairment

As depicted on [Figure 1](#), the spelled form of words is produced by accessing a graphemic buffer, a component that receives information from both the orthographic lexicon and the phoneme-grapheme conversion mechanism. This component maintains abstract letter information (i.e., case invariant information) while peripheral conversion mechanisms operate sequentially on each grapheme to produce the spelled form (e.g., letter-name conversion for oral spelling, letter-shape conversion for writing, letter-motor scheme for typing).

How should performance be affected if the graphemic buffer were impaired, assuming that the damage is not severe enough to preclude any form of output? The buffer holds the final spelling of both familiar words as well as graphemic sequences generated by spelling-to-sound conversion. Performance should therefore be unaffected by word-specific variables like concreteness, familiarity, and grammatical class. If the capacity of the buffer to maintain letter identities has been reduced, longer words should yield more impairment than shorter words. In addition, if activation in the buffer has been compromised so as to generate interference between letter identities, spelling errors should be more frequent in the middle than the end of words, because terminal letters have fewer adjacent letters to compete with their activation. This profile has been documented in a substantial number of dysgraphic cases. Their errors include doubling applied to the wrong letters (e.g., STREET spelled as STRETT; consistent with the idea that the doubled status of the letters is represented separately from the letters themselves), ordering errors (transpositions), substitutions, and omissions. A successful computational account of this dysgraphic subtype has been implemented (a 'competitive queuing model') based on principles derived from a class of models that deal with the

control of sequential output. The model includes the idea that response elements organized for sequential output are selected by means of an activation gradient; the more active an element the sooner it is produced. In addition, competition occurs between response elements. Random noise added to the sequence generation process yields the key features of a graphemic buffer dysgraphia.

A surprising variant of the syndrome shows many of the cardinal signs indicative of a damaged buffer but in addition, elements of deep dysgraphia, including word class effects (like concreteness) and semantic errors. Nonsense words are spelled very poorly. Like the more typical instances of the syndrome, letter deletions, substitutions, and transpositions occur and spelling is worse for longer than shorter words. However, errors increase monotonically from the beginning to the end of the word (whereas in the more typical case, as we have seen, lower error rates occur at the start and end of words). This variant can be understood if the output of the semantic pathway yields a degraded representation of letters in the graphemic buffer. Subthreshold activation of letter identities results in numerous errors, including premature termination of the word if the very low signal from the last few letters is taken to indicate that the end of the word has been reached.

It was originally assumed that the graphemic buffer's role was restricted to the writing domain. However, the buffer may also be involved in reading, maintaining the level of activation generated by letters in the word. Accordingly, patients with a lesion to the graphemic buffer frequently have difficulty reading items comprising many letters, especially when pseudowords must be read and the orthographic lexicon cannot contribute to the response. Normal readers supply converging evidence for a short-term visual memory needed to derive the pronunciation of unfamiliar words. In this framework, the only strictly peripheral agraphias are those coming from lesions to the letter-shape and letter-name conversion mechanisms.

More Peripheral Agraphias

Impaired writing can occur even though the spelled form of the word has been correctly retrieved. In this type of agraphia, the word TABLE would be spelled aloud as 'tee, ay, bee, ell, eeh,' yet errors occur when the letters are produced in written form. The spelling of the word is clearly available, therefore, at least in a form suitable for naming (but also for other tasks; e.g., constructing the spelled word using block letters), but their shapes are not correctly translated into movements. If the writing impairment is due to a failure in motor processes that govern neuromuscular execution and control, written letters are distorted often to the point of being unrecognizable, and errors include misplaced as well as incorrectly formed strokes of the pen.

More surprisingly, it is possible to observe instances of peripheral agraphia where the dominant error consists of well-formed letter shapes; TABLE would be written as F-A-P-L-E. The question of interest is whether such errors are visually related to the target or whether some other relationship exists, based on the sequence and placement of the movements needed to construct the letter. A question of additional import is whether

the action representation at this level of organization in the writing mechanism concerns movements of the hand or more generally, to any action that is intended to construct letter forms. The answer to the second question is straightforward; the representation affected is sufficiently abstract that impairment is seen even when letters are produced by tracing the shape with a foot. The first question is more difficult. Letters that require similar strokes for their production tend also to be visually similar; how then can we distinguish visually based from action-based errors? A reasonable way of proceeding is to invoke two empirically driven methods to arrive at separate metrics of visual and motor similarity between letters. For example, visual confusability can be assessed by examining the errors of normal readers under restricted viewing conditions; the higher the probability a letter is confused with another, the more they are perceptually similar. Motor similarity can be operationally defined by constructing a reasonable taxonomy involving, say, number of strokes, shape (line vs. curve), direction (up, down, clockwise, counterclockwise), and so on. In this way, it is possible to isolate letter pairs that are more confusable with respect to an underlying metric of motor than visual similarity. An analysis of errors using this methodological approach has disclosed that in some cases of peripheral agraphia, errors are based on stroke similarity between letters rather than visual similarity.

Peripheral agraphias offer the possibility of valuable insights into the processes that govern the production of letters, as the previous example illustrates. Additional evidence from individual cases reveals a degree of categorical organization imposed on the processes that translate letter identities into movement. Impairment can affect the formation of letters while numbers are unaffected; the letter O may be incorrectly written, in other words, but not the number zero! Other forms of peripheral dysgraphia disclose mechanisms that concern the distinction between upper and lower case forms of the same letter (alographs); patients may have severe difficulty in producing uppercase printed letters for example, but not lowercase cursive script. Finally, dysgraphia may involve a disconnection between hemispheres, so that one hand no longer has access to the representations that govern the production of letter shapes.

Alcohol: Psychosocial Effects

K J Sher, R Winograd, and A Vergés, The University of Missouri and the Midwest Alcoholism Research Center, Columbia, MO, USA

Glossary

Acute tolerance The phenomenon of alcohol having less effect on the descending limb of the blood alcohol curve (i.e., when blood alcohol levels are falling) than on the ascending limb (i.e., when blood levels are increasing even) at similar blood alcohol levels.

Alcohol myopia A prominent theory of acute alcohol effects that posits that many of the behavioral and emotional effects of alcohol can be explained as a consequence of the narrowing of attention that alcohol produces. Such narrowing results in the drinker attending to only the most salient aspects of the environment which, depending upon the nature of the environment, can result in a range of emotional and behavioral extremes, both 'prized' and 'dangerous.'

Alcohol outcome expectancies Beliefs or associations regarding the effects of alcohol on the drinker. Expectancies can either be positive (e.g., 'drinking alcohol makes me happy') or negative (e.g., 'I get sick when I drink'). Such expectancies can be acquired directly via the personal effects of alcohol or through vicarious learning. Expectancies have been shown to predict drinking behavior both cross-sectionally and prospectively.

Allostasis A chronic adaptation to a substance or activity that is reflected in homeostatic changes (e.g., changes in hedonic set point) associated with tolerance, withdrawal,

and negative affective states. Allostatic changes induced by chronic alcohol consumption are associated with dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis and alcohol dependence.

Balanced-placebo design A type of experimental design used to disentangle the pharmacological effects of alcohol from those attributable to alcohol expectancies. The design, in simplest form, experimentally manipulates both the belief that one has consumed alcohol (i.e., expect alcohol vs. expect no alcohol) and alcohol consumption (i.e., alcoholic beverage vs. a control beverage). This design extends the placebo-controlled design which merely holds expectancy constant and, therefore, doesn't evaluate expectancy effects.

Chronic tolerance The phenomenon of individuals experiencing reduced effects of alcohol with increasing drinking experience and/or needing increasing doses of alcohol in order to achieve a given effect of alcohol.

Pharmacodynamics The study of the physiological effects of drugs on the body.

Pharmacokinetics The study of how the body absorbs, distributes, metabolizes, and eliminates drugs.

Stimulation and sedation Two broad classes of effects on subjective experience. Stimulating effects occur primarily at low doses and early in a drinking episode; sedation occurs primarily at high doses and when blood alcohol levels are falling.

Introduction

From the beginning of recorded history, historians and anthropologists have documented the prominent role of alcohol in the daily life of humans across diverse societies. Thus, when we examine alcohol use and its consequences, we should keep in mind the fact that we are looking at a phenomenon that has been a significant part of human experience for thousands of years.

However, a scientific understanding of alcohol and its effects is only a very recent achievement. Today, epidemiological studies inform us about the widespread use of alcohol in many societies; this makes it a public health concern in those countries where it is used in excess or in hazardous ways. The World Health Organization suggests that as many as 2 billion people consume alcohol in the world, and that about 76.3 million have an alcohol use disorder (AUD); leading it to be considered as one of the most prevalent mental disorders in the world.

This article provides an overview of research on both the acute and the chronic psychosocial effects of alcohol use. Such effects are often highly influenced by moderating factors that are specific to the occasion (i.e., the particular drinking context) or the individual (i.e., some people tend to respond

differently than others); therefore, characterizing the effects of alcohol use requires the consideration of a number of factors, including those beyond the drug effect. Although a comprehensive description of alcohol effects is beyond the scope of this article, we highlight the nature and determinants of some of the most widely known psychosocial effects of alcohol, including increased aggression, sexual disinhibition, injury, stress reduction, and human capital accrual.

Acute and Chronic Effects of Alcohol

Acute Effects

When discussing the effects of alcohol we need to consider both the acute effects associated with having recently consumed alcohol and the chronic effects associated with a pattern of alcohol use over time. Both the acute and the chronic effects of alcohol can be understood in terms of how alcohol acts on the central nervous system (CNS) which is largely responsible for regulating cognition, affect, and behavior. The acute effects of alcohol can be classified into three broad categories: (1) positively reinforcing effects (e.g., euphoria, arousal), (2) negatively reinforcing effects (e.g., anxiety reduction, antidepressant effects), and (3) punishing effects (e.g., depression,

hangover, vomiting). These effects are likely to vary across individuals and contexts, they rely upon different underlying neurobiological processes, and are probably a combination of pharmacological processes as well as individual alcohol expectancies (for further discussion on this topic please see the section 'Beliefs and expectancies'). Controlled experimental studies are better able to disentangle the effects of alcohol and these expectancies compared to real-world environments as the pharmacological and expectancy effects are inextricably confounded in the latter.

Most of the positive reinforcing effects tend to be largely associated with an enhanced activity of the monoaminergic system, that is, neurotransmitters such as dopamine, serotonin, and norepinephrine. The arousing effects of alcohol can be explained by the enhancement of these neurotransmitters, and probably have a lot to do with the resulting increase in talkativeness and excitement that is often seen when someone is under the influence of alcohol. Negative reinforcing effects, however, are most likely the result of increased activity in the GABAergic system through the GABA_A receptor in a way that is not too different from that described for the benzodiazepines. Research has suggested that the anxiolysis (decreased anxiety), and possibly some antidepressant effects, are due to this increase in GABA_A activity, and could explain why some people use alcohol as a means of reducing stress and tension. Lastly, the immediate punishing effects of alcohol (like facial flushing, nausea, and vomiting, for instance, which are mostly pharmacological in nature) represent a heterogeneous set of mechanisms that include ethanol metabolism, direct effects of alcohol on the gastrointestinal system, brain mechanisms, and the behavioral consequences of drunken excess (e.g., unintentional injury).

Regarding the neurocognitive consequences of heavy drinking episodes (i.e., drinking to intoxication), researchers are still investigating for any evidence of significant cognitive impairment. Psychopharmacological studies suggest that, in the case of a single, standard binge episode, once the breath alcohol levels have returned to zero, there is little or no lingering impairment; although there are studies with rodents that suggest that very high ethanol exposures can cause a more persistent impairment. While researchers have yet to fully characterize the relationship between a single drinking episode and a lasting impairment in cognitive function, there are a number of acute effects on cognition. For example, researchers have studied the phenomenon of blackout, which is a period of time (during a single, heavy drinking episode) during which recall is impaired. This memory impairment can either be 'En bloc' (when a large segment of the drinking episode was never encoded and thus impossible to recall), or 'fragmented' (when memories were encoded though not readily recalled unless the person is presented with a cue which serves as a reminder). These acute memory impairments are thought to be due to a disruption in hippocampus activity which can be caused both directly (by interfering with circuitry within the hippocampal CA1 cells) and indirectly (such as inhibiting communication between the hippocampus and the medial septum).

While blackouts may be one of the most dramatic and recognizable acute impairments associated with excessive alcohol consumption, it can also acutely affect a number of cognitive functions, especially those that involve effortful processing

of information, task switching, divided attention, rehearsal, and self-regulation. A slower rate of information processing (e.g., visual encoding) can lead to delayed reaction times, as well as poorer performance on divided attention tasks (such as driving, which requires the ability to engage in multiple tasks, simultaneously). Alcohol consumption remains a major factor in motor vehicle crashes, which are a major source of unintended injury. Indeed, acute alcohol consumption is associated with a range of unintentional injuries; with the risk of injury dramatically increasing with an increase in alcohol levels (for a further discussion on this topic please see the section 'Unintentional and intentional injuries').

Chronic Effects

Those who drink heavily for long periods of time are likely to experience a range of chronic changes in emotional functioning, which are perhaps a result of frequent and reoccurring withdrawal symptoms. When present, withdrawal symptoms are associated with affective disturbance, particularly anxiety, which can lead to the initiation of a vicious cycle of continued drinking motivated by this affective disturbance. More importantly, some mood and anxiety disorders have been found to be induced by alcohol (i.e., substance-induced disorders), and these resolve after a period of abstinence. Additionally, substance-independent mood and anxiety disorders (i.e., they do not resolve with abstinence) often have an onset that follows the occurrence of an AUD at rates that are 'above chance expectation,' thus suggesting protracted affective consequences.

The broad term given to the changes associated with chronic drug or alcohol use is allostasis, which is the result of repeated drug/alcohol challenges to the brain and their resulting counterdirectional (i.e., compensatory, homeostatic) responses that strengthen when such challenges are repeated over time. In addition to providing a basis to the process of chronic tolerance (i.e., the need for increasingly larger doses to obtain a given effect) the allostatic perspective also provides an explanation for chronic mood changes. Specifically, the allostatic burden of adjusting to alcohol-induced homeostatic changes results in a downward drift of the hedonic set point (in the negative direction) via its effects on the hypothalamic-pituitary-adrenal (HPA) axis which result in a chronic negative affective state.

In addition to the chronic emotional effects, prolonged and heavy consumption of alcohol can result in cognitive impairment that ranges from mild to severe. The long-term effects depend on the quantity of alcohol consumed, with greater quantities being associated with a decrease in the chances of recovering lost cognitive functions (for further discussion on this topic please see the subsection 'Chronic effects' within the section 'Individual differences in moderating effects').

In addition to these examples of neurological disease, chronic alcohol use is associated with a broad range of physical health and organ system problems. Even for diseases that are not directly caused by alcohol use, the social and psychological factors associated with AUDs are inextricably linked to one's overall health (e.g., noncompliance with medical treatment). Irrespective of whether the relationship between alcohol and poor health is direct or indirect, statistics indicate that alcohol can be attributed to over 100 000 deaths per year

in the United States alone, making it the third leading cause of death in this country (following tobacco use and poor diet/lack of exercise). Approximately 15–20% of alcohol-related deaths are a direct result of alcohol use (e.g., cirrhosis of the liver or alcohol poisoning), while the remainder are due to disease or injury in which alcohol plays a significant role. Although the overall effect of alcohol on health is negative, moderate alcohol consumption can have a salutary effect on some diseases (e.g., coronary artery disease and ischemic stroke) except perhaps in moderate-drinking, middle-aged men who are at higher risk of heart disease and stroke, where these effects would be expected to be greatest.

Moderators of Alcohol Effects

Drinking Occasion Specific

Dosing and limb effects

The effects of alcohol are highly dose dependent and when discussing what alcohol can do, we need to be specific about the dose under consideration. Very low doses, the kind of dose often taken by moderate drinkers in the context of a meal, may have minimal effects on mood and behavior while binge or heavy drinking can lead to extremes in behavioral disinhibition and an impairment of cognitive and motor performance. Second, there are considerable individual differences in how quickly alcohol is metabolized, so that a specific administered dose (even after taking into account body mass and gender) of alcohol can result in very different blood and brain levels of alcohol in these individuals, depending upon the variability in pharmacokinetics. While most individuals eliminate alcohol from their system at a rate of about $0.015\text{--}0.020\% \text{ h}^{-1}$ (so that it would take, on average, 4.5 h for someone to have his or her blood alcohol concentration (BAC) go from 0.08% to 00%), there is as much as a threefold difference in the rate of metabolism in the general population which results in individual differences in the time taken to clear alcohol from the system.

Moreover, even with comparable blood and brain levels of alcohol, there are considerable individual differences in the magnitude of the physiological and behavioral responses or the pharmacodynamics. Thus, when we seek to explain the effect of alcohol, we must remember to consider the individual differences that occur at the pharmacological and physiological levels.

The effects of alcohol are highly dependent on the amount consumed with higher doses being associated with greater behavioral impairment, behavioral excesses, and a range of acute adverse physical, behavioral, and social consequences (for further discussion on this topic please see section 'Acute and chronic effects of alcohol'). While there is some degree of folklore surrounding the beverage-specific effects of alcoholic drinks, research has demonstrated little evidence for the type of beverage making a difference in the level or the type of intoxication (after controlling for differences in ethanol concentration). The alcohol content of beverages sold in retail outlets in the United States can range from 2% ('near bear') to 95% ethanol (Everclear), and what is considered a standard drink varies from country to country. For example, in the United States, a standard drink (equivalent to ~12 oz. of beer,

1.25 oz of distilled spirits, or 5 oz. of wine) is usually defined as 14 g of pure ethanol. However, there is less standardization of ethanol concentration and drink size than these guidelines imply. Beers tend to have about 5% ethanol and can have concentrations that are more than double this amount. Wine, which is typically around 12% ethanol, can have up to 16% or more. Distilled spirits are typically 40–50% ethanol but can be much higher. This variability, coupled with variability in the size of the drinking vessel and pour size, can make it difficult for individuals to gauge the number of standard drinks they have consumed. Moreover, across the world, what is officially considered a standard drink ranges from 6 g ethanol (Austria) to 19.75 g (Japan), a consideration to be mindful of when comparing drinking statistics and behavior across cultures.

Although a number of adjectives can be used to describe the subjective effects of alcohol, stimulation, and sedation are two 'umbrella' terms for classifying the subjective responses. The term stimulation refers to subjective states such as elation, vigor, loquaciousness, sociability, and euphoria. Sedative refers to subjective states such as sluggishness, difficulty in concentrating, and slowed thinking. Alcohol effects are frequently described as biphasic, a term that is used to refer to the differences associated with the dose administered and, as discussed below, with whether the blood alcohol level is rising (ascending limb; as when someone is initiating drinking) or declining (descending limb; as when someone has recently consumed alcohol but has now ceased and sufficient time has elapsed, and alcohol is actively being eliminated from the system more quickly than it is being absorbed). The limbs of the blood alcohol curve correspond to the biphasic effects of alcohol. On the ascending limb stimulation predominates, while on the descending limb stimulation decreases and sedation begins to predominate. While these are general reports, the magnitude of these subjective effects tends to vary as a function of the individual's typical drinking pattern, with heavier drinkers being more likely to associate alcohol with stimulant effects in general, and lighter drinkers reporting more sedative effects; this partially explains why the heavier drinkers consume more, as stimulation is usually more desirable than sluggishness.

The same BAC can produce different effects depending on the limb of the curve. For example, individuals typically perceive themselves as being more intoxicated and impaired, at the same blood alcohol level, on the ascending limb than on the descending limb. That is, one might feel much more intoxicated at a BAC of 0.08% when his or her blood alcohol level is rising than at the same blood alcohol level when it is falling. However, this acute tolerance (less response on the descending limb than on the ascending limb) to perceived intoxication can diverge from other alcohol effects. Most critically, when blood alcohol is rising, many individuals can perceive that their cognitive or behavioral abilities are impaired (in the ways discussed in section 'Acute and chronic effects of alcohol'). However, as blood alcohol begins to fall these same individuals may subjectively perceive themselves as being no longer impaired. However, objective impairment can show much less acute tolerance (i.e., individuals can still show high levels of objective impairment on cognitive and motor tasks). This combination of perceived low impairment in the presence of objective high impairment is characteristic of the descending

limb and can lead the drinker to misjudge his ability to safely engage in certain tasks (e.g., operating a motor vehicle) and is probably a major factor in hazardous use.

Situational context

In many, if not most societies, alcohol is typically consumed in a social context. Experimental research has shown that the presence of other people strongly influences the effects of alcohol. Research findings are consistent in showing that subjects, in a social drinking condition, report more positive subjective effects of alcohol than those who drink alone. Moreover, the presence of drinking companions can affect the amount and the rate of alcohol being consumed. In fact, research has shown that participants drinking in a social situation might consume almost twice as much as those drinking alone. However, this effect seems to depend on the specific composition of the group, since people in groups drink faster than those in pairs; mixed-gender pairs drink faster than same-sex pairs, and among males, those in all-male groups tend to drink more than those in mixed-gender groups. At least two different mechanisms are likely to be responsible for this pattern of findings. One is the imitative modeling of other drinkers. A number of studies have shown that heavy drinking models (usually the confederate of the experimenter) tend to increase the amount of alcohol being consumed by a companion (the experimental subject). Another potential factor is that alcohol modulates (via effects on the dopamine neurotransmitter system) natural reinforcers, and the presence of others is naturally rewarding for humans (especially in adolescence when alcohol use is typically initiated), as is in a number of animals.

However, there are a number of contextual aspects of drinking, beyond the presence of conspecifics, that can affect both mood and behavior, and these can range from the physical aspects of the drinking environment to specific interpersonal events. A variety of influential cognitive theories have been proposed to explain why there are such large situational determinants of, ostensibly, pharmacological effects of alcohol. Steele and Joseph have stated that alcohol intoxication reduces the ability to attend to and process multiple internal and external cues. Under these circumstances, only those situational cues that are most immediate and salient are likely to be attended to. Such alcohol myopia is predicted to lead to disinhibited behavior (e.g., increased aggression or risky sexual behavior) in situations in which the sober individual would normally experience an inhibition. In other words, in circumstances in which a sober person would perceive strong cues, either provoking or inhibiting a certain behavior, the intoxicated individual will only process the more immediate and salient cues that provoke the behavior. Similarly, salient pleasant stimuli would be more likely to improve mood while salient aversive stimuli would be more likely to worsen mood; both happen to a greater extent in intoxicated individuals compared to sober individuals. Other cognitive theories focus on how alcohol intoxication affects appraisal processes, such as, by diminishing the elaboration and integration of new information that typically takes place when one is confronted with a stressor. There is increasing evidence that the cognitive mediation of alcohol on emotion, through processes related to impaired cognitive processing, is most applicable to situations where low and moderate doses of alcohol are consumed. When intoxicating doses of alcohol are

consumed, it appears that alcohol directly affects the brain circuitry that is associated with reward and behavioral inhibition.

Individual Differences in Moderating Effects

Age

The acute and chronic effects of alcohol are known to vary and have different implications when considered as a function of the life course. Thus, in addition to considering variables such as dosing, limb, and situational context, we need to consider developmental factors that shape the immediate and lasting effects of alcohol.

Acute effects

In most Western countries, self-administration of alcohol does not begin until adolescence with rapidly escalating rates of both any and heavy use occurring across the teen years. Animal research has shown that adolescent rodents are less sensitive than adults to some effects of alcohol such as sedation, hangover, or motor impairment, and exhibit better acute tolerance. Moreover, repeated exposure to alcohol may further reduce their sensitivity to these acute effects. Such diminished sensitivity to some negative consequences of alcohol makes it possible for adolescents to drink relatively large amounts, even if they are still only novice drinkers. However, adolescents are more sensitive to the effects of alcohol on social facilitation and social interaction, a critically important activity at this stage of life. This combination, of diminished punishing alcohol effects with increased reinforcing effects (coupled with relative drinking inexperience and incomplete development of executive cognitive functions), probably represents the key vulnerability to hazardous and excessive alcohol use in adolescence.

The profile of alcohol effects changes over the life course. Studies have also shown that older adults tend to be more sensitive to the negative effects of alcohol than younger adults. For example, older adults have been found to demonstrate an increase in psychomotor impairment than younger adults. This difference most likely explains, in part, the decrease in alcohol use and AUDs that occurs with age. However, older adults develop alcohol problems with lower amounts of alcohol use, and in some situations, they even fail to report the impairment caused by alcohol, which can, alternatively, be observed by objective measures.

Chronic effects

The long-term effects of alcohol consumption on a developing organism can be traced back to the first trimester of prenatal development as prenatal exposure to alcohol can lead to a wide range of behavioral effects that are manifested in childhood, adolescence, and adulthood. Such fetal alcohol spectrum disorders (FASD) can range from attention and impulsivity problems, similar to those seen in attention deficit disorder, to full-blown fetal alcohol syndrome (FAS), which is characterized by distinctive facial dysmorphology (e.g., indistinct groove between the upper lip and nose, small eyes), brain abnormalities, a range of behavioral problems, and (usually) mild retardation.

During adolescence, the brain appears to be especially sensitive to the long-term effects of heavy drinking, presumably

because the brain is undergoing extensive remodeling during this time with dramatic 'pruning' of synaptic connections and the continued development of some brain areas (especially the frontal lobes). Structural and functional neuroimaging studies have shown that adolescents with patterns of excessive consumption show evidence of neurological impairment, and behavioral testing reveals that the impairment is of such a magnitude that it has real-life consequences on learning and self-regulation. At this point in time, neither the levels of exposure that are necessary to induce prolonged changes in brain function in adolescents nor the potential moderating factors such as pre-drinking brain function and other co-occurring substance use are well characterized.

Although it appears that in adults a level of social drinking is not associated with persistent cognitive changes, it is well documented that as drinking increases (e.g., exceeds ~21 drinks/week) various kinds of neurobehavioral deficits, including poor visual-spatial coordination, abstracting performance, verbal associative memory, and verbal fluency, can be observed. Much of this loss in function (e.g., new word learning) can return with the mere passage of time if drinking is reduced or eliminated, but other functions require active retraining (e.g., visuospatial learning, abstraction, problem-solving). In the extreme, well-characterized dementias, such as Korsakoff's psychosis, can occur with prolonged, excessive drinking patterns in vulnerable individuals.

Beliefs and Expectancies

Alcohol expectancies are beliefs that people have about the effects of alcohol. These usually refer to what an individual thinks will be the effects of alcohol on him or herself as well as on others. Expectancies begin to develop in childhood, and grade-school children can differentiate alcoholic beverages from other types of beverages and can express the knowledge that individual behavior can change as a function of drinking. During childhood, most expectancies surrounding drinking are negative but early in the course of adolescence a tipping point is reached where increasing positive expectancies begin to outweigh the negative expectancies. These positive expectancies continue to strengthen during adolescence, but weaken a little in early adulthood. This pattern of change in positive expectancies is consistent with the typical course of drinking in the general population of many cultures; this also peaks during later adolescence and decreases in early and middle adulthood. Although different types of expectancies have been identified across different studies, expectancies about reduction in tension, positive mood enhancement, social and/or sexual facilitation, and enhanced cognitive or motor performance, as well as expectancies for negative effects such as behavioral impairment and adverse physical consequences, have been recurrently found in a number of studies.

The strength with which an individual holds these positive alcohol expectancies has been shown, both cross-sectionally and prospectively, to be strongly correlated with alcohol use (both initiation and level of use) and drinking problems. Such alcohol expectancies have also been found to predict treatment outcome among people in recovery for alcohol dependence.

While most expectancy research, to date, has focused on explicit expectancies (i.e., what someone tells us verbally about

the anticipated outcome of consumption), in the recent years, implicit expectancies, measured unobtrusively and independently of typical explicit expectancies, have also been found to be associated with alcohol use. For example, the Implicit Association Test (IAT) measures the differential associations of alcohol-related words and positive and negative adjectives. Scores in the IAT have been shown to have some incremental predictive power of alcohol use above and beyond the association of explicit measures of expectancies, thus highlighting the fact that these implicit cognitions tap those relevant alcohol-relevant motivations that are not easily captured by what the drinker can tell us explicitly.

Alcohol expectancies change over the course of the lifespan, probably because the experiences that people have when consuming alcohol can modify their beliefs about the consequences of drinking in the future. Some authors have also suggested that expectancies may act as a self-fulfilling prophecy. That is, the beliefs that an individual has about the effects of alcohol can make that individual more susceptible to experience those effects.

In order to understand the nature of alcohol effects, it is important to distinguish between the pharmacological effects of alcohol and the effects attributable to alcohol expectancies. In order to accomplish this, researchers have used the so-called balanced-placebo design (BPD). The BPD is an experimental design in which participants are assigned to four different conditions: (1) subjects in the 'alcohol' condition are told that they will drink alcohol and indeed they are given alcohol to drink; (2) subjects in the 'placebo' condition are told that they will drink alcohol but instead they are given a nonalcoholic beverage to drink; (3) subjects in the antiplacebo condition are told that they will drink a nonalcoholic beverage but are, instead, given alcohol to drink; and (4) subjects in the control condition are told that they will drink a nonalcoholic beverage and indeed that is what they are given. Although it is hard to successfully implement the BPD at high doses of alcohol (i.e., the deceptions in the placebo and antiplacebo are difficult to accomplish), the BPD has shown that, in some cases, the effects that people experience after drinking alcohol are not completely due to its pharmacological effects, but are due to the expectancies that they bring to a drinking occasion. That is, sometimes, subjects in the placebo condition exhibit effects that are at least as strong as those of the subjects in the alcohol condition (for a further discussion on this topic, please see sections on 'Aggression' and 'Sex' below). However, it is also important to point out that the expected and the pharmacological effects of alcohol can be in opposite directions. For example, in one study, men who believed that they had consumed alcohol while watching an erotic film showed an increase in sexual arousal (regardless of whether they actually received alcohol) while those who actually consumed alcohol showed a decrease in sexual arousal, regardless of whether they believed they had received alcohol or not. These experimental findings lend credence to Shakespeare's observation that alcohol "provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off." Whether or not the placebo effects are iso- or counterdirectional to an alcohol effect appears to be dependent upon a number of factors. When

counterdirectional, it is often viewed as unmasking a preparatory or compensatory adjustment to maintain homeostasis.

Personality Differences

More than 80 years ago, William McDougall conjectured that an extraverted personality was particularly susceptible to the effects of alcohol. Although this is consistent with clinical and anecdotal evidence, research on personality-based differences in alcohol sensitivity has been sparse. However, recent interest in the neuropharmacological basis of personality has provided a further rationale for these ideas by providing a neurobiological foundation to the association between personality type and alcohol sensitivity. That is, if alcohol affects the major neurotransmitter and hormonal systems that are thought to underlie variations in personality, then these individual differences in personality could reflect variation in the baseline functioning of these systems. This baseline functioning could determine, in part, the nature and extent of the effects of alcohol on these systems.

This line of research has shown that some specific personality traits are associated with a higher sensitivity to alcohol. For example, individuals who are high on the trait of impulsivity/disinhibition are more sensitive to the stress-reducing properties of alcohol. With respect to overt behavior, individuals who are high on trait hostility or low on empathy are more likely to exhibit aggression when intoxicated. This means that individual differences in alcohol effects are associated with individual personality differences.

Family History of Alcoholism

Research in the last decades has confirmed the long-standing clinical observation that AUDs tend to run in families, with individuals who report alcoholism in a first-degree relative being at 86% greater risk for alcohol dependence than those without a family history of alcoholism. This phenomenon has led to an increasing interest in the family history of alcoholism as a predictor of alcohol consumption and AUDs, as well as in the mechanisms through which this variable has an impact on alcohol use.

One potential explanatory mechanism for the effect of family history of alcoholism is its impact on the subjective response to alcohol. Specifically, researchers have considered the possibility that the acute effects of alcohol are different among children of alcoholics compared to children of nonalcoholics. The accumulated evidence shows that, on one hand, children of alcoholics are less sensitive to the subjective intoxicating effects of alcohol which may lead them to drink greater amounts of alcohol, while on the other hand, they are more sensitive to some other effects of alcohol, such as stress response dampening and hyperreactivity due to the stimulating properties of alcohol. Newlin and Thomson have hypothesized that differences in alcohol effects between the children of alcoholics and nonalcoholics can be resolved by considering the limb of the blood alcohol curve. Specifically, those with a family history of alcoholism may be more likely to experience an enhanced reinforcement from alcohol early in the course of

intoxication. Later in the drinking episode, when blood alcohol levels are decreasing, children of alcoholics seem to become less sensitive to the effects of alcohol, which in this phase of the blood alcohol curve, tend to be more punishing. This greater sensitivity to the reinforcing effects of alcohol, and decreased sensitivity to the negative effects of alcohol, could lead to greater amounts of consumption with relatively fewer aversive side effects.

Selected Important Acute and Chronic Effects of Alcohol

Aggression

Alcohol is known to reduce inhibitions and alter perceptions of risk. Epidemiological studies have found that alcohol use is associated with episodes of aggression and violence. For example, estimates on the percentage of homicides that have been preceded by alcohol use range from 7 to 85%. Although this range suggests a low reliability of the findings, most studies have found that 60% or more of homicides have been committed by individuals who had consumed alcohol prior to the offense. Also, 40–50% of violent crimes, and 30% of cases of intimate partner violence occur under the influence of alcohol, with greater alcohol use being associated with more severe violence. Moreover, some prospective studies have shown that alcohol problems, or alcohol-related disorders, predict subsequent aggression. However, increased aggression has also been found to predict alcohol problems in the future. With regard to the mechanisms that explain this strong association, studies using the BPD have, generally, found that the effects of alcohol on aggression are primarily due to the pharmacological effects of alcohol.

Although the facilitative effect of alcohol for the expression of aggression is strong, there are some factors that moderate this association. For example, although alcohol increases aggression in both men and women, the effect is much stronger in men and, often, can only be demonstrated if there is direct provocation and sufficient dosage. Other variables, such as personality traits, related to aggressivity and neurocognitive executive functioning appear to moderate the effect. Thus, although there is a clear strong association between alcohol and aggression, some of it is due to aggressive people tending to drink more. When there is a direct alcohol effect, it appears to be limited to certain individuals, drinking heavily, and under certain contexts (e.g., provocation).

Sexual Behavior

Alcohol use has been found to alter sexual behavior in both men and women. Moreover, the consumption of alcohol is associated with impairments in judgment and decision-making. Findings from studies using the BPD indicate that, at least at lower doses, the expectancies regarding the effects of alcohol on sexuality are more powerful than the pharmacological effects of alcohol. However, this effect has been consistently found only in men but not in women. Although these studies provide evidence for expectancy-based theories, there is also research that provides evidence for the alcohol myopia theory in the context of alcohol–sexual behavior association. Research has

shown that impelling (e.g., sexual arousal) or inhibiting (e.g., fear of contracting AIDS) cues can affect the likelihood of risky sexual behavior. That is, whereas sober individuals can weigh both the impelling and the inhibiting cues that are related to risky sexual behavior, the behavior of intoxicated participants reflects the more salient cues in their environment.

Across adolescent and adult samples, both homosexual and heterosexual, cross-sectional data show that those who drink more heavily are more likely to engage in risky sexual practices. Moreover, greater levels of alcohol consumption relate to an increase in the likelihood of contracting a sexually transmitted infection. However, methodological limitations, and the inherent difficulty of conducting research in this area, make causal inferences, regarding the role of alcohol in risky sex, extremely difficult. Furthermore, some event-based studies (i.e., studies focusing on one particular occasion of sex, such as the first or the last intercourse) have not been able to replicate this association and there is good reason to suspect that third variable explanations (e.g., sensation seeking or impulsive personality traits and situational factors) mediate much of this relation between alcohol consumption and high-risk sexual behaviors; although more recent studies have found consistency in the findings from between subjects and the event-based studies.

Recent studies suggest that certain individual and situational characteristics may increase the likelihood of engaging in risky sexual acts following drinking. Variables such as age (the association between alcohol and risky sexual behavior increases with age among men who have sex with men) and gender (rates of unprotected sex increase with number of drinks in men but not in women) or partner's level of alcohol consumption (when partner has also been drinking, the association between alcohol use and unprotected sex becomes stronger among women), and partner type (i.e., casual vs. steady; such that the use of a condom is less likely in women having sex with casual partners after drinking) may provide important information with regard to predicting, under what conditions and for whom there is, an association between risky sexual decisions and the consumption of alcohol on a given occasion.

Unintentional and Intentional Injuries

Alcohol consumption contributes to both intentional and unintentional alcohol-related injuries. Motor vehicle crashes are one of the most common forms of unintentional injury due to alcohol and have resulted in 11 773 deaths in 2008. Blood samples are positive for alcohol in approximately half of the traffic fatalities. Injury deaths account for 45% of all alcohol-related deaths each year, and, in addition to vehicular accidents, can occur as a result of falling, fires, sports activities, being cut, or overdosing. Findings from hospital studies suggest that each episode of alcohol consumption significantly increases one's short-term risk for injury, with a greater increase in risk for violence-related injury. Interestingly, people who typically drink the least have the greatest risk for injury after alcohol consumption.

Intentional injuries from alcohol consumption can be self-inflicted injuries, assaults, or homicides, with self-inflicted injuries being the most common. Alcohol-related homicides

are most likely to occur with the presence of firearms (stabbing and strangling may be just as common but are less likely to result in death). Motivations behind these intentional injuries can be understood through the effect of alcohol on aggression, lowered inhibitions, or low mood. As noted repeatedly, individual differences such as drinking context, peers, drinking pattern, and baseline mood have a large impact on the subsequent effects of alcohol, making the alcohol-injury association highly conditional upon multiple cofactors.

Coping/Stress Reduction

The concept of people drinking to cope with negative emotions is clearly connected to the concept of self-medication. Extensive research on drinking motivations has demonstrated that in addition to enhancement (i.e., drinking to have fun), another common reason to consume alcohol is to reduce or manage dysphoria (i.e., drinking to cope with negative emotions). Many people consume alcohol when they are anxious or overly aroused, with the belief or expectation that the alcohol will reduce their stress levels. Though alcohol is not uniformly stress-reducing across people and situations, people who are strongly motivated to drink, on a regular basis, for coping, have been found to drink larger quantities of alcohol, to drink more frequently, and experience more negative consequences as a result of drinking than those who do not use alcohol to cope; perhaps because they are more likely to drink at inappropriate times or when negative consequences are more likely to result – like before work or during an emotionally vulnerable period. One explanation for people who frequently use alcohol as a means of regulating negative emotions is that they lack other ways of effectively coping with stress.

Human Capital Accrual

Because alcohol can cause role and cognitive impairment and because excessive and problematic alcohol use are most prevalent during adolescence and young adulthood, when schooling is a primary role, the effect of alcohol on human capital accrual is an important issue. That is, to the extent that alcohol interferes with learning and schooling, the effects of alcohol are likely to be long lasting since the human capital that accrues during this period of life plays a large role in determining the economic well being of the individual over his/her life span. When studying the effect of alcohol misuse on educational and occupational attainment, it is important for researchers to look at other potential explanatory variables like general deviance and a family history of alcoholism, as these could clearly be highly related to both the above outcomes (alcohol abuse and poor academic or job performance). Studies that have accounted for these factors have found that, while alcohol abuse in late adolescence does have a modest association with academic and vocational achievement, this association is partly attributable to background variables such as family history, gender, parental education, and previous (early) academic achievement. Also, individuals who have a history of good academic performance (in high school, for example) are most likely to experience negative academic consequences as a result of excessive alcohol abuse (in college). Regarding occupational attainment, research suggests that only those with the most extreme alcohol problems

(early in their career) experience negative impacts in this area. Thus, alcohol misuse can have a negative effect on educational and occupational attainment but the relationship is not particularly strong when other characteristics of the drinker are taken into account. Indeed, there is some evidence that alcohol use, in general, is associated with good educational attainment, probably because it facilitates engagement during college among those who attend, which result in higher rates of degree attainment. Alcohol use appears to be most problematic with respect to educational and vocational achievement when use is early, excessive, and persistent.

Summary

Throughout much of the world, alcohol is a frequently used drug that has been integrated into many aspects of social life but also has a range of effects on health. As a drug, its effects are highly variable, both acutely and chronically, and this variability is due to many factors that relate to the way in which the drug is used, such as individual differences among drinkers, and the context in which it is used.

Alexithymia

V Panaite and L M Bylsma, University of South Florida, Tampa, FL, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Alexithymia Inability to describe emotions in a verbal manner.

Construct An abstract collection of ideas that serves as an explanatory concept.

Dysphoria A negative mood state characterized by prolonged bouts of sadness.

Emotion regulation The process through which emotional arousal is redirected, controlled, or modified to facilitate functioning.

Empirical Controlled observation and measurement.

Validity Refers to the extent to which what was observed is the same as what was claimed to be observed.

History

The alexithymia construct has a history that goes back about 40 years. The term alexithymia came from the Greek phrase *a lexis thymos*, which literally means having no words for emotions; the term, however, was initially used in its current form by Sifneos, a psychoanalyst who coined it in 1973. Some of the early insights we have about alexithymia came from observations made by clinicians in the late 1940s, such as Ruesch and MacLean, who described patients struggling to express emotions; these patients seemed to channel their feelings inward rather than outward through expressive behavior.

Following these initial descriptions, additional reports of patients with alexithymia, who were unresponsive to psychoanalysis, became known. Psychoanalysts Horney and Kelman described their patients as having a limited internal emotional activity, including a decreased awareness of feelings, lack of emotional experience, and what seemed like a lack of creativity and openness. *La pensee operateire* (or operational thinking) was the next step in conceptualizing alexithymia. Marty, deM'Uzan, and David described patients with psychosomatic illnesses who, while being treated with psychoanalysis, were less aware of their inner worlds and more preoccupied with their physical experiences.

The information that surfaced over time from these observations became significant once Sifneos and Nemiah's systematic investigations and descriptions of patients with psychosomatic illnesses culminated in alexithymia becoming a formalized construct. Specifically, they described patients with alexithymia as having a 'marked difficulty describing subjective feelings and a communicative style characterized by a preoccupation with minute details of external events and a paucity or absence of drive related fantasies' (p. 28).

Much of the initial evidence for the construct of alexithymia came from observations of patients with psychosomatic illnesses. Continuing this trend, Krystal and Raskin and Brusch reported characteristics similar to those described earlier in patients with other psychiatric illnesses, such as posttraumatic disorders and anorexia nervosa. Ever since, considerable research has been conducted, bringing support for this construct. The operational definition of the alexithymia construct has changed little over the years (e.g., *La pensee operateire* is now maintained under the facet of externally oriented thinking),

although the perspective from which we describe this construct has moved from one of a psychodynamic nature to a view focused on interconnections between alexithymia and both physical and mental health. The development of scales and of studies looking at the relationship between alexithymia and other constructs has afforded a more in-depth understanding of this concept. This has brought about the development of theoretical subtypes of alexithymia, as well as a clearer perspective on its relationship with both physical and psychological health.

Measurement of Alexithymia

The field of alexithymia measurement had been initially concerned with validation of the construct alexithymia itself. In this process, several measures were developed and investigated. Available measures for alexithymia vary widely in their presentation and focus. While historically this area focused on projective techniques, such as TAT, Rorschach, or the Objectively Scored Archetypal Test, such instruments have become obsolete with the development of other scales for measuring alexithymia.

More recently, a new self-report scale, the Toronto Alexithymia Scale (TAS), and its revised version, the 20-item Toronto Alexithymia Scale (TAS-20), have brought support for the alexithymia construct with a more robust psychometric profile. TAS-20 is the latest version of the scale, and it has been shown to have good internal consistency and test-retest reliability. Factor analytic investigations brought up the three factors supporting the alexithymia construct: (1) difficulty in identifying feelings, (2) difficulty in verbalizing emotions, and (3) externally oriented cognitions.

Haviland and colleagues developed the Observer Alexithymia Scale (OAS). The 33-item scale was designed for observers (e.g., family, friends) to report on the alexithymia features of a patient. The items can be divided into five subscales: distant, uninsightful, somatizing, humorless, and rigid. The scale and its subscales have been psychometrically investigated and good reliability and validity were found for clinical and nonclinical populations. The scale was also found to be a useful tool in differentiating between people with clinical and nonclinical levels of alexithymia.

One measure, Levels of Emotional Awareness Scale (LEAS), was proposed as a valid measure of level of emotional awareness. Although not specifically created to measure alexithymia, it was proposed by Lane and colleagues as an alternative conceptualization of alexithymia – a topic developed in more detail below. Unlike the previously presented measures, LEAS uses descriptions of emotion-evoking situations to which subjects are asked to respond by describing emotional reactions from both personal and other perspectives. LEAS has empirical support for good internal consistency and inter-rater reliability.

One of the most recent self-report measures was developed by Vorst and Bermond: the 40-item Bermond–Vorst Alexithymia Questionnaire (BVAQ). In the scale development, alexithymia was conceptualized as having five facets. Using the original TAS scale as a model, the five factors of the BVAQ are emotionalizing, or the incapacity to experience emotions; fantasizing, or having a poor fantasy world; identifying/differentiating emotions; analyzing or showing low levels of emotional analysis; and verbalizing emotions. Validity and reliability were investigated initially through two studies using samples from three different countries. Convergent validity was established by showing correlations between BVAQ and TAS-20.

Related Constructs

Although alexithymia has been conceptualized as a distinct construct, its independence has been questioned. Several other constructs have been proposed as potentially overlapping with alexithymia. This has raised the question of whether alexithymia is a unique construct or whether it can be fully explained by combinations of other existing constructs.

Given alexithymia's conceptualization as a personality trait, its relationship with other personality traits, particularly neuroticism, extraversion, and openness, has been investigated. While positive correlations between alexithymia and neuroticism and a negative correlation with extraversion and openness were indicative of the relationship between all these traits, important differences also surfaced. For example, the ease of emotional expressivity of introverts given their introspective nature is not common to people high in alexithymia. This feature sets introverts and alexithymics apart given the difficulty with which people with alexithymia express emotion. In a similar vein, neuroticism is connected to strong emotionality, which is one of the core deficits in alexithymia; low scores on openness related to externally oriented thinking and low levels of openness to feelings in alexithymia.

Other constructs that have been proposed are repressive coping style, inhibition, and big five personality dimensions. Bonnano and Singer originally proposed that alexithymia may be part of or connected to the repressive coping style identified by defensiveness. Despite defensiveness being in line with the emotional dysregulation found in people with alexithymia, their relationship was not detected by subsequent research. King found that inhibition and alexithymia are positively correlated, although while the former entails control, the latter is primarily conceptualized as a deficiency. Luminet and colleagues also supported the proposition that alexithymia may be

related to other personality traits. However, while alexithymia was related to a certain degree to traits such as proneness to depression and negatively related to other traits such as proneness to positive emotions or openness to feelings, it was not entirely represented by one trait and so, finally, investigators concluded that the construct of alexithymia is distinguishable from these other traits.

Constructs that have raised further questions about alexithymia's independence are somatization, dysphoria, and depression. Somatization and, more specifically, somatosensory amplification – the tendency to focus on bodily responses to emotional stimuli – have been associated with alexithymic individuals. However, somatization does not account for all the clinical facets that create alexithymia. Both somatization and dysphoria have been conceptualized as potential outcomes of emotional dysregulation. High correlations between depression and alexithymia have raised questions about the latter being a part of depression. Although, as noted earlier, while depression may exacerbate alexithymia traits, alexithymia tends to remain stable even once depression subsides. In addition, Parker and colleagues found that by factor analyzing the Beck Depression Inventory (BDI) and TAS together, they loaded on separate orthogonal factors, further supporting the independence of the constructs of depression and alexithymia.

Asperger's and Autism spectrum disorders more recently have gained general interest and have come to alexithymia researchers' attention, given the similarities in the lack of emotional expressivity between these constructs. However, empirical work directly examining the relationship between the two is still sparse. A letter to the editor makes a compelling argument for the importance of investigating these constructs in connection with alexithymia given extensive similarities. The authors talk about similarities in the lack of social interest exhibited by people with either of these disorders. People with alexithymia and Asperger's show a lack of interest and pleasure from interacting with others, and interactions are generally detached. Another central similarity noted by the authors is the poor emotional understanding and functioning, among others. However, research investigating similarities between these constructs has yet to fully develop, although strides are being made in this direction.

Looking at the relationship between alexithymia and other constructs has been an important part in the process of validating alexithymia as a distinct construct. While clinical and empirical evidence points to the similarity and some overlap between alexithymia and other personality traits (i.e., neuroticism) and mental disorders (i.e., depression), the body of work that exists to date has provided the basis to speak of alexithymia as a distinct construct.

Cognitive Aspects

One core characteristic of alexithymia is the difficulty in identifying and describing one's feelings. Lane and Schwartz created a cognitive development model for emotion on the basis of Piaget's theories of cognitive development. They proposed that this ability to identify and describe feelings develops over time just as cognition does. The cognitive development model as applied to emotion has five stages of emotional

experience, starting with physical sensations, action tendencies, single emotions, blends of emotion, and blends of emotional experience. Additionally, the level of emotional development also depends on what and how much people know about emotions.

Research shows that people who score high in alexithymia not only have difficulty in verbal and nonverbal emotion recognition but also show impaired recognition of facial expressions. Cognitive deficits in alexithymia have also been proposed to potentially be adaptive, to the extent that people capable of a complex cognitive understanding of emotions also being more likely to potentially be more impacted by extreme emotional experiences (i.e., traumatic experiences). Given that alexithymia has often been observed in people with mental or physical illnesses that are likely to be associated with increased emotional distress, such a trait can be protective in the short term, although marked deficits in emotional processing most often have been shown to lead to protracted anhedonia and apathy.

Physiological Aspects

As alluded to earlier, the relationship between alexithymia and psychosomatic disorders has a long history with a considerable amount of literature supporting it. An important subsection of this research has focused on aspects of physiology in people who have high alexithymia scores. It has been proposed that alexithymia is related to a higher baseline arousal. This was viewed as a dysregulation of the autonomic nervous system and system linked to pervasive dysphoria in people high in alexithymia and various other mental and physical disorders. Anxiety disorders, such as panic disorder and posttraumatic stress disorder (PTSD), depression and personality disorders, eating and substance abuse disorders, coronary heart disease, diabetes mellitus, and hypertension, all have been seen as related to the deleterious effect of a prolonged state of arousal.

Initially, people high in alexithymia were also thought to experience higher reactivity to emotional stimuli compared to healthy people. Three different theories have been proposed to explain the increased physiological arousal in response to emotional stimuli: Papciak and colleagues' decoupling hypothesis, Martin and Pihl's stress hypothesis, and Cacioppo and colleagues' discharge theory. The decoupling hypothesis proposes that in people high in alexithymia there is a disconnect between emotional experience and physiological automatic response when exposed to stress that results in high somatic response but lack of emotional expression. The stress hypothesis proposes that through the inability of alexithymic people to identify emotion and emotionally charged stimuli, they are also unable to identify stressful situations and, therefore, are not signaled to engage adaptive emotional regulatory tactics, leaving them vulnerable to experience more stressors, or more prolonged stress. Discharge theory views emotional expression as the outward channeling of energy. Alexithymia is characterized by an inward emotional expression through increased activation of the nervous system, given the deficit of individuals high in alexithymia to direct expression of emotion outward through speech or emotional behavior.

More recently, in contrast to previous theories, Linden and colleagues proposed the hypoarousal theory, which suggests that people high in the alexithymia trait will react less to emotional stimuli than other individuals. Evidence for the physiological aspects of alexithymia is still equivocal, although more recent studies have found more considerable support for the theory that people with alexithymia experience low physiological arousal to emotional stimuli. This is perhaps a direct result of decreased awareness of emotions in people high in alexithymia.

Neurological Aspects

Alexithymia is primarily conceptualized as a personality trait, and personality theories emphasize genetic attributes as important contributors to personality development. Research and theory have proposed neural mechanisms as propellers of what constitutes personality. In explaining alexithymia, two main views have crystallized to date, although much is left unknown about this area. One view proposes that alexithymia is a result of poor communication between the left and right hemispheres of the brain. This view is supported by a body of research in split-brain patients. What investigators have found is that such patients exhibit traits similar to those that describe people high in alexithymia: difficulty in recognizing and describing emotions. This view has also been investigated among patients whose brains were intact, by looking at the efficiency or deficit in interhemispheric communication. It was observed that while the transfer of linguistic information was similar among alexithymic and normal individuals, the two differed in the processing of nonlinguistic information, those high in alexithymia showing a deficit in interhemispheric communication. This is meaningful in interpreting the lack of recognition of emotional faces in people high in alexithymia.

Another view proposes that the difficulty in emotional processing experienced by people with alexithymia is due primarily to a dysfunction in the right hemisphere of the brain. This view has been supported by observations of patients with damage to this part of the brain. The right hemisphere has been found to have a role in information processing about emotion of facial expression. This observation has often been documented in people with depression, for example, who have similar difficulties with emotional recognition, which potentially points at one explanation for the relationship between depression and alexithymia. But the role of emotional processing by the right hemisphere goes beyond that of recognition of facial expression, to facilitating information processing of other stimuli with an emotional characteristic. Without a capacity to process different emotional stimuli, a poverty in experience with emotion often occurs.

Two specific areas of the brain that have been theoretically and empirically connected to emotional processing are the amygdala and the hippocampus, both of which have been investigated using diverse methods (i.e., fMRI, PET, EEG). The amygdala has been primarily connected to giving emotional meaning to different sensory information, thus helping individuals integrate experience and memories with an emotional value. The amygdala has also been connected

to emotional behaviors, such as facial expressions. All of these pieces seem to be interconnected in that individuals' experience of an event is determined by the emotional valence attributed to the event, which may depend on the emotional behavioral experience. The hippocampus, on the other hand, has an important role not only in emotional processing, but also in memory, which may be important in creating the emotional schemata that individuals use in expediting information processing. It becomes apparent that a dysfunction in either of these areas can impact the emotional development outlined in Lane and Schwartz's model.

The findings of these different studies attest to the complexity and breadth of alexithymia. The studies looking at the potentially poor interhemispheric communication bring support for the lack of verbal recognition and expression of emotion. Poor emotional experience of people high in alexithymia is mirrored by dysfunction in the right hemisphere and the amygdala corresponds to a low behavioral emotional expressiveness. The hippocampus was connected to emotional memories that may connect further to a poor fantasy world in people with alexithymia.

Alexithymia and Emotional Expression/Regulation

Given that alexithymia has been conceptualized as involving deficits in emotion recognition and expression, one line of research that has looked at emotional expression in alexithymia has been research on crying behavior. Crying, like other emotional behaviors, is sparse among people with alexithymia, possibly due to an unpleasant arousal during crying. Rottenberg and colleagues also found a connection between alexithymia and increased negative affectivity after a crying episode, potentially further supporting the lack of emotional recognition as well as identification of potential roots to the negative affect among people high in alexithymia.

As a consequence of the decreased ability to express and recognize one's emotions, emotion regulation is a major problem in people high in alexithymia. Unable to recognize their emotions, they often mislabel physical symptoms as illness rather than emotional responses to stimuli. Individuals with alexithymia are rarely able to intervene and regulate these emotions. Additionally, people high in alexithymia traits are poor evaluators of others' emotions and so, rarely offer empathic support that would in turn create the social support often employed in adaptive emotion regulation. Alexithymia has also been connected to compulsive behaviors, such as binge eating and drinking, or starvation in anorexia nervosa, all potential indicators of dysfunctional regulatory attempts.

An inability to recognize emotions among people high in alexithymia can potentially interfere with the identification of the source of emotions for adequate problem solving and downregulation of negative emotions. Consequently, people with alexithymia may be prone to experiencing more negative emotion and protracted dysphoria may interfere with the experiencing of positive emotions. Poor emotional processing interferes, not only with personal experience, but also with interpersonal affective exchanges that may lead to poor social experiences.

Alexithymia and Physical Health

A significant body of literature on alexithymia proposes and supports its connections to physical health. Lumley and colleagues wrote a critical review of the literature where they established a model of the connections between physical health and alexithymia. One of the proposed links is that alexithymia is an antecedent to somatic illnesses. Lumley proposes two potential mechanisms by which alexithymia may cause physical illnesses: through physiological changes and unhealthy behaviors. Empirical studies have found thus far that alexithymia is related to a low immune function and, consequently, connected to diseases with an immune component, such as precancerous deficits. There also seems to be a connection between cardiac activity and alexithymia. People with alexithymia have been found to have an increased resting physiological arousal, although high reactivity to stressors has yet to be found. On the contrary, attenuated reactivity as shown by a low RSA fluctuation has been seen in people with alexithymia. A low immune function, high resting arousal, and low reactivity can impact physical health by creating vulnerability for somatic disease. People high in alexithymia have also been found to engage in a variety of unhealthy behaviors, such as unhealthy eating, smoking, drinking, drug abuse, and gambling as well as unhealthy nutrition and lifestyle in general.

According to Lumley and colleagues, 'illness behavior,' which was conceptualized as somatization and health care seeking, is another pathway between alexithymia and physical illness. Research studies have found a relationship between alexithymia and symptom endorsement, without any objective evidence for illness that would warrant the experience of those symptoms. So, in short, alexithymia seems to be connected to the subjective experience of illness-like symptoms, but not to the objective illness. It seems likely that this subjective experience of different symptomatology prompts people with alexithymia to become more engaged in seeking health care services, which is what some empirical studies have shown. Interestingly, however, this finding seemed to be highly dependent on the specific facet of alexithymia for which an individual is elevated. So, Lumley concludes that, at least given what we know now, people with alexithymia who have difficulty in identifying and describing emotions, rather than those highly externally oriented, may have a higher awareness of their bodies and be more likely to identify and seek help on the basis of subjective experiences of illness.

Another proposed pathway between alexithymia and physical illness that Lumley and colleagues identify in their model is physical illness as an antecedent of alexithymia or, as they call it, 'secondary alexithymia.' In support of this possibility, the authors present empirical evidence from literature primarily on stress and trauma that have been shown to result in outcomes similar to qualities of alexithymia. However, the authors recognize that given the strong evidence for alexithymia being a stable trait, it is more plausible that it is an antecedent. Although, given the scarcity of this literature, it is plausible that 'secondary alexithymia' is in the realm of possibilities and this area would benefit from longitudinal studies following healthy people at risk for future trauma or stress (e.g., soldiers).

One last arm proposed by Lumley and colleagues in the model connecting alexithymia and physical illness introduces a third factor as the connecting antecedent of the two. While there is some literature, primarily on depression and other negative affect constructs, the overall status of the evidence currently is that the 'third variable' pathway is not supported. It is possible that with further studies examining genetic and temperamental third variables, they may surface as potential connectors between alexithymia and physical illness.

In conclusion, while there is literature supporting the different proposed pathways, the bottom line is that much of the literature on alexithymia and physical health seems to be mostly based on cross-sectional and correlational studies. While this evidence is an adequate start up point, further investigation using more complex models would be warranted to further the state of this area.

Alexithymia and Mental Health

It is often the case that extreme or chronic stress and trauma result in mental and emotional disorders that are characterized by deficits in affect regulation, and hence have been identified with alexithymia. Two areas relevant to alexithymia that have received extensive attention and empirical support are anxiety and mood disorders. The symptoms associated with these disorders have been conceptualized as potentially adaptive in normative samples in the form of signals of a negative event that is either about to happen (i.e., anxiety-like symptoms) or that has happened (i.e., sadness due to loss). At clinical levels, these symptoms often indicate a dysregulation of affect due to an overwhelming overpowering by emotions resulting from extreme or traumatic events.

Anxiety disorders that have been particularly viewed as portraying a profound deficiency in emotion regulation are panic disorder and PTSD. In people with panic disorder, the focus on bodily sensations and symptoms becomes excessive as they become tuned in with these feelings in an attempt to recognize when the next attack will happen. Because of this high focus on physical arousal and low capability to cognitively regulate these feelings, alexithymia is highly prevalent among people with panic disorder. Similarly, there is considerable overlap between the presentation of PTSD and alexithymia, including rich evidence for a relationship between alexithymia and childhood abuse or adult trauma. Moorman and colleagues developed the Reality Escape Model to explain, among others, the role of alexithymia in victims of childhood sexual abuse: the manifestation of a 'nonfeeling state that is so characteristic of traumatized individuals' (p. 82). In this model, it is thought that alexithymia victims of sexual abuse are able to switch off negative feelings and emotions that are too unbearable to deal with in order to cope with the traumatic events that often are a repeat offense. Unfortunately, as the authors note, the impact of such a manner to 'regulate' emotions is farther reaching, potentially affecting multiple areas and resulting in a generalized state of anhedonia that has been connected back to alexithymia. Abuse in childhood, according to these authors, is particularly deleterious and likely to be connected to alexithymia due to its timing in a period

during development when personality formation may be most vulnerable. Interestingly enough, alexithymia in adults who have experienced childhood sexual abuse seems to be of a certain kind: experientially, they seem to be unharmed, but cognitively they are incapable of recognizing and accepting emotions, making these adults good candidates and potentially rather responsive to cognitive interventions.

The connection between depression and alexithymia is less obvious, given that depression is often conceptualized as a disorder of mood, characterized by intense feelings of sadness, guilt, and excessive ruminative negative cognitions. However, these symptoms are not necessary for a diagnosis of depression. In western cultures, for example, a depression that has marked anhedonia as the primary symptom is clinically recognized. In non-Western cultures, a focus on negative affectivity is not the norm. Somatic symptoms rather form the construct of depression in these cultures and are often mislabeled and missed altogether, especially when somatization is coupled with a culturally encouraged lack of emotional expression. Both anhedonia and somatization have been connected to alexithymia and draw the link between alexithymia and depression.

A substantial body of research has also been developed on the relationship between alexithymia and substance abuse, also characterized by emotional dysregulation. Empirical studies have shown that about 50% of people with clinical levels of substance abuse (primarily alcoholism) score in the clinical range of alexithymia scale. It has been proposed that the primary link between alexithymia and substance abuse disorders is emotional dysregulation. Studies have shown alexithymia to be a stable trait in alcoholics; however, longitudinal studies with younger populations have been proposed to further support this contention. Given that many alcoholics have battled their condition for long periods of time, this may have enabled changes in personality and physiology that are similar to those observed in people with alexithymia.

Another area of psychopathology that has been related to alexithymia is eating disorders, also through a deficit in emotion regulation. An additional aspect that links alexithymia to eating disorders is a difficulty in people with various eating disorders to identify or recognize bodily signals (e.g., those that would signal hunger) and the difficulty to recognize emotions in people with alexithymia. Empirical studies have shown that these two deficiencies correlate closely, and that about 50–60% of people identified as having an eating disorder will also meet the criteria for alexithymia. Similar to other psychopathologies, alexithymia was found to be a stable trait in people with eating disorders, although alternative explanations have been proposed for this finding, such as comorbid psychopathology and continuation of subclinical levels of the eating disorders.

Treatment

Historically, given the initial popularity of psychodynamic therapy, it was the treatment of choice when the first patients with alexithymia were observed and described by clinicians such as Sifneos and Nemiah. However, it was observed that such therapies were not adequate given the reliance on free

verbalization of emotions and internal processes, which go counter to what has been observed in people with alexithymia. Alternative treatment recommendations, in the past, have included therapies focused on support. Other therapies that were considered to be more efficacious were therapies that would focus on teaching *how* to communicate emotions rather than *what* should be communicated.

Many therapies for people with alexithymia are mainly educational in nature, teaching these patients skills such as relaxation techniques to help regulate emotions that are often mislabeled as physical symptoms. Although most therapies for alexithymia target bodily sensations and emotion identification, they also incorporate cognitive behavioral techniques meant to help attend to physiological symptoms and understand them from an emotional and cognitive perspective. Additionally, teaching patients that physical symptoms are time limited has also been successful in helping people with alexithymia. Another psychoeducational technique was developed by Ronald Levant for the treatment of what he called 'normative male alexithymia' to help men express their emotions verbally.

Despite showing a deficit in cognitive and affective understanding of emotions, alexithymia was found to have positive effects on treatment outcomes in cognitive behavioral therapies. The reasoning offered was that people high in alexithymia are more inclined to use specific cognitive styles to manipulate information. Consequently, therapies that target these skills and put less emphasis on affect recognition and expression would better fit these individuals.

Group therapy has been proposed as an option for treating patients with alexithymia, as it affords interaction with other people and direct observation of emotional expression. It is important to note that people with alexithymia are less emotionally responsive and so may provide little emotional support to those in a group therapy. Empirically, group therapy has been evaluated in people suffering from a physical illness (e.g., heart disease) who were also high in alexithymia. Group therapy, in this context, was found to be beneficial in lowering both TAS scores as well as experience of a variety of cardiac events. Given the connection between alexithymia and physical health, it is difficult to disentangle the impact one outcome can have on the other; however, it is hoped that group therapy will be a viable option for people with alexithymia. The group setting affords observation of emotional expression as well as room to practice emotional expression with other peers. It is also important to note that improvements in physical health in conjunction with decreases in TAS scores further reinforce the connection between alexithymia and physical illness.

Despite the use of pharmacotherapy for the treatment of emotion regulation dysfunction in many disorders, psychotropic medications have not been evaluated in patients with alexithymia. However, some studies have looked at the impact of alexithymia on antidepressant treatment of depressed patients showing that alexithymia was related to negative outcomes of treatment. It is, however, possible that people with alexithymia did not experience an increase in adaptive emotional regulatory behaviors with the decrease in low mood, as people without alexithymia may experience with treatment for depression.

Although treatment has not been a focus of research in alexithymia, what has been done so far showed overall encouraging outcomes: CBT and group therapy, in particular, seem to have shown substantial impact in patients with alexithymia, especially in areas that can potentially be life threatening, such as cardiovascular disease. Although the importance of research on treatment for people with alexithymia has been acknowledged and commenced, a long road is still ahead of us in this domain and further attention needs to be directed toward finding empirically supported interventions.

Controversial Issues

Alexithymia Types

There is a limited body of research that has proposed and supported the suggestion that there are two distinct types of alexithymia. Type 1 is considered alexithymia characterized by poor affective and cognitive emotional experience and it presents with distinctive behavioral patterns that set it apart from healthy typologies of behavior. One core aspect of type 1 alexithymia relates to social interaction. People with this type of alexithymia are aversive to what they may perceive as forced social interactions and intrusive social behaviors of others. Some have described this pattern of behaviors as a fear of enmeshment, when one's identity becomes intertwined with that of another, making it indistinct on its own. This becomes particularly meaningful for both treatment and understanding of further ramifications of this trait, as people with this type of alexithymia will not rely on social support as a coping mechanism. Type 1 describes the prototypical person with alexithymia.

Type 2 alexithymia is considered a lower level alexithymia: while it is characterized by a similar deficiency in cognitive emotional awareness as type 1, the emotional experience is present. People with this trait have a low sense of self and, while also retracted from social engagement, it is primarily because of a sense of social inadequacy and insecurity, where feelings of failure are predominant. Although through a different underlying mechanism, just like those with type 1 alexithymia, people with the type 2 trait exhibit similarly poor social coping skills that revolve around abandonment fears and attempts at avoiding it. Type 2 alexithymia has been proposed to primarily identify victims of sexual abuse.

The description of these types of alexithymia affords a look at the full range of characteristics of people high in alexithymia. It becomes clear that social engagement is possibly central in learning emotional coping and emotional understanding, both of which are core aspects that are missing in alexithymia. However, this area is still controversial given that research on the different types has been limited to certain populations. Further research may be needed for the generalization of these traits.

Trait Versus State Alexithymia

Alexithymia has been proposed as a personality dimension, and validation of the construct comes through the work of Taylor and colleagues on the TAS and TAS-20. Both of these scales have been validated by examining their relationships with scales that would tap into deficits observed among people

with alexithymia (e.g., access to one's feelings). Concomitantly, there are studies that support the idea that alexithymia could also be a state reaction to different mental and physical conditions. Longitudinal studies have looked at the stability of alexithymia in the context of different levels of stress. Overall, these studies supported the trait view by demonstrating the long-term stability of alexithymia, thus supporting Taylor's conceptualization of alexithymia as a stable personality trait. In contrast, studies on clinical populations have suggested that when connected to psychopathology, alexithymia is viewed as state dependent, or as an outcome of the experienced vulnerability during stressful situations that subsides with the alleviation of symptoms.

To reconcile these two views, it was proposed that when speaking of personality traits a distinction between relative and absolute stability is warranted. *Absolute stability* is reached if people with alexithymia score the same on an alexithymia scale over time. *Relative stability* refers to temporal stability or people's relative position on levels of alexithymia, even though their absolute score may change. Similar trends are seen in other personality dimensions such as neuroticism and extraversion. Saarijärvi and colleagues offer empirical support for the idea that the two views don't have to be mutually exclusive, but that they can complement each other for a more complex understanding of alexithymia. In their study, while alexithymia scores decreased as depression decreased, overall, subjects remained high in this trait even after reduction of depression. In conclusion, a temporary increase in negative affect may exacerbate alexithymia traits, but this change was not found to explain the entire trait in any given person; hence, those scoring high on alexithymia most likely possess this trait.

Future Directions

Despite the great advancements that have been made in the past three decades in particular, a great deal is still to be investigated and understood about alexithymia. One particular area of research that has not reached a consensus despite great advancements in measurement of alexithymia and research methods in general is emotional reactivity and expressivity in individuals with alexithymia. In spite of the most recent research bringing further support for the hypoarousal theory of alexithymia, the results are still tentative and further research is needed. Emotional expression research has to continue to reach a better understanding of reasons for people high in alexithymia not to experience the benefit of expressing emotional behaviors, like crying. Additional inquiry is needed in the area of treatment for people with alexithymia, as the limited research that has been done indicates that certain types of interventions can be beneficial. Furthermore, while investigators have started posing questions about the overlap or connection between alexithymia and constructs such as Asperger's and Autism spectrum disorders, this area is still in its infancy and considerable work is warranted. Finally, additional empirical inquiry is needed to bring further support to some of the propositions that are still controversial in alexithymia research. For example, longitudinal studies on samples of youth at risk to develop alexithymia could potentially bring further clarification to the state-trait debate.

Summary

Alexithymia as a personality trait has developed rapidly and has attracted interest in areas as diverse as personality and neurobiology, health psychology, and clinical psychology, which have brought support for this construct with diverse, yet specific research agendas. Since the first reports of clinical observations, empirical evidence has added support to this construct. Notable advancements have been made in measurement, with the goal of having a valid and reliable measure of alexithymia having been reached with scales such as the TAS-20 or the BVAQ, among others. Neurobiology has found specific brain structures that are related to alexithymia and that changes in these structures could interfere with this personality trait. Great advancements have been made in understanding connections between alexithymia and both physical and mental health, and consequently how it may impact treatment strides. In spite of all the knowledge that has accumulated about alexithymia over the past 4 decades, areas such as emotional regulation and expression, or types of alexithymia, need further empirical inquiry.

Glossary

Altruistic helping Helping behavior motivated by concern for the person in distress; selfless helping.

Egoistic helping Helping behavior motivated by concern for the benefits and costs to the helper; selfish helping.

Helping behavior Actions intended to assist another person with a problem or to relieve distress.

Prosocial behavior Positive forms of behavior, including helpfulness; the concept stands in contrast to antisocial behavior.

HELPING BEHAVIORS are activities where people provide assistance in solving the problems of other people. In this article, we review the characteristic forms of helping behaviors, a continuum that begins from spontaneous help which is often given in emergencies, to episodic help such as blood donation, and finally to long-term help which is typically provided by volunteers working for nonprofit organizations. Along the way, we examine the research that has focused on the thoughts, feelings, and behaviors of those involved in helping. We then describe a process model that focuses broadly on the antecedents, experiences, and consequences of helping. Among the many personal and situational influences on helping, we discuss its motivational underpinnings. For example, altruism designates a case where the assistance being provided is motivated by concern for the other person, whereas assistance motivated by concern for self is regarded as egoistic. We maintain a consistent emphasis on the situational and interpersonal contexts that surround any act of helping and contribute to its form and efficacy. Lastly, we examine the consequences of helping with respect to the recipients and the helpers, as well as for the larger community and society.

Forms of Helping

Whereas human beings are clearly capable of extreme cruelty and violence toward others, they are also capable of displaying extraordinary acts of kindness, generosity, and sacrifice on behalf of their fellow human beings. Amidst the horrors of Nazi-dominated Europe were cases of the Gentiles rescuing and hiding the Jewish victims of the Final Solution. In the southern United States, during the 1950s and 1960s, white participants in the civil rights movement were working actively with black participants in political organizing and voter registration. These dramatic acts of helpfulness may well be infrequent occurrences, yet many smaller and more ordinary acts occur with great regularity. During the course of our everyday lives, we can assist others with disabled vehicles or dropped articles, give directions or loose change, to name but a few opportunities. In addition to these brief help-giving encounters, people help on a sustained basis, oftentimes in the form of volunteer work. We find, for example, people providing companionship to young people or the elderly, counseling those who are psychologically distressed, and tutoring illiterate

adults or disadvantaged children. Moreover, national surveys have found that approximately half of all American adults reported having performed some kind of volunteer activity in the previous 12 months.

Clearly, prosocial activities are widespread and include a broad range of actions. One attempt to uncover the differences among this wide assortment of helpful acts applied statistical procedures to helping behaviors, utilized as dependent measures in research, and found helping situations to vary along three dimensions. [Table 1](#) presents helpful actions that are representative of the combination of the three dimensions.

The first dimension looks at whether the helper *directly* provides help or *indirectly* helps the person in need by providing a resource that can be used to alleviate the need. The second dimension is whether the helping situation arises *unexpectedly*, with the helper being surprised by the need for help (e.g., emergencies), or is *planned*, with the helper deliberating before acting and, perhaps, even seeking out the opportunity. Finally, the situation in which the need for help arises may be *serious* or *not serious*.

Researchers have often limited their studies of helping behavior to particular forms of helping. For example, they have studied spontaneous or unplanned helping, episodic helping, and long-term helping; in each case, the situation may have been serious or not serious, and the action direct or indirect. Many studies take just a single type of helping (e.g., blood donation) as their central focus. We now turn to each of these forms of helping and the research that supports them.

Spontaneous Help

For behavioral scientists in the 1970s and 1980s, the central question of interest was whether or not a person would help when he/she was placed in a situation in which a stranger needed help. A major impetus for behavioral scientists' attention to helping behaviors was a dramatic episode of a failure to help. In 1964, Kitty Genovese was murdered by a knife-wielding attacker as she returned to her New York City apartment building in the early hours of the morning. The episode consisted of two separate attacks over an approximately 30 min time period and was witnessed by at least 38 people who were watching from their apartments. None of the observers assisted her. Although recent archival work suggests that some aspects of this 'parable' may be apocryphal, the subsequent

Table 1 Dimensions of helpful actions and representative acts

	<i>Planned help</i>		<i>Unplanned help</i>	
	<i>Serious situation</i>	<i>Not serious situation</i>	<i>Serious situation</i>	<i>Not serious situation</i>
Indirect help (giving)	Donate blood	Save cartons for art students	Telephone for a medical emergency	Give money for bus fare
Direct help (doing)	Crisis counseling	Volunteer for experiment	Perform CPR for a heart attack victim	Look for lost contact lens

experimental research did offer important scientific insights into the situational factors that influence whether or not bystanders will intervene in an emergency, using the Genovese story as a model for their studies. College students participating in an experiment, for example, have been exposed to a medical emergency or a theft, and from these studies, one consistent finding has emerged: the presence of other people, and particularly strangers, inhibits intervention during emergencies.

From the attempts which have been made to explain the inhibitory effect of the presence of others has come a framework for the intervention process in emergencies (see **Figure 1**). The first condition that must be met before a potential helper can intervene is attention to the event and, interestingly, several factors can actually lead to a failure in noticing even a dramatic emergency. These include being overwhelmed by stimuli (as might be the case when one lives in a large urban area), distraction from external events (because one is focusing attention on one's own problems), or time pressure. Upon noticing, however, the potential helper must then interpret the episode as a situation that requires help. An interpretation that the episode is an emergency is hindered by any set of conditions that make it ambiguous – for example, is an altercation between a man and woman an attack or a lover's quarrel?

The conditions mentioned up to this point could occur regardless of whether one is facing a possible emergency alone or with others. More directly related to the inhibitory effect of other people is the social process of *evaluation apprehension*. This involves people's desire to present themselves as 'calm, cool, and collected,' and the fear of any embarrassment being caused by acting as if the situation is serious when, in fact, it is not. The unfortunate upshot of this process is that when a group is faced with a potential emergency, individuals present a calm mask while looking around at others' faces to determine if the situation is serious – and if others are acting similarly. The end result is often an interpretation that the event is not an emergency and so no one intervenes; this state of affairs, in which everyone believes that others have confirmed that there is nothing to worry about, is known as *pluralistic ignorance*. When alone, the absence of others removes the audience and gives the individual more latitude in making the interpretation that an emergency has indeed occurred.

Having made an interpretation that the event is an emergency, a person must still decide whether or not he or she will intervene. Again, several factors affect this final step, including an estimation of whether one possesses the skills necessary to assist the person in need. In terms of the inhibiting presence of others, an important aspect of this final decision is the *diffusion of responsibility*. When alone, the responsibility for helping a victim rests solely with the individual. When others are present,

**Figure 1** The bystander intervention process.

however, several individuals psychologically distribute responsibility for the action and each individual's own sense of responsibility is lessened. Thus, while the processes of evaluation apprehension and diffusion of responsibility reduce the probability of helping amongst a collection of individuals, recent research does offer a potential caveat to this dire claim, as findings suggest that when other bystanders are friends or members of the same social group they do not inhibit helping (and may even encourage it), particularly, if the victim is a member of the same social group.

Other situational factors may also influence spontaneous helping. Simple acts of spontaneous helping, such as picking up a dropped pen for someone or making change when asked, may be affected by the immediate environment. In particular, unplanned and nonserious helping may be inhibited in American cities with greater population size or density (perhaps via distraction and sensory overload or diffusion of responsibility). Another inhibition may be the perceived costs that the helper foresees in terms of time, energy, or money. Moreover, some situations which call for serious help are clearly dangerous for the intervener; rescuers of Jewish victims of the Holocaust, for example, faced possible execution if caught. Even in the absence of physical harm, some situations involve victims who are severely injured and suffering, and people can find exposure to these situations psychologically distressing. Even though helping can certainly be costly, there are also costs associated with failing to help (e.g., the disapproval of others).

Yet, spontaneous help is not simply the result of perceiving a lower number of potential losses. People can benefit through helping and the availability of potential rewards increases the likelihood of help. The benefits available to helpers often seem to center on approval in terms of the approval of others for helping, the gratitude of the recipient, or self-approval. With respect to self-approval, helpers can reinforce themselves as having acted in accordance with their values and/or for having 'made a difference.' Moreover, through helping, a helper can experience an increase in self-confidence and, more generally, self-esteem.

A number of other studies have examined why situational features may make spontaneous help more or less likely. Manipulations of a positive mood (e.g., finding a coin in a phone booth or having an experience of success) increase the likelihood of help. Several psychological mechanisms appear to contribute to this relationship, including the tendency for people in a good mood to view things in a more positive light, be reminded of their own good fortune, and the desire to maintain the positive mood state. The relationship of negative moods and helping is more complex, and varies with the specific negative mood. Guilt is generally associated with increased helping, and is especially so when one feels responsible for the potential recipient's state of need, as helping provides a mechanism for reducing that guilt. The relationship of sadness and helping, however, is more variable. Helping becomes more probable if the sadness is directed at the distress of another person, but is less likely if the sadness is directed at oneself. Thus, a potential helper's internal mood state, positive or negative, which is generated by the current situational features or carried into the situation with the helper (as a result of prior events), can clearly influence helpfulness.

Other studies have looked not just at the ways that current affect influences spontaneous helping, but also at how currently accessible cognitions may do so. For example, participants who are running late for another engagement have been found to be less likely to help; thus, competing goals may block spontaneous helping. Researchers have also primed helpfulness in participants; for example, after describing the characteristics of superheroes (a very helpful group), participants were more willing to sign up for volunteer work (and actually follow through with their commitment) compared to a control group. These primes, which often operate at an implicit or unconscious level, may make certain goals that are focused on helping more accessible in thought, and when opportunities arise to act on these goals, primed individuals are more likely to do so.

Besides goals, other cognitions may become active in some situations and can influence spontaneous helping behavior. Here, a great deal of research has examined the role of salient norms in ensuring helpful action. For example, when presented with unexpected opportunities to help, witnessing another person helping increases the incidence of behaving helpfully; a motorist with a flat tire received more offers of assistance when travelers had earlier observed another motorist with a flat tire receiving assistance. In part, witnessing the helpfulness of another person increases the observer's helpfulness by teaching new behaviors and by demonstrating that certain behaviors are appropriate in a situation. Modeling of the helping behavior by others has been shown to have both immediate effects (by making norms salient) and long-term effects (by socializing children to learn social norms or even personal goals). In particular, models may remind those who witness their actions of the *norm of social responsibility*. According to this norm, we should help those who are dependent on us, such as young children, the sick, and people in need.

Whereas research is consistent on the prediction that helping increases as dependency increases, explanations which focus on norms like social responsibility are often criticized on the grounds that they are vague, general, and appear to be present in situations where there is a failure to help (e.g., when

bystanders are present in emergencies). Furthermore, there are social norms that discourage helping, as exemplified by the admonishment 'mind your own business.' Nonetheless, many societies have norms, such as social responsibility, which serve as a backdrop to events in which others are in need and can exert an influence when combined with other factors.

A clearer case of a help-related norm influencing helping behavior concerns the *norm of reciprocity* – we should help those who have helped us. This guideline is not just limited to the realm of helping, but applies more broadly to our relations with others. Reciprocity also appears to represent a universal norm and some societies have very clear-cut guidelines about how and when one returns a gift (e.g., the Kula ring among the Massim peoples found in several small islands near New Guinea). Yet, receiving help does not guarantee that the recipient will later return the help. Recipients of help seem to feel less obligated to reciprocate when the gift represents a small portion of the helper's overall resources or if the original help was given accidentally rather than deliberately. Reciprocal help also seems to be less likely if the helper is judged to have had ulterior motives for acting helpfully. In this case, recipients may experience 'psychological reactance' – a negative motivational state where people wish to reassert their freedom to act, which may result in a refusal to reciprocate.

The conditions under which prior help is more likely to be returned raise a larger question about the potential recipient of help as a situational determinant of helping – when are people in need more likely to receive help? Research suggests there is an increased tendency to help when the need of the victim increases (e.g., in clearly defined emergencies). This tendency, however, is moderated by the potential helpers' judgment about whether or not the victim deserves help. People tend to help more when the victim is viewed as needing help because of circumstances beyond his or her control, compared to when he or she is known to have created his or her own predicament. Subway riders, for example, were more likely to help a fallen rider when his fall appeared to be due to sickness rather than drunkenness. In a related vein, more help is forthcoming when the need seems legitimate and necessary, as in requesting money for purchasing milk, rather than a more unnecessary and trivial need (e.g., requesting money for beer). Finally, there is a tendency to help others more when the person in need appears to be similar to us, as signaled by the person's salient social group memberships.

Thus, a considerable amount of research has been devoted to the social processes that inhibit or enhance spontaneous helping, particularly in emergency settings, and also with less serious behaviors. However, until relatively recently, researchers in behavioral sciences appeared less interested in investigating helping behaviors that occur more frequently or even for long periods of time. We turn next to these, more sustained, forms of helping.

Episodic Helping

When it comes to planned helping behaviors, those who wish to assist others may choose to do so in a limited fashion by engaging in relatively short-term helping behaviors. The most obvious prototype of episodic helping is blood donation, but participation in walkathons or paintathons also falls into this

category. Indeed, a lot of literature has developed which examines the factors that influence charitable giving, and this may sometimes be the helpful choice of those who find themselves time-poor (conversely, those who are resource-poor may choose volunteering time over money).

One approach to examining the giving of time, blood, and money, has focused on the roles that the participants adopt when they choose to engage in these forms of helping and how these roles can become a central part of a person's identity or the sense of self. Research on episodic helping often targets the predictors of this ongoing commitment, rather than only that which led the givers to engage in helping in the first place (which we cover in a later section). Regular ongoing blood donation has been shown to increase as a function of the positive expectations of other people in the donor's social network and as a function of the donor's donation history. Indeed, at a certain point in their donation career, individuals may experience a 'role-person merger' whereby the role of blood donors (or volunteers) becomes a central and important part of who they are, and this is made stronger by the fact that other people in their social network are also likely to acknowledge the importance of this role for these persons; this can help to maintain the role-consistent behavior.

Aside from 'opportunity costs' (e.g., those costs that one must bear if one is to use one's time to engage in helpful behaviors rather than to pursue other goals or leisure activities), other factors may also influence whether or not someone gets involved, episodically. For example, recalling that a parent or another significant role model engaged in the same activity is associated with greater commitment to episodic helping (blood, money, and time); as is the perception that people have a moral obligation to engage in these behaviors. Social marketing research also suggests that episodic helping may also be a function of catching people at the right time and place, or of finding ways to make helping behaviors more convenient and/or a regular part of a person's daily schedule (e.g., blood-mobiles and workplace-sponsored helping). Finally, reducing the costs associated with helping opportunities (such as those involved with driving to the location or giving up time on the weekend) can increase the likelihood of episodic helping.

Long-Term Helping

From the late 1970s onward, behavioral scientists began to turn their attention beyond short-term or emergency helping and the factors that influence it, to the sort of planned and sustained helpful behaviors that are epitomized by volunteerism. In many nations, volunteers provide an enormous resource to communities, free of charge, which can be the equivalent of many billions of dollars per year in labor costs. They get involved in organizations that focus on helping other people (*public-serving* organizations, such as the Red Cross or Habitat for Humanity) or those that focus on bringing like-minded people together or promoting a particular activity (*member-serving* organizations, such as local arts organizations or interest groups). These organizations provide many helping opportunities that range from those focused on improving the health and well-being of adults, youth, or children, to those that focus on specific issues, such as education, the environment, or human rights (including many political organizations), and to

those that help to organize arts, sports, and cultural activities. Within these organizations, volunteers take on many roles, with some requiring few skills and little training (picking up garbage on beaches, delivering meals to housebound elders), and others requiring increasing amounts of training, orientation and existing skills (serving as a mentor to troubled youth, fundraising, coaching a sports team).

Sociologists have examined the ways in which background characteristics may be associated with a greater likelihood of volunteering. First, people with greater stores of 'human capital' resources, such as higher education or higher status jobs, compared to those who have fewer such resources, tend to volunteer at higher rates, perhaps because they are more aware of the social issues that require volunteers' services or because they are more frequently asked to volunteer. Second, volunteering also occurs at higher rates for those who possess greater social resources, or social capital. Having a large social network and belonging to more organizations can create more opportunities for volunteering, as in the type of volunteering that involves people helping the schools or churches that their friends and family attend. That is, through family, friends, and other people they know, people learn about problems and the opportunities to solve them. They get asked to volunteer, but they also develop shared interests and concerns, and become enmeshed in relationships that involve trusting and being trusted, potentially, as part of a community that shares beliefs and norms about the importance of contributing to the public good.

A Process Model of Helping

With volunteerism as a case in point, we now review the antecedents, processes, and consequences of helping behavior and the different theories and findings that have explored this prosocial behavior.

Antecedents

The most distal cause of helping behavior considers the possibility that humans may have evolved to engage in helping behavior, with the discussion centering on the adaptive advantages of helping in the survival of the individual and the species. Evolutionary psychologists have demonstrated that people are more likely to help those with whom they have close biological ties than those with whom they share no genetic similarities (known as kinship selection). Such helping clearly promotes the transmission of one's genes to the next generation if those carrying similar genes are assisted when in need. But humans may also help those who are not blood relatives, to the extent that these strangers are later, more likely, to return the favor. Such reciprocal altruism (as it is known) offers evolutionary advantages, at the group level (by invoking a norm of reciprocity), that may have enabled some early humans (our ancestors) to outlast others who did not develop such a norm of reciprocal altruism with others. Other modern revisions of Darwin's Evolutionary Theory point to other advantages in forming communities, trusting others, and helpfulness; these stand in contrast to earlier suggestions that human selfishness is evolutionarily programmed in ways that discourage the helping of strangers.

A more proximal influence on helpfulness comes from socialization experiences. Parents explicitly teach their children about moral and social rules and principles, and about norms for behavior, using praise and other rewards as well as punishments, to guide and shape children's behavior. For example, people who endorse the values of benevolence (seeing the importance of helpful action toward specific known others) or universalism (seeing the importance of promoting the welfare of all) are more likely to help than those who endorse more hedonistic values. However, parents also provide a more implicit form of learning for children by the example of their own behavior. Social learning theory has demonstrated that children often engage in behaviors, either prosocial or aggressive, that they have seen modeled by adults, particularly when those adults received rewards (and not punishments) for engaging in such behavior. And, indeed, children whose parents have engaged in volunteer work are more likely to volunteer later in life. For example, a group of committed civil rights activists reported that their parents had been activists of an earlier era (i.e., modeled helpfulness), as well as having established warm, positive relationships with their children. This combination appears to be especially important for internalization of such help-related norms and goals: children are more likely to adopt, as their own, those standards that are based on a nurturant model. Research has also shown that preaching helpfulness in the absence of action is ineffective, with children, not surprisingly, imitating this model's (nonhelpful) behavior.

The question has also been asked whether specific personality traits are associated with helping behavior. Relative to nonvolunteers, volunteers have been observed to possess greater degrees of self-efficacy, emotional stability, empathy, an internal locus of control, and intrinsic religiosity. Under conditions of unplanned or unexpected opportunities to help, traits, observed to be related to helpfulness, have included self-esteem, agreeableness, ascription of responsibility, dispositional empathic concern, and a high need for nurturance combined with a low need for succorance. Two important qualifications have been noted regarding the relationship of personality traits and helping behavior, especially in unexpected/unplanned situations. First, a stronger relationship between traits and helping is obtained when one combines several traits into a composite measure, as this composite better captures the more general predisposition to help others and is thus seen as indicating a prosocial (or altruistic) personality. Second, it appears that whether or not a particular trait correlates with helping depends on the fit between the trait and the specific situation. Nurturance, for example, was found to be correlated with willingness to counsel high school students but unrelated to willingness to collate and assemble class materials; this latter activity, however, was related to autonomy.

More broadly, research has shown that personality and other personal factors (such as one's values or beliefs) are more likely to affect helping behavior in certain kinds of situations, rather than in all. Specifically, such situational factors seem to operate as more powerful influences in those situations where the opportunity to help arises unexpectedly and the resulting help is unplanned (e.g., emergencies). Conversely, in situations where the help is planned and may even

involve the helper seeking out the opportunity to help (e.g., volunteer activities), there is a tendency for important personal factors to emerge as predictors of behavior. This variation in the strength of situational and personal factors, as a function of the type of situation, seems to be a general relationship: situations possessing highly salient external cues for behavior reveal situational determinants, whereas situations possessing less salient external cues reveal personal dispositions and desires that guide behavior.

One area of study where both personal and situational influences may be involved is the study of prosocial motivation. Research suggests that there may be individual differences in the ability to see the perspective of another person and, when the other is in need, to feel empathic concern for them. *Empathic concern* is an emotional state marked by feeling 'sympathetic,' 'compassionate,' and 'tender' in response to another's need and represents an orientation toward the other person's distress. Individuals with a disposition to empathize may be more likely to feel prosocial motivation and are therefore, more likely to help; their distinctiveness from other people may be most obvious in those situations when helping may be easily avoided (e.g., when those who can't empathize avoid helping). However, other research has shown that empathic concern may be the result of specific situational factors, particularly the features of the person who needs the help. Perspective-taking and empathic concern are easily achieved by potential helpers who are similar, in some way, to the person needing their help. Moreover, if a potential helper feels dissimilar from the person needing help, they may only feel distress at seeing them in need. *Personal distress*, characterized by such feelings as being 'alarmed,' and 'upset' when in a situation requiring help, may lead a person to try and leave the situation, if it is possible, so as to escape their own negative feelings rather than help. If escape is not possible, they may help but then that help is impelled by an egoistic desire to reduce their own distress rather than to reduce the other person's distress.

Studies in this area have contributed to a major debate in behavioral science which questions if helping is ever truly altruistic and motivated solely by concern for another person's welfare without reference to any personal benefits or costs for the helper, or, whether it is basically egoistic and offering benefits (or avoiding downsides) for the helper. If help to another person is offered, even at a cost to the helper and with no expected benefits, it may be determined to be purely altruistic, especially if the help is given when it would be easy to avoid doing so. On the other side of the debate, researchers continue to point out benefits that helpers can achieve through helping, which include a positive feeling about having done the right thing. Another egoistic possibility available in even the most selfless-appearing help (aside from anticipated social approval and gratitude) is the potential for a feeling of 'oneness' or a merging of self and other, which creates a feeling of shared positive outcome. This is more likely if the person needing help has a close relationship with the helper; this also means that in the most communal relationships, helping the other is essentially self-help.

Research on planned helping has usually eschewed the debate over whether helping is altruistic or egoistic and instead, has focused on the fact that helping behavior may be

motivated by both other-focused and self-focused goals at the same time, and indeed, by many different goals. This principle, and the idea that different people may engage in the same helping action for different reasons, are hallmarks of the functional approach to volunteerism (which investigates the functions that volunteering serves in the lives of those who volunteer). Researchers using this approach have identified a number of reasons for which people get involved in volunteer activities (see Table 2).

Processes

Indeed, researchers have long recognized that merely understanding the antecedents of helping behavior may not be sufficient to fully explain the experience of helping and its consequences. Actual helping is often theorized to be the result of an interplay between background characteristics (e.g., dispositions, motivations) and situational features (e.g., characteristics of the recipient of help, specific affect, and cognition that are aroused by the experience). For example, the functional approach to volunteerism suggests that motivations to volunteer have an impact on positive outcomes such as satisfaction and future intentions to volunteer only to the extent to which the volunteers' actual experiences allow them to achieve these instigating goals.

One important manifestation of the interplay of personal factors and situational features concerns the actual interactions of the helpers and the recipients, especially when helping activities involve people from different social backgrounds or with different group memberships. When a helper and a recipient of the help belong to different social groups, a number of issues may arise which influence how people feel about the experience. Researchers have long suggested that receiving help may be threatening to one's self-esteem, suggesting a weakness or an inability to take care of oneself. That is, helping often involves a relationship that is unequal in power, and may carry a suggestion that the recipient is incompetent, with the result that needing help can be embarrassing and humiliating. Also, helpers vary in the ways in which they give assistance; some are caring and supportive, whereas others may assist in more negative and threatening ways. Certainly, help that is given in a more negative and threatening manner is experienced as being more unpleasant for the recipients.

When help comes from another person who belongs to a higher status social group, the threat involved with receiving

help may take on a new meaning. Findings suggest that low-status participants may be less willing to seek help from high status participants (e.g., studies that have involved Israeli Jews and Israeli Arabs), unless it is clear that the help is designed to enable them to learn the skills that will allow them to help themselves in the future. This type of help, epitomized by the phrase, "Give a man a fish and he will eat tonight, teach a man to fish and he will eat from now on," is called *autonomy-supportive help*. In contrast, *dependency-oriented help* does nothing to help the low-status members of society to change their situation and is more likely to be rejected when such group status differences are seen as illegitimate. Following theoretical traditions that suggest that there are personal benefits to showing favoritism to one's own ingroup (and occasionally derogating outgroups), research also shows that high-status group members are less willing to offer autonomy-supportive help to low-status group members and instead prefer to offer dependency-oriented help. This pattern of behavior can serve to reinforce the existing hierarchical differences between the involved groups. As such, helping experiences may become that much more fraught when they involve bringing together people from unequal backgrounds; however, as we shall see below, the opportunities for greater social benefits may also be higher in such intergroup interactions.

Consequences

The final area to be examined concerns the impact of the help given, and particularly, if the help given was effective. Helpful actions do not necessarily carry a guarantee of success, as attested to by the proverb that 'the road to hell is paved with good intentions.' Moreover, it seems unlikely that there is some basic skill that reliably leads to effective helping. Rather, successful help is most probably related to specific skills being applied to the specific demands of a situation. It is important to point out that research has shown that possessing the relevant skills also affects the decision to help in the first place. In a staged emergency that involved a victim of electrical shock, subjects having experience with electrical equipment were more likely to intervene than those lacking this experience.

At the same time, a relevant skill is not just another variable that influences the decision to help. This was demonstrated in an experiment where subjects, either before or after receiving Red Cross training, were exposed to a mock arterial bleeding emergency. *Whether* subjects intervened or not was influenced by some of the usual bystander intervention variables (e.g., the presence or absence of other people), but *how* these people helped was affected by training – those with training were more likely to provide direct help (the application of direct pressure to the wound) whereas those without training were more likely to engage in indirect help (finding other assistance). Moreover, in the context of the medical emergency used here, failure to apply direct pressure within 4–10 min usually results in death, so indirect help may be of no help. Thus, whether a person will help, or not, is not the same as how one will help.

Research has also examined the attributions of responsibility that helpers and the recipients of their help make about both the causes of the current problem and its solution. In most studies, psychological well-being was *positively* associated with taking responsibility for solutions to problems.

Table 2 Why people volunteer

Motivation	Description
Values function	To act on and to express their prosocial values
Understanding function	To gain a sense of understanding of the world, an issue, themselves, or other people
Enhancement function	To feel more positively about themselves
Protective function	To protect themselves from feeling bad
Social function	To fulfill their social obligations and to fit in with the expectations of others
Career function	To obtain career experience and advantages

Investigations from several areas are generally consistent on this point, with an improvement being more likely when the recipients of help become active participants in solving their own problems. Research on psychotherapy provides one such example in which successful outcomes are associated with the clients' attributing the change to their own efforts.

So, the consequences of helping for recipients of help may vary depending upon the skills and abilities of helpers, the amount of responsibility taken on by recipients (if appropriate), and a number of other factors, including the magnitude of the recipient's need, the difficulty of implementing a solution (e.g., some problems require environmental, political, or social changes for a solution) and the resources that are available to assist in the act of helping. These factors may also influence the consequences of helping for helpers, the communities to which these individuals belong, and to the larger society.

Most research that examines whether helpers also benefit from offering help has examined the goals that helpers may seek to meet in their helping activities. As discussed earlier, numerous egoistic benefits can be achieved from helping and volunteers cite career benefits, social benefits, esteem benefits, and gains in understanding, as desirable personal consequences of their good work. Other research suggests that volunteerism is associated with greater well-being, better mental and physical health, and even longer lives for the elderly (although this latter effect may dissipate if too many hours are committed). However, one recent study suggests that greater well-being is only associated with motivation to help others because of the pleasure that can be derived, and helping motivated by external pressure is less related to well-being. Similarly, those who perceive a requirement to volunteer (often imposed by academic institutions as a condition of graduation) to be too controlling of their actions indicate that they will be less likely to volunteer in the future (as compared to those who are unaffected by such requirements), even if they had already demonstrated a commitment to volunteering freely in the past. These findings are not inconsistent with the notion that there are egoistic benefits to be achieved from helping, but clearly, helpers must be attuned to and value the available benefits. When volunteers find themselves in this situation, research suggests that self-focused motivation may be a greater predictor of continued volunteering than other-focused motivation. That is, those who indicate that they are purely altruistic and selfless may burn out faster than volunteers who possess a mix of self- and other-oriented motives.

Finally, helping behaviors can also have consequences for the organization that is sponsoring the helping activities (if any), the relationship between the helper and the recipient, the community at large, and the greater society. For example, researchers have examined the extent to which volunteers perceive a congruence between their own values and the mission of any organization to which they contribute their time and energy, as a predictor of continued helping (at that organization). Indeed, the respect that an organization shows to its volunteers and the pride that volunteers feel in being part of the organization can contribute to the continued commitment by volunteers, and concomitantly, to the health of the organization and its ability to achieve its mission.

Perhaps even more important for consequences at the macro level is the way in which helping behavior can create positive bonds of trust and reciprocity between helpers and

recipients. Theories focused on the generation of social capital have suggested that such bonds can be created through social participation, either as part of a member-serving organization or a public-serving organization. Although bonds between people from similar backgrounds, dubbed bonding social capital, may be easier to create, bonds between people from different backgrounds, dubbed bridging social capital, may offer more benefits to society and help override social ills that may come about when there is hostility or prejudice between groups in society. However, it is not yet clear if such helping interactions can indeed create bonds of trust across previously established group lines. Most studies of intergroup contact suggest that interactions have more positive outcomes when people meet in circumstances that offer equal status to all participants; however, such is not always the case in helping interactions where helpers and recipients may differ in power. Nevertheless, research does suggest that trust and a sense of community can be realistic outcomes of volunteerism and social participation. As such, societies may need to further promote helping behavior as a way of ensuring that these qualities are in good supply in order to assist with the many problems facing the world.

Conclusions

As with human behavior in general, prosocial action is a complex phenomenon that is affected by a variety of factors and considerations. Whether or not one helps in a situation where another person is in need depends on social forces operating in the situation, the characteristics of the particular needs of the situation, and the motivations and abilities of the potential helper. Having decided to help, the helper must decide how, and in what way, to help, with the specific type of help and approach to helping being influenced by some of the same factors, as well as by others (e.g., the helper's fundamental assumptions about the helping process). An act of helping, then, can be broadly constructed as an interactive function of the characteristics of the helper and characteristics of the helping situation.

In several respects, helping behavior is not as simple an issue as it may appear at first glance. As we have seen, there are different influences on short-term and long-term helping and both distal and proximal influences may guide the course of a helping interaction and its consequences for the recipient, the helper, and the context around them. An array of different theoretical and empirical approaches has been developed to examine helping, both in the abstract and in very specific concrete situations (as with blood donation). However, within this complexity, a generally positive view of human behavior has emerged, with evidence which shows that people are willing to help each other under many different conditions and in many different ways. The scientific endeavor continues to offer data to support new ways of understanding helping behavior and speaks of ways to ensure that it leads to benefits for all.

Glossary

Acetylcholine A common neurotransmitter.

Amyloid angiopathy The formation of protein fragments called amyloid inside the walls of cerebral blood vessels.

Amyloid beta The main constituent of plaques in the brains of AD patients.

Amyloid plaques Hard, insoluble plaques made of protein fragments called amyloid accumulated between neurons.

APOE (apolipoprotein) gene A gene that is involved in regulating cholesterol levels. The E4 type of this gene is the major genetic risk factor for late-onset AD.

APP (amyloid precursor protein) A protein from which neurons make amyloid beta.

Autoantibody An antibody that attacks an individual's own proteins.

Blood–brain barrier A separation between the blood and the cerebrospinal fluid restricting molecules from entering the central nervous system.

Cerebrovascular Of or related to blood vessels that supply the brain.

Cholinergic Referring to cells or structures that use the neurotransmitter acetylcholine.

Dementia Loss of cognitive abilities severe enough to interfere with daily functioning.

Diabetes A condition in which normal insulin function is disrupted, resulting in an overaccumulation of glucose in the blood.

Dyslipidemia An abnormality in the lipid content in the blood.

Enzyme Biological catalysts that speed up chemical reactions in the body.

Hippocampus Brain structure important for memory.

Hypertension High blood pressure.

Inflammation The response of the immune system to injury, irritants, or infection.

Inflammatory Of or referring to inflammation.

Neurodegeneration Progressive damage to and loss of neurons.

Neurofibrillary tangles Aggregates of the protein tau found inside neurons of AD patients.

Neuropsychiatric Of or referring to psychiatric disorders attributable to nervous system disease, such as hallucinations, delusions, aggression, and depression.

Neurotransmitter Chemicals used by neurons to communicate with other cells.

Oxidative stress Increased release of unstable oxygen causes damage and possibly death of neurons.

Plaques Abnormal deposits of amyloid cell debris in the brains of AD patients.

Tau The main constituent of neurofibrillary tangles.

Alzheimer's disease (AD) is the most common form of dementia, constituting about 60–80% of all dementia cases. Dementia is defined as loss of cognitive abilities severe enough to interfere with daily functioning. AD is a progressive, degenerative, and terminal disease that currently afflicts more than 25 million people worldwide. The disease is characterized by deterioration of cognition and memory and a gradual loss of the ability to perform activities of daily living. Because the occurrence of AD is strongly associated with increasing age and because life expectancies have been rising across the world, the prevalence (occurrence) of the disease could quadruple by 2050, reaching 107 million people. Lack of effective treatment, high healthcare costs, and increasing numbers of patients make AD one of the most challenging medical conditions of our times.

History

AD was first described in 1906 by Dr. Alois Alzheimer, a German psychiatrist. The report was based on the case of a middle-aged woman with impaired memory, disorientation, a gradual loss of higher mental functions, and brain

abnormalities (plaques and tangles). Dr. Emil Kraepelin, who was Dr. Alzheimer's boss, named the disease after him in a textbook. For many years after Dr. Alzheimer's initial description, AD was not considered a major disease. Cognitive decline and dementia were considered part of normal aging and usually referred to as senility. Not until the 1970s did AD become recognized as a specific disease with well-defined abnormalities of the brain, leading to increased public awareness and research funding. It is now recognized that subtle cognitive changes do occur with aging, but very marked changes are indicative of an underlying disease process.

Symptoms

AD is characterized by a subtle onset and gradual decline. Although each person with AD is different, most individuals advance through a series of stages with progressively more serious symptoms. Because of its subtle onset, AD can progress for many years before being diagnosed. The most prominent early symptom is memory impairment, particularly the ability to remember recent events or names of familiar people or objects.

Other types of memory are initially relatively unimpaired, such as old memories from the person's past, memory for skills, and the ability to benefit from prior experiences in the performance of some task without conscious awareness of these experiences (implicit memory). Early AD is accompanied by other, initially subtle, cognitive deficits, such as impaired verbal, spatial, or problem-solving skills, as well as impaired planning, cognitive flexibility, and abstract thinking. For example, some people may have difficulty working with numbers, following a recipe, driving to a familiar location, following a conversation, or keeping track of bills. Language problems are mainly characterized by a shrinking vocabulary and word-finding difficulties (reduced verbal fluency). Other symptoms may include disorientation, increased irritability, suspicion, mood swings, depression, anxiety, withdrawal from work and social activities, apathy (or loss of motivation), and sleep disturbance.

As the disease progresses, delusions are common, as are behavior problems (e.g., aggression, wandering, disregard for normative social conduct, etc.). Reading and writing skills are progressively lost. Complex motor skills become less coordinated and there is an increased risk of falling. Patients may have trouble recognizing close relatives. In the later stages of the disease, basic activities of daily living, such as eating and dressing, become impaired. Late-stage AD is marked by the loss of recognizable speech and the inability to control bodily functions, leaving patients completely dependent on caregivers. Muscle mass and mobility may deteriorate to the point where patients are completely bed-bound, can no longer feed themselves, and may have difficulty swallowing. AD ultimately leads to death, although the cause of death may not be the disease itself but some external factor, such as infections.

The first symptoms of AD usually appear late in life, although they can occur earlier. Late-onset AD occurs after age 65 and accounts for 90% of all AD cases. Early-onset AD begins around age 30–60 years. There do not appear to be any differences in the symptoms of early- and late-onset AD.

Prevalence and Mortality

Today, the global prevalence of AD in individuals aged 60 and older is estimated to be about 5–7%. This rate doubles approximately every 5 years after age 65 so that up to 40% of individuals over age 85 are afflicted by AD. Overall, the prevalence rate of AD in the United States and Europe is higher than in developing countries. However, as life expectancy is increasing in developing countries, the prevalence of AD is projected to rise in those regions. Cross-cultural studies indicate that lifestyle factors associated with living in developed nations also increase the rates of AD in developed compared to developing nations. For example, Indians from Northern India and Yoruba from Nigeria have a significantly lower rate of occurrence of AD than Indians living in Pennsylvania and African-Americans living in Indiana, respectively. Although women are more likely to have AD than men, this is largely explained by the fact that women live longer than men. AD significantly shortens life expectancy, but survival among those with the disease varies widely. Once diagnosed with the disease, the median survival time ranges from 3 to 12 years. AD is one of the leading causes of death in developed nations.

Both the prevalence of AD and the survival time following diagnosis of AD have been reported to vary across ethnic and racial groups, but it is currently unclear whether those differences are due to genetic heritage, health, or social or cultural differences between groups. For example, compared to Americans of European descent, African and Hispanic Americans are at a greater risk for AD, whereas Asian and Native Americans are at lower risk. At the same time, the life span following a diagnosis of AD has been shown to be shortest among non-Hispanic whites than among Hispanics and African-Americans. When variables such as years of education, literacy, health status, and socioeconomic status are taken into account, these group differences are greatly reduced or disappear, suggesting that they are due to factors other than race.

Causes

The causes of AD have not been well understood, and several competing hypotheses have been proposed to explain the causes of AD.

Cholinergic Hypothesis

According to the cholinergic hypothesis, the degeneration of cholinergic neurons (neurons that use the neurotransmitter acetylcholine) in the basal forebrain of patients with AD leads to a deficiency in the neurotransmitter acetylcholine in the cerebral cortex and hippocampus of these patients. The cerebral cortex and hippocampus are brain structures that are vital for cognition, behavior, and memory. The reduction in acetylcholine transmission is thought to contribute significantly to the progressive decline in cognitive function seen in AD. Consistent with this hypothesis, acetylcholine has been linked to cognition, memory, and attention in both humans and animals. More recently, it has been suggested that non-cognitive symptoms of AD, such as depression, aggressive behavior, psychosis, and overactivity, may also be partially attributable to cholinergic dysfunction.

The cholinergic hypothesis has served as the basis for the first drug treatment approaches for AD. In support of the cholinergic hypothesis, drugs that increase acetylcholine levels are associated with modest improvements in cognition, function, and behavior of AD patients in clinical trials. However, these modest benefits are not sustained in the long term and the disease continues to progress while patients are receiving treatment. This and other findings have led some researchers to conclude that acetylcholine deficits may not be directly causal to AD, but the result of widespread brain damage and loss of neurons.

Amyloid Hypothesis

The most prominent hypothesis about the cause of AD is the amyloid hypothesis, first put forward in 1991. This hypothesis proposes that amyloid beta protein (also written A β or A-beta) deposits are the causative factor of the disease. Amyloid beta deposits are the main constituents of plaques (also called neuritic plaques, senile plaques, or amyloid plaques) that are characteristically found in postmortem brains of AD patients.

According to the amyloid hypothesis, soluble forms of amyloid beta protein may be toxic to the brain, causing programmed cell death, other brain abnormalities, such as tau tangle formation, and the clinical features of AD. Amyloid beta may also disrupt the metabolism of neurons by inhibiting certain enzyme functions and changing how neurons utilize glucose, their main source of energy.

Amyloid beta protein is a fragment of a larger protein called amyloid precursor protein (APP) that is located in the membrane of neurons. The primary function of APP is not known, but it may be important for neuron growth and survival. One mechanism by which amyloid beta accumulates in the brains of AD patients is an increase in the rate at which enzymes cleave APP into smaller fragments, thereby generating increased levels of amyloid beta. Other mechanisms for amyloid beta accumulation are faulty clearance of amyloid beta from the brain and overproduction of amyloid beta caused by genetic mutations that have been linked to early- and late-onset AD. Thus, individuals with early-onset AD typically have genetic mutations in APP or the presenilin proteins, the latter of which form subcomponents of an enzyme that cuts APP into smaller fragments to produce amyloid beta. Both the APP and the presenilin mutations act by increasing the overall production of amyloid beta or by increasing the relative or absolute level of the toxic form of amyloid beta. In addition, elevated amyloid beta deposition has been linked to inheritance of the E4 type of apolipoprotein E (APOE) gene, which is the major genetic risk factor for late-onset AD. Additional support for the amyloid hypothesis comes from the finding that the gene for APP is located on chromosome 21 and that patients with an extra copy of this chromosome, known as trisomy 21 or Down's syndrome, almost invariably develop AD by 40 years of age.

Despite all the evidence consistent with the amyloid hypothesis, a number of findings have raised questions about it. Few studies have been able to demonstrate that amyloid beta is substantially toxic to neurons and induces cell death. Rather, it appears that the toxicity is dependent on the presence of the protein tau, the main constituent of the neurofibrillary tangles. More importantly, drugs that reduce amyloid beta or clear amyloid plaques in the brain seem to have little effect on the symptoms of AD or the progression of the disease. Although there are likely to be a number of reasons for the failure of these drug studies, they strongly suggest that factors other than amyloid beta are important for the development of AD. A possible explanation for why amyloid-reducing drugs may be ineffective in ameliorating the symptoms of AD is that amyloid beta triggers tau tangle formation and other disease-related processes that, once initiated, cause the progression of AD despite reduced levels of amyloid beta.

Also problematic for the amyloid hypothesis are findings from recently developed amyloid imaging studies that are able to measure the amount of amyloid beta deposits in living human subjects. These studies have shown that up to one-third of cognitively normal older individuals show substantial amyloid beta deposits at a level that is similar to that seen in AD patients. This indicates that the presence of amyloid beta alone is not sufficient for cognitive impairment and AD. Moreover, amyloid appears to increase linearly throughout the latter years of life and the rate at which amyloid accumulates in the

brain does not appear to differ between cognitively normal individuals and AD patients. It is now believed that significant amyloid beta deposition occurs prior to the clinical symptoms of AD, which instead are linked to the degree of neurodegeneration (progressive damage to and death of neurons). Recent studies indicate that the cognitive and functional decline seen in AD patients clearly correlates with brain atrophy (shrinkage) that is not linked to the accumulation of amyloid beta in the brain. An updated version of the amyloid hypothesis suggests that a close relative of amyloid beta protein may be the culprit in the disease, whereas amyloid beta plays a complementary role. In this view, an amyloid-related mechanism that is involved in pruning neural connections early in life to eliminate nonproductive neural circuits may be triggered later in life to cause the death of neurons seen in AD.

Tau Hypothesis

The third major hypothesis about the causes of AD is the tau hypothesis. According to this view, abnormalities in the protein tau, the main component of the neurofibrillary tangles, cause the progressive neurodegeneration and clinical symptoms of AD. In this model, tau proteins pair with other threads of tau to form tangles inside neurons. These cause the disintegration of the neurons' internal support structure and transport system (the microtubules), disrupting communication between neurons and later leading neurons to collapse and die. Consistent with the tau hypothesis, the degree of tau tangle aggregation correlates with neuronal loss and appears to agree with clinical indicators of disease severity. In line with the clinical progression of AD, tau tangles first form in brain regions that are important for memory (hippocampus and entorhinal cortex), then spread to other cortical regions involved in cognition and behavior, and only later affect sensory and motor cortex, which control sensation and movement. Also consistent with the tau hypothesis, the APOE4 gene, the main genetic risk factor for late-onset AD, has been associated with increased tangle load through a different mechanism than its effect on amyloid beta. Based on these findings, potential tau-based drug treatments are currently being investigated.

Other Potential Causes

In addition to these three main hypotheses regarding the causes of AD, a number of other mechanisms have been proposed that may cause or contribute to the cause of AD. The mitochondrial cascade hypothesis holds that late-onset AD is caused by alterations in the function of the cell's mitochondria, which are responsible for energy production in cells. Increasing amounts of evidence also indicate that inflammatory processes are involved in the neurotoxicity of AD. Inflammation is the response of the immune system to injury, irritants, or infection. However, it is not clear whether inflammation is a causative agent or a downstream reaction to other events, such as amyloid and tau pathology. AD brains also show evidence of injury mediated by oxidative stress, in which increased release of unstable oxygen, such as free radicals, causes damage and possibly death of neurons. Furthermore, insulin resistance, which is seen in type 2 diabetes, has been linked to AD, although the causal mechanism is unclear. Because most

patients with AD also suffer from small-vessel cerebrovascular disease (narrowing of the small blood vessels in the brain), it has been suggested that there may be a common cause for both AD and small-vessel cerebrovascular diseases or that the two diseases are mechanistically linked. Taken together, current research suggests that multiple factors contribute to the causes of AD and that the balance among these various causes may vary from patient to patient.

Diagnosis

The most definitive diagnostic method is through postmortem examination. The suspected AD brain is tested for amyloid beta plaques, neurofibrillary tangles, and amyloid angiopathy (the formation of amyloid inside the walls of cerebral blood vessels) using antibody stains. According to postmortem diagnosis of AD, 80–90% of the antemortem clinical diagnoses are correct.

Diagnosis of AD in a person with memory complaint is based on criteria specified in the Diagnostic and Statistical Manual IV – Text Revision and from the National Institute of Neurological and Communicative Disorders and Stroke and Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA). The set of criteria states that memory loss should be established and disrupted function occurs in at least one other cognitive domain, such as language or perception, or that executive function is impaired. Some additional common symptoms include confusion, hallucinations, withdrawal, and agitation. To distinguish AD from other cognitive debilitating diseases, the onset of the symptoms must be subtle and the condition deteriorates gradually. Mild cognitive impairment (MCI) describes the category of patients who do not fit into the AD diagnosis but who do display noticeable cognitive deficits such as memory complaints. The symptoms of MCI patients do not interfere with daily life.

Many screening tests have been developed for AD diagnosis. The most commonly used is the mini-mental state exam (MMSE), which assesses competence in language, memory, basic motor skills, and orientation. Despite MMSE's widespread usage, its weaknesses include lengthiness, insensitivity to the extremes of the disease spectrum, and vulnerability to differences in education level, gender, age, and cultural background. The modified version of MMSE includes additional tests for executive function and visuospatial ability to improve the tests' reliability and validity, but the modifications have lengthened the test even further. Some medical practitioners recommend using other more accurate cognitive tests in place of MMSE, such as the Montreal Cognitive Assessment (MOCA), the DemTect, the 7-minute Screen, the General Practitioner Assessment of Cognition, and the Behavioural Neurology Assessment Short Form. The MOCA and the DemTect, in particular, are more sensitive to MCI diagnosis. The MOCA covers a wider array of cognitive abilities than the MMSE, such as clock drawing, executive functions, and abstraction. The DemTect includes word recall, semantic word fluency, backward digit span, and number transcoding.

Screening tests enable quick detection of potential AD occurrence, but a full neuropsychological assessment is necessary to accurately diagnose the disease and to distinguish it

from other dementing diseases. A typical testing battery assesses both verbal and nonverbal memory, language, attention, praxis, problem solving, and activities of daily living. Examples of tests administered to assess these abilities include the Selective Reminding Test (SRT) for verbal memory, the Benton Visual Retention Test (BVRT) for nonverbal memory, the Boston Naming Test (BNT) for language ability, the Digit Span subtest of the Wechsler Adult Intelligence Scale-Revised (WAIS-R) for attention, the Block Design subtest of the WAIS-R for praxis, the Wisconsin Card Sorting Test for problem solving/abstract reasoning, and the Philadelphia Geriatrics center Forms for activities of daily living.

A full neuropsychological battery is crucial to AD diagnosis. Loewenstein et al. (2001) reported that, rather than a single factor, multiple distinct cognitive domains are impaired in AD. To confirm a dementia diagnosis, two or more cognitive functions have to be abnormal as determined by neuropsychological tests. Studies have further shown that different stages of AD have distinct neuropsychological profiles and may help to identify milder forms of AD. For example, Vliet et al. (2003) found that memory and abstract reasoning deficits best differentiated a group of mild AD patients from healthy elders, while scores on memory tests separated MCI patients from healthy elders.

An important diagnostic step is to administer laboratory tests to exclude the possibility of other diseases, such as thyroid diseases and anemia, which may explain the observed symptoms and thus can potentially reverse the memory deficits. Vitamin B12 deficiency contributes to cognitive deficits and has to be ruled out as a possible cause of symptoms as well.

Biomarkers

Another diagnostic step is to test for specific biomarkers found in AD. The biomarkers with the highest specificity and sensitivity are decreased levels of amyloid beta, increased total tau levels, and increased phosphorylated tau in cerebrospinal fluid. However, the necessity of a lumbar puncture, an invasive and uncomfortable procedure, to obtain these biomarkers contributes to these tests being underutilized. A number of AD biomarkers can be obtained with the less invasive method of blood draw, including amyloid beta autoantibodies, APOE, and isoprostanes, but these produce less reliable results.

Brain imaging has traditionally been used as a diagnostic tool for excluding lesions as a cause of symptoms. With recent development in imaging, however, it is becoming a valuable tool for confirming AD diagnosis. Using high-resolution structural magnetic resonance imaging (MRI), the amount of atrophy of the hippocampus, a structure that is vital for forming new long-term memories, provides high sensitivity and specificity for distinguishing AD, MCI, and healthy controls. Calculation of atrophy level is currently most accurately performed manually and takes up to 2 h. Even though programs are being developed to automate the process, which reduces the calculation time to 30 min, there is a lack of a well-validated automated procedure. Other structural imaging modalities being evaluated as a potential AD diagnostic tool include voxel-based volumetry (measures reduction in cortical gray matter), deformation-based morphometry (quantifies the amount of structural deformations in the brain from a standard template), and cortical thickness measures. These methods combined

with multivariate statistics have great potential for clinical diagnosis of AD and MCI.

Research efforts are also underway toward the imaging of brain metabolism for AD diagnosis. Fluorodeoxyglucose positron emission tomography (FDG-PET) measures glucose metabolism in the brain, which shows different patterns of activation in the parietotemporal areas for AD and normal controls with a sensitivity of 90% and a specificity of 70%. Rather than relying on glucose metabolism, a more direct technique uses Pittsburgh Compound B (PiB)-PET, which binds to amyloid plaques and fibrils to image brain regions with amyloid deposition. While studies have found greater PiB binding in AD and to a lesser degree in MCI patients, conflicting results have been reported regarding the relationship between PiB binding and memory abilities. Nevertheless, PiB-PET is under extensive research as a potential diagnostic tool for AD and MCI. Functional magnetic resonance imaging also has potential utility in AD diagnosis. For example, synaptic loss can be located with cerebral blood flow and cerebral blood volume, allowing disease progression to be tracked over time.

A comprehensive AD diagnosis procedure should include a selective combination of the instruments introduced here. For example, the Preclinical AD Scale (PAS), developed to distinguish MCI patients who will convert to AD within 5 years of MCI diagnosis from those who do not, includes six instruments: age, MMSE score, functional impairment, cognitive test performance, hippocampal atrophy, and APOE genotyping. As each of the instruments are developed and validated by further research, a more comprehensive battery of instruments will provide better accuracy in AD diagnosis.

The Brief Smell Identification Test

An interesting diagnostic test that takes advantage of olfactory deficits occurring early in AD and progressing with disease severity is under investigation at Columbia University. Ten items from the lengthier University of Pennsylvania Smell Identification Test (UPSIT) were selected to create the Brief Smell Identification Test (B-SIT) to accommodate the need for short tests in a clinical setting. Study results showed promising diagnostic capability in the B-SIT to distinguish AD, MCI, and normal controls. Furthermore, the test also identified patients who would convert from MCI to AD in follow-up visits. Replication is needed, however, to validate the test by other research groups.

One criticism of using UPSIT items for testing people with cognitive decline is its reliance on memory of odors and verbal ability. As an alternative, the Sniff Magnitude Test (SMT) uses foul smells to test for olfactory deficit and only asks subjects to report the presence or absence of smell in sniff canisters, and thus may be a better diagnostic tool.

Genetics

Genetic contributions to the development of AD differ by disease onset. Early-onset AD, characterized by disease onset before 65 years old, is attributed to mutation in genes that encode APP and the presenilins (PSEN1 and PSEN2), while the risk of having late-onset AD is associated with a gene that

encodes APOE. Hundreds of other genes have been reported to mediate the risk for late-onset AD, but none has been consistently associated with the disease. Familial AD, characterized by two or more family members diagnosed with AD, occurs in 25% of AD cases. Familial AD can be early as well as late onset, with mutations in the APP and presenilin genes accounting for 71% of early-onset familial AD. Mutation in the APP gene is classified as AD1 and occupies 10–15% of early-onset familial AD. Mutations in the PSEN1 and PSEN2 genes are classified as AD3 and AD4, respectively. Whereas AD3 occupies 20–70% of early-onset familial AD, AD4 is rarely observed.

APOE contributes to an increased risk of having late-onset AD via influencing amyloid beta metabolism. APOE has three isoforms (alleles $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$), of which $\epsilon 4$ is associated with the highest risk for AD such that relative to someone without an $\epsilon 4$ allele, having one $\epsilon 4$ allele increases AD risk by 2–3 times and having two $\epsilon 4$ alleles increases the risk by 12 times. The $\epsilon 4$ allele may exert its effect via the onset, location, and amount of amyloid beta accumulation in the brain. Studies have found that in cognitively normal subjects, the amount of amyloid fibers that make up the plaques in AD increases with the occurrence of APOE $\epsilon 4$ allele. Having the $\epsilon 4$ allele does not confirm an AD diagnosis; 42% of AD patients do not have the APOE $\epsilon 4$ allele. The $\epsilon 2$ allele, however, decreases the chance of developing AD, but the incident of individuals with this allele is very rare, making the investigation of allele's protective mechanism difficult to perform.

Individuals with Down syndrome have an extra chromosome 21, which contains the gene for APP, resulting in the overexpression of APP and thus an accumulation of amyloid beta in the brain. AD symptoms are observed by the age of 40 in almost all Down syndrome individuals.

Risk Factors and Prevention

Vascular Diseases and Diabetes

A number of factors have been identified to increase the risk of developing AD, and understanding these factors can help prevent the disease. Among the major risk factors are cardiovascular diseases such as hypertension (high blood pressure), dyslipidemia (an elevation of lipids in the blood), and diabetes. Hypertension in midlife has been shown to increase the risk of AD, but the result is less consistent for hypertension developed in late-life due to the decrease in blood pressure prior to and after dementia onset. Antihypertensive drug trials have shown conflicting results in the effectiveness of reducing hypertension on lowering the risk of AD. Hypertension may increase the likelihood of developing AD by increasing the permeability of the blood–brain barrier to proteins, which results in amyloid beta accumulation in the brain. There is evidence that high cholesterol, similar to hypertension, is most predictive of AD when it is developed in midlife. However, study results have been inconsistent, and further longitudinal studies are needed to clarify its relationship to AD.

While a number of studies have shown that diabetes may increase the risk of developing AD, a few other studies did not find a significant correlation between diabetes and AD. The inconsistency may be due to confounding factors such as APOE genotype. When these effects were adjusted for, diabetes

was found to be a significant risk factor for AD. It can be difficult to isolate the effects of diabetes on AD because of the tendency for diabetes to develop in conjunction with cerebrovascular disease, which is a major risk factor for AD. Hyperglycemia (high blood sugar), which is the defining characteristic of untreated diabetes, causes oxidative stress and damage to brain tissue, which are associated with increased risk of AD. Insulin and insulin-degrading enzyme have also been found to worsen amyloid beta metabolism, further increasing the risk of AD.

Cognitive Reserve

The idea of cognitive reserve originated from the observation that given two different people with similar brain injury, one of them may exhibit obvious cognitive dysfunction, while the other may have no behavioral symptoms. This is best demonstrated by cases in which women were diagnosed with AD at autopsy but had no cognitive abnormality before death. Cognitive reserve enables the brain to maintain cognitive abilities despite brain damage, and thus, having a high level of cognitive reserve can help reduce the risk of AD symptoms.

A number of factors are positively associated with cognitive reserve: education, occupation, physical activities, and social and leisure activities. The majority of studies relating the level of education to the incidence of dementia found that education has a protective role in developing dementia, but a few studies have also reported the effect of lack of education with dementia. Furthermore, even in healthy elders, a higher level of education is associated with slower cognitive decline. Similarly, the degree of cognitive complexity in different occupations and the amount of personnel management have been shown to be associated with a lower risk of dementia. Overall, the risk of dementia is lowered with increased education, more demanding occupation, greater amounts of physical exercise, and more engagement in social and leisure activities.

A possible mechanism through which cognitive reserve decreases the risk of AD is the availability of more neuronal connections and more efficient processing, such that damage in one pathway may be compensated by using another pathway. This way, normal function can be maintained despite damage. Life experiences may increase cognitive reserve by inducing changes in neuronal processes such as greater cerebral activation and increased glucose and oxygen metabolism, and possibly reduced neurodegeneration. Higher education level and career complexity may also be associated with a healthier lifestyle and thus lower exposure to neurotoxins such as heavy drinking. The most likely possibility, however, is a combination of these different causes.

Diet

Studies on the relationship between individual nutritional components, such as antioxidants, vitamins, folic acid, and dietary fats, and risk of AD have not produced consistent results. An exception is moderate alcohol intake in which moderate amounts of alcohol (less than three servings per day) has been shown to lower the risk of AD. There is accumulating evidence, however, suggesting that certain dietary patterns are effective in lowering the risk of AD. One of the most

promising dietary patterns is based on the Mediterranean cuisine (the Mediterranean diet), consisting of vegetables, legumes, fruits, cereals, olive oil, fish, and a moderate amount of alcohol. The Mediterranean diet is associated with a lower risk of AD, and oxidation, inflammation, vascular, and metabolic disease. Furthermore, a reduction of 61–67% in AD risk was reported when the Mediterranean diet was followed along with physical exercise in elderly individuals.

Other Risk Factors

Experimental evidence suggests that traumatic brain injury may contribute to AD development. Studies have found that APP accumulates in injured axons (projections of neurons that transmit information away from the neuron's cell body), which could result in amyloid beta production. In a pig model, amyloid beta and APP were found in neurons after injury to axons. Similarly, amyloid beta accumulation and amyloid plaques were also reported in patients with axonal injury. Nevertheless, consistent evidence is lacking in epidemiological studies relating head trauma to AD.

Cigarette smoking and obesity have also been shown to increase the risk of AD, most likely because of their effect on cardiovascular health. Exposure to metals and solvents has been suggested to increase the risk of developing AD, but these findings could not be confirmed by other studies. The evidence for a link between AD and exposure to electromagnetic fields, such as power lines, electrical wiring, radio waves, X-rays, and microwaves, is also inconclusive. Occupational exposure to heavy metals, such as aluminum or mercury, has also been linked to increased risk of AD, but the evidence is mixed.

Treatment

Currently, there is no cure for AD, or a treatment that slows the neurodegeneration seen in AD. However, some drug treatments are available that can ameliorate or slow down the worsening of the symptoms of AD for a limited time in some individuals. Non-drug-based psychosocial treatments are frequently used in clinical practice, but few studies have examined their effectiveness in controlled double-blind trials.

Drug Therapies

Most currently available drugs to treat AD are based on the cholinergic hypothesis (see section 'Causes'). These drugs, also called cholinesterase inhibitors, act by increasing levels of the neurotransmitter acetylcholine in the brain to counteract the loss of cholinergic neurons. Clinical trials have shown modest improvements in cognition, function, and behavior of AD patients treated with cholinesterase inhibitors, with the greatest benefits being apparent in early stages of the disease. There seems to be little difference in the efficacy of various cholinesterase inhibitors, although some of them tend to be better tolerated by patients and have fewer side effects. Prescribing cholinesterase inhibitors to patients with MCI does not seem to delay the onset of AD. Another type of drug, memantine, reduces the effect of the neurotransmitter glutamate in the

brain. It was developed based on the finding that AD is associated with excessive release of glutamate, which can be toxic to neurons. In the United States, memantine is approved for the treatment of moderate-to-severe AD, while in Europe it is used to treat a variety of neurological disorders. Memantine has shown consistent but small effects in improving cognition and global assessment. It is associated with a few mild adverse side effects.

In general, treatment effect sizes for both cholinesterase inhibitors and memantine tend to be small, though statistically reliable, for measures of cognition and global assessment. Effects on behavior and quality of life seem to be less consistent. Both types of drugs have shown some improvement of neuropsychiatric symptoms associated with AD, such as delusions, hallucinations, apathy, and aggression. The benefits of cholinesterase inhibitors and memantine tend to be lost when the drug is discontinued. The usage of standard antipsychotics, antidepressants, anticonvulsants, and antianxiety drugs for the treatment of AD-related neuropsychiatric and behavioral symptoms is problematic, because their modest effectiveness is offset by the risk of serious adverse side effects and increased risk of mortality.

Several other drug treatments have been proposed, but they are not recommended for routine use at this time because of insufficient efficacy and/or safety in placebo-controlled trials. These include vitamins B, C, and E, folic acid with or without vitamin B12, the herbal extract ginkgo biloba, nonsteroidal anti-inflammatory drugs (such as aspirin or ibuprofen), hormone replacement therapy, the hormone melatonin, cholesterol-reducing statins, and the iron-reducing agent desferrioxamine. Currently, many other products are being tested, such as tau and tangle-reducing drugs and stem cell therapies to replace injured neurons.

Psychosocial Therapies

Much of the published evidence regarding psychosocial treatments is characterized by several limitations, including inadequate sample sizes, short study duration, use of non-standardized evaluation methods, lack of proper controls, and inadequate information on the persistence of treatment effects. In addition, studies are often not specific to AD but focus on dementia in general. Overall, the beneficial effects of psychosocial treatments are small and of a short duration. The effectiveness of particular treatments also seems to vary greatly from patient to patient. Therefore, psychosocial treatments may work best in specific, time-limited situations, tailored to the needs and preferences of an individual. Some interventions may provide pleasure for the patient and/or caregiver and for this reason be valuable despite not being effective in the treatment of the disease. Psychosocial therapies for AD can be classified into four broad groups: behavioral, cognitive, emotion-based, and stimulation-oriented approaches.

The goal of behavioral interventions is to modify specific, maladaptive, or self-destructing behaviors by learning more appropriate behaviors. Overall, behavioral interventions are not effective in treating the overall functioning of patients, but some evidence supports their use in lessening or eliminating specific problem behaviors, such as urinary incontinence.

The benefits of behavioral treatments seem to disappear when treatment is discontinued. The goal of cognitive therapies is to reduce or slow the cognitive decline seen in AD. They include cognitive orientation, cognitive retraining, and skills training. Although modest, short-lived gains in cognition, behavior, and mood have been demonstrated with cognitive therapies, some patients may experience frustration. Stimulation-oriented therapies aim to provide sensory and cognitive stimulation and seem to be modestly effective in improving behavior and mood, and enhancing socialization and the quality of life. They include recreational activities (crafts, games, pets, etc.), music and art therapies, multisensory stimulation, exercise, and aromatherapy. Emotion-oriented treatments focus on improving emotional and social functioning of AD patients and ultimately, the quality of life. They include reminiscence therapy, validation therapy, supportive psychotherapy, sensory integration, and simulated-presence therapy. Currently, there is limited evidence supporting the effectiveness of emotion-oriented therapies.

Societal Impact

Caregiver

Across the world, families are fundamental for the care of patients with dementia. This is particularly true for developing countries, where residential care units are generally unavailable. Individuals with AD need assistance with various aspects of everyday tasks, ranging from legal and financial management to feeding and bathing. AD patients are more likely to need help with everyday tasks than patients with other diseases: 32% of AD patients need help dealing with bladder and bowel incontinence versus only 13% of patients with other diseases. Care is provided by both paid and unpaid individuals, in which unpaid caregivers consist of family members, friends, or neighbors, with ages 50–64 occupying the greatest percentage. Most family caregivers are women, but the number of male caregivers is rising. Due to the slow progression of the disease, providing care for AD and other dementias also lasts for a longer duration than for other types of diseases. The need for care increases as the disease progresses and can be up to 10 h day⁻¹ for patients with severe AD.

The greater demand and longer duration of care leaves the caregiver of an AD patient more susceptible to depression and other illnesses, and can place more strain on the caregiver's finance and career. Studies have found that unpaid caregivers experience greater level of stress and have lower immune function. Some caregivers have to quit their jobs in order to take care of the AD patient, losing financial support and benefits. Caregiver interventions have been effective at increasing caregiver knowledge about AD, improving mood of caregivers, decreasing caregiver stress and depression, decreasing neuropsychiatric symptoms of patients, and delaying nursing home placement of the patient.

Economic Impact

Due to the longer term and extensive care AD patients require, healthcare costs for AD patients can be three times that for individuals of the same age group and will continue to rise as

the number of AD cases increases with the aging population. According to an estimate by the Karolinska Institute, the worldwide cost of dementia amounts to US\$315 billion per year, of which 72% is contributed by high-income countries. Healthcare costs for individuals with AD are not only paid by patients, their families, and government agencies; private businesses also pay indirectly through work missed by employees caring for an AD patient. In the developing world, caregiving is associated with substantial economic disadvantage due to cuts in paid work. A reason for the high healthcare cost for AD patients can be attributed to the tripling of hospital stays relative to the elderly without AD. Besides hospital stays, costs of healthcare for AD patients include greater likelihood of needing to stay in nursing homes and requiring home healthcare.

Glossary

Alcoholic blackout Amnesia without loss of consciousness, in which the intoxicated person retains the ability to perform certain 'automatized' behaviors, without any subsequent memory for the episode.

Amnesia A special case of forgetting in which the memory loss is greater than would be expected under ordinary circumstances. Anterograde amnesia affects memory for events occurring after the instigating event; retrograde amnesia affects memory for events occurring before the instigating event.

Amnesic syndrome A profound deficit in learning and memory usually associated with bilateral damage to the diencephalon or the medial portions of the temporal lobe. It always involves an anterograde amnesia, and may involve a retrograde amnesia as well.

Functional amnesia A significant loss of memory attributable to an instigating event, usually stressful, that does not result in insult, injury, or disease affecting brain tissue. Its most common forms are psychogenic amnesia, psychogenic fugue, and multiple personality disorder.

Implicit memory In contrast to explicit memory, which entails conscious recall or recognition of past events, implicit memory refers to any effect of a past experience on subsequent experience, thought, or action – for example, priming effects.

Infantile and childhood amnesia An amnesia observed in adults, affecting memory for personal experiences occurring in the first 5–7 years of life. Infantile amnesia commonly covers the period before language and speech develop.

Posthypnotic amnesia A retrograde amnesia induced by means of hypnotic suggestion; it may be canceled by a prearranged reversibility cue.

Priming A phenomenon where an event facilitates (positive priming) or impairs (negative priming) performance on another, later task.

Source amnesia A phenomenon where a subject retains access to new information acquired during a learning experience, but forgets the learning experience itself; it is commonly reflected in *cryptomnesia*, or unconscious plagiarism.

Transient global amnesia A benign and temporary amnesia characterized by sudden onset, apparently caused by momentary vascular insufficiencies affecting brain tissue.

Trauma-memory argument The notion, rooted in the nineteenth century ideas of Sigmund Freud and Pierre Janet, that psychological trauma causes amnesia by virtue of a process of repression or dissociation.

Traumatic retrograde amnesia A retrograde amnesia resulting from a concussive blow to the head; most of the affected memories are eventually recovered, except for a 'final RA' affecting the accident itself.

Amnesia

Amnesia may be defined as a special case of forgetting, where the loss of memory is greater than would be expected under ordinary circumstances. A head-injured patient is no longer able to learn things that he was once able to master easily; a patient with psychogenic fugue loses her personal identity as well as her fund of autobiographical memories. Amnesia includes frank pathologies encountered in neurological and psychiatric clinics, such as the amnesic syndrome, Alzheimer's disease (AD), traumatic retrograde amnesia (RA), and the interpersonality amnesia characteristic of multiple personality disorder (MPD). But it also includes abnormalities of memory observed ubiquitously, such as infantile and childhood amnesia, the exaggerated forgetfulness associated with normal aging, and the memory failures associated with sleep and general anesthesia. These naturally occurring failures of memory have their counterparts in amnesic states induced in otherwise normal, intact individuals by means of experimental techniques, such as electroconvulsive shock (ECS) in laboratory rats and posthypnotic amnesia in college sophomores.

Experimental research on memory began with the publication of Ebbinghaus' *Über das Gedächtniss* (*On Memory*) in 1885,

but the clinical description of amnesia dates from even earlier. Korsakoff first described the amnesic syndrome that bears his name in 1854. And in 1882, Ribot published *Les Maladies de la memoire* (*Diseases of Memory*), with a detailed description of the consequences for memory of brain insult, injury, and disease, as well as a unified theory of memory and amnesia. On the basis of his observations, and Hughlings Jackson's principle that ontogeny recapitulates phylogeny, Ribot concluded that brain disorder produces a progressive loss of memory that affects memories in the reverse order of their development. Thus, in traumatic RA, memories for events occurring immediately before the accident are most likely to be lost. This principle, now known as *Ribot's law*, does not always hold, but it was an important first step in the journey from clinical description to scientific theory.

For reasons that are not completely clear, clinical and experimental study of amnesia languished for the first half of the twentieth century, but was revived by observations of a patient, H.M. (full name: Henry Molaison), who became amnesic following surgical resection of portions of his medial-temporal lobes, including the hippocampus, in a desperate attempt to relieve intractable epileptic seizures. From the time of his operation in 1953, at the age of 27, until his death in 2009 at the

age of 82, he had no conscious recollection of any episode in his life. In addition, George Talland's 1965 pioneering monograph, *Deranged Memory*, reported an extensive psychometric and experimental study of amnesic patients with Korsakoff syndrome. These studies ushered in a 'golden age' of amnesia research in which clinicians and experimentalists joined forces under the banner of *cognitive neuropsychology* (later, renamed cognitive neuroscience) – a discipline that attempts to integrate evidence obtained from the intensive study of brain-damaged patients with theories of normal cognitive function.

The Amnesic Syndrome

The amnesic syndrome represents a profound deficit in learning and memory; it is by far the most commonly studied pathology of memory. Its most characteristic feature is a gross anterograde amnesia (AA), meaning that the person cannot remember events that have occurred since the time of the brain damage. Short-term memory (as measured by digit span, for example) is unimpaired; but after even a few moments' distraction, these patients cannot remember what they have said or done, or what has been said or done to them, just recently. In the classic case, the patient's cognitive deficits are specific to long-term memory: general intelligence, perception, reasoning, and language functions are spared. But this AA is associated with several different etiologies, and these disparate origins are associated with somewhat different patterns of memory and cognitive deficit. For more details, see 'Amnesia and the Brain' by Race and Verfaellie, following this article.

One form of the amnesic syndrome, now known as *diencephalic amnesia*, was first described by Sergei Korsakoff in association with alcoholism. These patients typically show RA as well as AA, meaning that they also have difficulties in remembering events from their premorbid life, especially those from the years immediately preceding their disease. Remote memory, such as for childhood events, is apparently preserved. Note that such a pattern conforms to Ribot's law. Chronic alcoholics often suffer from a deficiency of vitamin B₁ (thiamine) which results in bilateral damage to structures of the diencephalon, including the upper portion of the brainstem, the mammillary bodies, the dorsomedial nucleus of the thalamus, and the mamillothalamic tract. The acute phase of illness, known as Wernicke's encephalopathy, is characterized by confusion, disorders of visual function, and ataxia; Korsakoff's syndrome emerges as the chronic phase (the entire course of illness is sometimes known as Wernicke–Korsakoff syndrome). Although this disease is now typically prevented by the introduction of vitamin-enriched commercial foods, other etiologies, including vascular insufficiencies, tumors, and frontotemporal brain damage can have similar effects.

Another form of amnesic syndrome, known as *temporal lobe amnesia*, stems from bilateral lesions in the medial portion of the temporal lobe, and especially the hippocampus, entorhinal cortex, and surrounding structures (again, there are also material-specific amnesias resulting from unilateral damage to these structures). The most famous case is patient H.M., but there are many other famous cases. Other cases have been caused by brain tumors, ischemic episodes, head trauma, and herpes encephalitis. Temporal-lobe amnesics show AA by definition.

The occurrence of RA in these patients is somewhat controversial, and may vary if damage extends beyond the hippocampus itself. H.M. showed little RA; another patient, R.B., showed an RA covering only about 1 or 2 years prior to his surgery; yet another, K.C., displayed an RA covering his entire premorbid life.

There is also *frontal-lobe amnesia*, which is qualitatively different from the amnesic syndrome. Frontal-lobe patients are not globally amnesic, but they frequently show deficits on tasks requiring memory for temporal order, as well as memory for the source of newly acquired knowledge. They also lack *metamemory* capabilities – that is, they have little appreciation of the contents stored in their own memories, or in the availability of appropriate memory strategies. Patients who have frontal damage in addition to diencephalic or medial-temporal lobe damage experience their greatest difficulties on memory tasks requiring strategic planning and organization, suggesting that frontal damage may impair executive function, rather than memory per se.

Finally, *transient global amnesia* is a temporary (typically lasting several hours) condition characterized by sudden onset. It closely resembles the permanent diencephalic and medial-temporal lobe amnesias, in that it involves both AA and RA, but – as its name implies – it is brief. The condition, while frightening, is benign: after remission, there are no signs of permanent brain damage (and little risk of another episode in the future). Transient global amnesia appears to be caused by temporary vascular insufficiency affecting brain tissue; interestingly, many cases appear in association with physical exertion or mental stress.

In the absence of permanent brain damage, something akin to the amnesic syndrome may be observed in cases of *alcoholic blackout*. Blackout involves amnesia without loss of consciousness. The intoxicated individual may engage in conversation or perform other actions normally; but after regaining sobriety, he or she will have no memory for the episode. Blackouts are most commonly observed in chronic alcoholics, though they do occur to nonalcoholics who are severely intoxicated. In any case, blackout is most likely to occur when the person ingests large quantities of alcohol rapidly, especially when fatigued or hungry. Alcohol folklore suggests that the amnesia is an instance of state-dependent retrieval – that is, that the memories return when the person resumes drinking. However, laboratory research clearly indicates that the memories covered by blackout are unrecoverable, and thus that the amnesia reflects an encoding deficit. Sedative drugs, such as barbiturates and benzodiazepines, also produce irreversible AA.

The different patterns of task performance offer clues about the nature of the memory deficit in the amnesic syndrome. In principle, any instance of forgetting may be attributed to a failure at one or more of three stages of memory processing: encoding (the creation of a memory trace of a new experience), storage (the retention of trace information over time), and retrieval (the recovery of trace information for use in ongoing experience, thought, and action). Logically, a syndrome that affects memory for postmorbidity but not premorbidity events is most likely due to encoding failure. And, in fact, it has been suggested on the basis of laboratory experiments with lesioned rats and monkeys that the hippocampus and other structures in the medial-temporal lobe mediate the consolidation and storage of new memories. An alternative formulation assumes

that representations of the various elements of an event are distributed widely in the cortex, and that the hippocampus creates a kind of index and binds the elements together. In either case, the occurrence of AA means that the hippocampus is crucial for memory formation, even though the memories themselves are not stored there.

What about the RA? Some degree of RA is usually, but not always, observed in the amnesic syndrome. Logically, damage to a structure that consolidates and organizes new memories should have no effect on old ones. In some cases, RA may reflect the disruption of premorbid memories that were incompletely consolidated at the time of disease onset; this would produce a temporal gradient, but the extent of RA observed would seem to imply that proper consolidation requires weeks, months, or years instead of seconds, minutes, or hours. On the other hand, if the hippocampus serves a binding and indexing function, its destruction will create an RA by effectively preventing the retrieval of memories that remain available in storage; this would produce an amnesia for remote as well as recent memories and would not necessarily produce a temporal gradient. In some cases, what appears as RA may in fact be AA, reflecting the slow onset of an insidious disease process – and producing the appearance of a temporal gradient; this suggestion is particularly plausible in the case of diencephalic amnesia associated with chronic alcohol abuse but cannot account for amnesias of sudden onset. It has also been suggested that the RA may reflect the fact that, once activated and retrieved, premorbid memories are then *re-encoded*: as a result, the same encoding failure that produces the AA for postmorbid events results in a progressive loss of premorbid memories as well, and emergence of RA.

Even conclusions about encoding deficits must be qualified to some extent. At first glance, the AA observed in the amnesic syndrome appears to be a complete inability to acquire new information. However, closer examination indicates that certain aspects of learning and memory are spared even in the densest cases of amnesia. Thus, the patient H.M. learned to solve the Tower of Hanoi puzzle, but he did not recognize the puzzle as familiar. Amnesic patients who study the word *ELATED* do not remember it just minutes later; but when presented the stem *ELA* and asked to complete it with the first word that comes to mind, they are more likely to produce *ELATED* (as opposed to *ELASTIC* or *ELABORATE*) than would be expected by chance. The ability of amnesic patients to acquire cognitive and motor skills, and to show priming effects in word-stem completion and other tasks, shows that they are able to acquire new information through experience – although, somewhat paradoxically, they do not remember these experiences and may not be aware that they possess this knowledge.

The limits of such learning are still being studied, but already they have motivated a distinction between two expressions of episodic memory, *explicit* and *implicit*. Explicit memory (EM) refers to the conscious recollection of a previous episode, as in recall or recognition. By contrast, implicit memory (IM) refers to any change in experience, thought, or action that is attributable to such an episode, such as skill learning or priming. The dissociation between EM and IM in amnesic patients indicates that some forms of learning and memory are preserved. According to one view, amnesics suffer from a specific inability to encode declarative knowledge about

specific events, but retain an ability to acquire procedural knowledge. This would account for their ability to acquire new cognitive and motor skills. Preserved priming has been attributed to the automatic activation of declarative knowledge structures that were stored prior to the brain damage, or to the encoding of new episodic representations in a primitive perceptual memory system that lacks the kinds of information (e.g., about the meaning of an event, or its spatiotemporal context) that would support EM.

Traumatic RA

Another form of amnesia occurs as a consequence of head trauma. A very severe blow to the head can bruise gray matter and shear white matter, producing both cortical and subcortical damage that may result in AA and RA similar to that observed in the amnesic syndrome. Even in the absence of such damage, a blow to the head can result in a concussion, or temporary cessation of electrical activity in the cortex and loss of consciousness. The recovery of consciousness begins with the return of simple reflexes, then the gradual return of purposeful movement, and then speech (another pattern predicted by Ribot's law). After the patient appears fully oriented, he or she will display an AA for some time, as well as an RA for the accident itself and the events leading up to the accident. Typically, the AA is immediate, that is, it will start at the time of the trauma. But if the loss of consciousness is delayed, the onset of the AA will be delayed as well. Such *lucid intervals* suggest that the AA is a result of vascular complications that may take some time to develop.

The RA in traumatic amnesia is characterized by a temporal gradient, meaning that it is densest for events nearest the time of the accident – yet another example of Ribot's law at work. However, the gradient is broken by *islands of memory* consisting of isolated events, not necessarily personally important, that are remembered relatively well. The extent of the RA is correlated with the extent of the AA. Although the memories covered by the AA are permanently lost, apparently reflecting an encoding deficit, the RA gradually remits. It was once thought that this recovery began with the earliest memories and proceeded forward, which again would be predicted by Ribot's law. Although the most recent events are generally recovered last, more careful studies show that the shrinkage of amnesia is accomplished by filling in the gaps that surround the islands of memory, leaving a *final RA* covering the accident itself and the moments or minutes leading up to it, and perhaps a few *islands of amnesia*. The shrinkage of amnesia clearly indicates that traumatic RA is a disorder of retrieval, and that the islands of memory act as anchors to support the recovery process. However, the final RA may reflect either a loss of memory from storage or, more likely, a disruption of consolidation.

A nontraumatic form of RA is observed in psychiatric patients who are administered *electroconvulsive therapy* (ECT) for acute affective disorder. In ECT, electrical stimulation (e.g., 100 V, 500 mA for 500 ms), delivered from surface electrodes applied over the temporal lobe, induces a convulsive, tonic-clonic seizure not unlike those of *grand mal* epilepsy; after a short series of such treatments (e.g., 6–10 sessions over 2–3 weeks), patients often experience a rapid return to their normal mood state (ECT is not a cure, as episodes of

depression or mania may recur). Because they are anesthetized when the treatment is delivered, patients experience no pain or distress from the convulsions themselves; because they receive muscle relaxants, the convulsions do not result in bone trauma. However, the seizure does produce both AA and RA as adventitious consequences (i.e., unrelated to treatment success). The RA shows the same sort of temporal gradient observed following concussive blows to the head. Because there is less memory impairment (though no difference in treatment outcome) with unilateral than with bilateral electrode placement, ECT is usually delivered to the nondominant hemisphere. The RA gradually clears up (except for the moments before ECT is actually delivered), but memories affected by the AA cannot be recovered.

The amnesia induced by ECT shows a dissociation between EM and IM similar to that observed in the amnesic syndrome. In one experiment, patients who studied a list of words within 90 min following administration of ECT showed a deficit in recognition, but no deficit in priming on a word-stem completion test. In another study, patients who read word strings presented in mirror-reversed fashion before delivery of ECT later showed an advantage in reading those words, even though they failed to recognize these words as familiar.

What about the memories covered by the final RA? Although ECS may disrupt encoding processes, it does not appear to remove the memory traces from storage. The relevant evidence comes from studies of the effects on memory of ECS administered to animals. A common research paradigm is called one-trial, step-down, passive avoidance learning. A rat is placed on a shelf above an electrified floor. If the animal steps down, it receives a footshock, and jumps back up on the shelf. Under ordinary circumstances, the animal will not return to the floor: it learns in one trial to avoid the shock by doing nothing. But if the animal received a dose of ECS, after it recovers, it steps down onto the floor after being placed on the shelf. It is as if it has forgotten all about the shock.

ECS-induced amnesia shows a temporal gradient similar to that observed in other forms of traumatic RA. If the ECS is delayed from the time of the original learning experience, there is less amnesia than if it is administered immediately afterward. But the extent of amnesia also depends on how memory is measured. The same time at which the amnesic animal steps down (as if the footshock never happened), it shows a marked increase in heart rate (as if it is afraid). Moreover, if the animal receives *reminder treatments* such as tail shock in another environment or immersion in circulating ice water, it will remain on the shelf and avoid the floor. The *desynchrony* between behavioral and psychophysiological indices of fear is analogous to the dissociation between EM and IM observed in human amnesic patients; and the effectiveness of reminder treatments shows that at least some aspects of the forgotten event have been preserved. Memories covered by the final RA may never be accessible to conscious recollection, but they may nonetheless be expressed as implicit memories.

Functional Amnesia

Clinically significant amnesias are not confined to cases of organic brain syndrome. Psychiatrists and clinical psychologists

sometimes encounter forms of *functional amnesia* in a group of mental illnesses known as the *dissociative disorders*. Functional amnesia may be defined as a loss of memory that is attributable to an instigating event that does not result in insult, injury, or disease to the brain. Because there is no evidence of head injury, such memory failures are also labeled as *psychogenic amnesia*. In the classic formulation, which owes much to Sigmund Freud and Pierre Janet, traumatic stress causes amnesia via a psychological process variously labeled as *repression* or *dissociation*. Several forms of functional amnesia are listed in the *Diagnostic and Statistical Manual of Mental Disorders* under the category of the *dissociative disorders*, all of which entail a disruption of conscious memory and identity.

In the twentieth century, the *trauma-memory argument* became an important fixture of popular culture as well as clinical folklore, but empirical evidence in its favor has been surprisingly lacking. Careful prospective analyses indicate that the vast majority of victims of documented trauma, including childhood sexual abuse, remember their experiences perfectly well. Any forgetting that is observed appears most likely due to infantile and childhood amnesia (see later paragraphs), the mere passage of time, or a failure to appreciate the nature of the experience at the time it occurred (meaning that the 'trauma' was not experienced as such). Moreover, both human and animal studies indicate that high levels of physiological arousal, such as would accompany traumatic stress, enhance rather than impair memory – probably due to the activation of β -adrenergic receptors. The problem with patients suffering from posttraumatic stress disorder is not that they cannot remember their trauma; it is that they cannot forget it.

In *dissociative amnesia*, the patient cannot remember specific events, usually covering a continuous period of time, resembling RA; there is no AA. As in the amnesic syndrome and traumatic RA, the patient's fund of semantic and procedural knowledge remain intact. Compared to traumatic RA, dissociative amnesia appears to be more extensive and longer lasting. Clinical lore holds that dissociative amnesia can be reversed by hypnosis or barbiturate sedation, but evidence for the reliability of recollections produced by these techniques is largely lacking. Because of concerns about the inherently suggestive nature of hypnosis, most American legal jurisdictions forbid witnesses from offering testimony based solely on hypnotically 'refreshed' memories.

Dissociative fugue entails a more extensive loss of autobiographical memory, covering the whole of the person's life, a loss and/or change in identity, and sometimes physical relocation (from which symptom the syndrome derives its name). Such cases often come to the attention of police and health providers when a person cannot identify himself; or when she comes to herself in a strange place and does not know how she got there. Interestingly, fugue patients lose self-knowledge and autobiographical memory, but they do not seem to lose their fund of semantic memory, or their repertoire of procedural knowledge. Upon recovery the patient is left with an amnesia covering the events of the fugue state itself, and retains no knowledge of whatever identity he or she may have adopted in that state. Examination of such cases after they are resolved sometimes reveals an instigating episode of psychological stress.

In *dissociative identity disorder* (DID; formerly known as MPD), two or more personalities appear to inhabit a single body, alternating control over experience and action. One of these personalities is often 'primary,' in that it is the one that has been manifest the longest, and known by most other people. Most important in the present context, the various 'alter egos' appear to be separated by an amnesic barrier that prevents one alter ego from gaining access to the memories of another. In many cases, the amnesia is asymmetrical, in that Personality A may be aware of Personality B, but not the reverse. The amnesia largely affects identity and autobiographical memory; as a rule, the various personalities share semantic memory and procedural knowledge. The most widely accepted theory of DID holds that it develops in defense against abuse, trauma, or deprivation in early childhood – but again, actual evidence for a causal link between trauma and any form of amnesia is very weak.

Reports of DID were relatively common in the clinical literature before 1920, and then virtually disappeared. There was a resurgence of DID, bordering on epidemic, beginning in the 1970s, but it is not clear how many of these cases – and there were hundreds if not thousands of them tabulated in the literature – were iatrogenic in nature, or simply misdiagnosed. Where the alternate personalities were initially elicited through hypnosis or other special techniques, or when an amnesic barrier was absent, the case is especially suspect.

DID is sometimes offered as an insanity defense, claiming that a second personality is actually responsible for crimes of which the first personality is accused. DID does raise interesting issues of criminal law: in principle, the actions of one personality may be outside another personality's ability to control; interpersonality amnesia may prevent the accused from assisting in his or her defense; and techniques intended to elicit testimony from a personality may violate constitutional safeguards against self-incrimination. However, DID has rarely proved successful as a defense against criminal charges.

Several experimental studies confirm the existence of interpersonality amnesia in DID. Thus, for example, one alter ego is often unable to recall or recognize a list of items studied by another. Interestingly, there is some evidence that IM may be spared in these cases. Thus, one alter ego may show savings in relearning, interference, transfer of training, or priming effects involving a list studied exclusively by another one. Although the available research is somewhat ambiguous, in general it seems that the amnesic barrier is permeable in the case of implicit memories.

Just as the amnesic syndrome finds its experimental analog in drug-induced amnesia, and traumatic RA in ECT and ECS, the functional amnesias seen in the dissociative disorders have their laboratory parallel in *posthypnotic amnesia*. Following appropriate suggestions and the termination of hypnosis, many subjects cannot remember the events that transpired while they were hypnotized. After the hypnotist administers a prearranged cue, the critical memories become accessible again; the fact of reversibility marks posthypnotic amnesia as a disruption of memory retrieval. The amnesia does not occur unless it has been suggested (explicitly or implicitly), and memory is not reinstated merely by the reinduction of hypnosis; thus, posthypnotic amnesia is not an instance of state-dependent memory. Response to the amnesia suggestion is highly correlated with individual differences in hypnotizability: while

hypnotic 'virtuosos' typically show a very dense amnesia, their insusceptible counterparts show little or no forgetting.

Like the organic amnesias, posthypnotic amnesia selectively affects episodic as opposed to semantic or procedural memory. The subject may forget which words appeared on a study list, but retains the ability to use these words in speech and writing. Skills acquired in hypnosis transfer to the posthypnotic state, and suggestions for amnesia have no impact on practice effects. Subjects who learn new factual information while being hypnotized may retain it despite suggestions for amnesia, but these same subjects may well forget the circumstances in which this knowledge was acquired – a phenomenon of *source amnesia* that has also been observed in the amnesic syndrome and elsewhere. Finally, there is good evidence that priming effects are preserved in posthypnotic amnesia. That is, subjects who cannot remember words from a study list are more likely to use those words as free associations or category instances than would be expected by chance. Thus, posthypnotic amnesia shows the familiar dissociation between EM and IM.

Because functional amnesia occurs in the absence of brain damage, and because posthypnotic amnesia occurs in response to suggestion, questions inevitably arise about malingering, simulation, and behavioral compliance. Unfortunately, it is difficult to distinguish between genuine and simulated amnesia in either clinical or experimental situations. Claims of amnesia are readily accepted when there is palpable evidence of brain damage. It should be understood, however, that evidence of a significant interpersonal or sociocultural component does not necessarily mean that functional amnesia is faked. Rather, it means that functional amnesia is complex. Hypnosis may be a state of altered consciousness, but it is also a social interaction; thus, it should not be surprising to discover that the subject's response to amnesia suggestions will be influenced by the precise wording of the suggestion, the discourse context in which it is embedded, the subject's interpretation of the hypnotist's words, and perceived social demands. The social context may be important in the organic amnesias, but its role is magnified in their functional counterparts.

Amnesia Through the Life Span

Some forms of amnesia occur naturally in the course of psychological development. For example, adults rarely remember much from early childhood: the earliest memory is typically dated between the third and fourth birthdays, and is limited to a relatively small number of isolated fragments until about 5 or 7 years of age. The appearance of childhood amnesia is not merely an artifact of the long retention interval between childhood encoding and adult retrieval: something special seems to happen to memories for childhood events. *Infantile and childhood amnesia* affects only memories for personal experiences. Children acquire a vast fund of information, and a considerable repertoire of cognitive and motor skills, which they carry into adulthood. Whether this selectivity reflects merely the effects of constant rehearsal, or the dissociation between EM and IM similar to that observed in source amnesia, is not clear.

Infantile amnesia, covering the first year or two of life, may be attributed at least in part to the lack of language and to the

immaturity of the neocortex and other critical brain structures. However, the exact mechanism for childhood amnesia, covering the years after the second birthday, remains uncertain. The classic explanation for childhood amnesia was proposed by Freud. In his view, during the phallic stage of psychosexual development, the child resolves the Oedipus complex by repressing infantile sexual and aggressive impulses, as well as any thoughts, images, and memories that might be related to them. Since (according to the theory) the young child's entire mental life is concerned with these topics, all memories of early childhood are repressed – except a couple of banal *screen memories* that aid repression by giving the person something to remember. Recall that the major goal of psychoanalysis is to lift the repressive barrier, so that patients can acknowledge and cope realistically with their primitive instinctual urges. Other theories emphasize the relationship between cognitive processes employed at encoding and retrieval. For example, Ernst Schachtel proposed that memories encoded by preoedipal, 'primary-process' modes of thought cannot be retrieved by postoeidipal, 'secondary-process' schemata. A similar account can be offered from Piaget's perspective, emphasizing the incompatibility between sensory-motor and preoperational encodings, and the retrieval processes characteristic of concrete and formal operations. Note that all these theories predict that memories of childhood experience should be accessible to young children, who have not undergone the 'five-to-seven shift' (so named because of the major cognitive change occurring between these ages) between preoperational thought and concrete operations. In contrast, some theorists have argued that young children simply do not possess the information-processing capacity – specifically, the ability to pay attention to two things at once, like an event and its episodic context – required to encode retrievable memories. In this case, the prediction is that children will know little more about their childhood histories than adults do.

Although infantile and childhood amnesia are often attributed to autochthonous aspects of cognitive and neural development, it is clear that the child's interactions with other people are extremely important determinants of whether he or she will remember some past event. After all, as Ulric Neisser has pointed out, the 'five-to-seven year shift' is not simply a matter of moving from the preoperational period to concrete operations (or, for that matter, from before to after the acquisition of a theory of mind). It is also when the child first goes to school, and moves into an environment that is more structured with respect to time and place – thus affording the child an opportunity to distinguish one event from another. Even before the child enters school, research by Katherine Nelson, Robyn Fivush, Judith Hudson, and others underscores the important role played by joint reminiscence between child and parent in shaping the child's appreciation of narrative structure, including the causal as well as temporal relations among events, thus strengthening individual memories and connecting them both with each other and with the present.

At the other end of the life cycle, it appears that even the healthy aged have difficulty learning new information and remembering recent events. *Normal aging* has little effect on primary or short-term memory, as reflected in digit span or the recency component of the serial-position curve; but it has

substantial effects on secondary or long-term memory, especially after moderately long retention intervals. Again, the deficit primarily affects episodic memory: the elderly do not lose their fund of semantic information (although they may become slower on such semantic-memory tasks as word-finding); and their repertoire of procedural knowledge remains intact, provided that they have been able to maintain these skills through practice.

At the same time, it should be noted that episodic-semantic comparisons almost inevitably confound the type of memory with retention interval. Memories of recent experiences have, by definition, been encoded recently; most semantic knowledge was acquired while the individual was relatively young. Surprisingly, little is known about the ability of older individuals to learn new vocabulary or acquire new world knowledge. The aged do show impairment in episodic memory for remote events, but it is not clear whether this reflects age differences in retrieval processes, or simply the effects of the retention interval and opportunities for proactive and retroactive interference.

A relatively recent topic in research on aging memory compares EM and IM. Compared to the young, the aged show definite impairments on EM (especially free recall, less so on recognition); but they show less deficit, or none at all, on IM tasks such as stem completion. Part of the reason for their problems with EM may lie in the difficulty that the elderly have in processing contextual information. Spatial context, temporal context, and source are necessary for distinguishing one event from another, and thus crucial to conscious recollection. Whether this difficulty is specific to contextual features of events, or merely a reflection of a more general limitation on cognitive resources, is unclear.

Memory problems are confounded in the *dementing illnesses* often associated with aging – for example, AD. The severe memory problems associated with AD are likely related to the increase of neuritic plaques and neurofibrillary tangles, particularly in medial-temporal regions of the brain. These changes, as well as neuronal loss and depletion of neurotransmitters in other cortical and subcortical areas, especially the hippocampus and other medial-temporal lobe structures, contribute to the extensiveness of the disease process. Both AA and RA emerge early in the course of these diseases, and progressively worsen. In contrast to the amnesic syndrome, however, the memory deficit in dementia affects 'short-term' as well as 'long-term' memory, and forms part of a larger cluster of deficits affecting a broad swath of cognitive and emotional life, including impairments in semantic and procedural memory as well as episodic memory. In the latter stages of their illness, demented patients may show *anosognosia*, or a lack of awareness of their deficits.

Does the abnormal forgetting observed in aging and dementia extend to IM as well as EM? Research on this question is still at a very early stage, but already it seems fairly clear that IM is relatively spared in normal aging. Thus, elderly subjects fail to recognize studied words, but show priming effects on word-fragment completion. With respect to AD and other forms of dementia, however, some controversy remains. There is some evidence of intact motor-skill learning in AD patients, but there is also evidence of impaired performance on priming tasks. The issue is complicated by the fact that AD is

a progressive illness. Although impairments in EM may be observed quite early in the course of the disease, deterioration of IM may wait until later stages.

Amnesias of Everyday Experience

Amnesia is a symptom of neurological or psychiatric disorder, but it is also something that occurs in the ordinary course of everyday living. The most familiar example is *sleep*. A great deal transpires while we are asleep, including events in the external environment and endogenous activity such as dreams, nightmares, and (in some cases) episodes of somnambulism (sleep-walking) and somniloquy (sleeptalking), but virtually none of this is remembered in the morning. In fact, our inability to remember what has been happening is often the phenomenological basis for inferring that we have been asleep. Similarly, attempts at sleep learning have been almost uniformly unsuccessful, leading investigators to conclude that we are able to learn during sleep only to the extent that we stay awake. A paradox here is that a large body of evidence now indicates that sleep plays an important role in the consolidation of *presleep* memories.

Most investigators explain sleep-induced amnesia in terms of an encoding deficit or consolidation failure. According to this view, the low levels of cortical arousal characteristic of sleep effectively impair complex information-processing functions. Thus, events in the environment are not noticed, relevant information in memory is not retrieved, and traces of new experiences are not encoded in retrievable form. Some evidence favoring this view comes from studies of memory for dreams. Sleepers who are awakened during REM sleep almost invariably report a dream, apparently by virtue of retrieval from primary memory; but dreams are rarely reported upon awakening in the morning, which requires access to trace information in secondary memory. However, subjects will remember a dream in the morning if they awaken directly out of REM sleep. And dreams reported during REM awakenings will be accessible in the morning, provided that the dreamer has remained awake long enough to rehearse the dream before returning to sleep.

Most evidence of sleep-induced amnesia comes from studies of EM, leading to speculation that evidence of memory for sleep events, including successful sleep learning, might be obtained with measures of IM. Research on this topic has only just begun, but the available evidence is negative. When care is taken to insure that there is no evidence of cortical arousal indicative of awakening, subjects show neither EM nor IM for events that occurred while they were sleeping. Even if positive evidence for sleep learning were obtained, it would almost certainly not be as efficient as learning in the normal waking state.

Amnesia is also an important component of *general anesthesia* induced in surgical patients. Clinically, the success of general anesthesia is indicated by the patient's lack of response to instructions, suppression of autonomic and skeletal responses to incisions and other surgical stimuli, and absence of retrospective awareness of pain and other events occurring during surgery. Thus, by definition, amnesia is a consequence of adequate general anesthesia. But, as with

sleep, the amnesia is always assessed in terms of EM, leaving open the possibility that even adequately anesthetized patients might show IM for surgical events. Some anecdotal evidence favoring this proposition is provided by occasional cases in which patients awaken from surgery with an inexplicable dislike of their surgeon – an attitudinal change which is plausibly traced to unkind remarks made about the patient by members of the surgical team.

In recent years, this question has been the object of considerable investigation, and in fact research employing paradigms derived from studies of the amnesic syndrome has sometimes, but not always, provided evidence of spared IM. Thus, patients who are presented a list of words during surgery, sometimes show significant priming effects. Such effects are not always obtained, however; and even when they are obtained, they are relatively small. Certainly the scope of information processing during general anesthesia cannot compare to what is possible when the patient is awake and properly oriented; for example, IM after anesthesia may well be limited to the processing of the physical properties of stimuli, but not their meaning. What accounts for the different outcomes across the available research is not clear. Perhaps some anesthetic agents impair EM but spare IM, while others impair both. Such a result might yield interesting insights about the biological foundations of memory.

Theoretical and Practical Implications

Research on amnesia is intrinsically interesting, but it also has theoretical and pragmatic implications. At the theoretical level, amnesia engages our attention because it seems to carve nature at its joints. Amnesia is selective, and the difference between those aspects of memory that are impaired in some form of amnesia, and those that are spared, promises to provide information about the processes underlying memory functioning and the organization of memory into different systems. Such conclusions are based on the *logic of dissociation*. In single dissociations, Variable A affects performance on Task Y but not Task Z; in double dissociations, Variable A affects Y but not Z, while Variable B affects Z but not Y; in reversed associations, changes in A increase Y and decrease Z, while changes in B decrease Y and increase Z; in stochastic independence, performance on Task Y is uncorrelated with performance on Task Z. All other things being equal, differences such as these suggest that the tasks in question differ in qualitative terms. If they were only quantitatively different, they would be correlated with each other, and influenced by the same variables.

Such dissociations are commonly observed in amnesia. For example, the fact that the amnesic syndrome affects the recency portion of the serial-position curve, but not the primacy component, has been cited as evidence that primary (short-term) and secondary (long-term) memory are qualitatively different memory systems, perhaps with different biological substrates (one affected by the brain lesion, the other not). Evidence from amnesia also has been used to support other structural distinctions: between declarative and procedural knowledge and – within the domain of declarative knowledge – between episodic and semantic memory. Thus, amnesic patients have

difficulty learning new factual information, but retain an ability to acquire new cognitive and motor skills; and if they do retain new factual knowledge, they display amnesia for the circumstances in which this information was acquired. Logic and experience tell us that when something breaks, it does so along natural boundaries, which form lines of least resistance. When a disorder of memory separates past memory from new learning, procedural and declarative knowledge, or episodic and semantic memory, it tells us that these distinctions, conjured in the minds of theorists, actually mean something in the real world. The fact that these kinds of dissociations are observed in all sorts of amnesia – not just the amnesic syndrome, but in traumatic RA, psychogenic amnesia, and posthypnotic amnesia as well – strengthens the conclusion that the theoretical distinctions are psychologically and biologically valid.

Of particular interest in recent theory are the various dissociations between explicit and implicit expressions of episodic memory. To date, three broad classes of theories have been proposed to explain these dissociations; each has several exemplars. According to the *activation* view, the activation, by a current event, of preexisting knowledge representations is sufficient for IM; but EM requires elaborative activity, in which individually activated structures are related to each other. According to the *processing* view, IM is an automatic consequence of environmental stimulation, while EM occurs by virtue of controlled processes that are limited by attentional resources. According to the *memory systems* view, IM reflects the activity of a perceptual representation system that holds information about the form and structure of the objects of perception, and EM reflects the activity of an episodic memory system that represents knowledge about the meaning of events and the context in which they occur.

Research on the amnesic syndrome, including studies of both human patients and animal models, indicates that the medial-temporal lobe, including the hippocampus, entorhinal cortex, and perirhinal and parahippocampal cortex, forms the biological substrate of EM. But the diencephalic form of amnesic syndrome seems to indicate that the mammillary bodies and the dorsomedial nucleus of the thalamus are also critical for memory. And, of course, the hippocampus itself is a complex structure, with many elements that may each play a special role in memory processing. As research continues, investigation of amnesia will make a unique and valuable contribution to understanding the relation between EM and IM, and the biological foundations of each.

At the same time, evidence of preserved memory functioning offers new insights concerning amelioration and rehabilitation in cases of amnesia. Loss of EM has debilitating consequences for afflicted individuals in everyday life. Amnesic patients are often unable to keep track of events, remember appointments or schedules, engage in educational or vocational pursuits, or manage home activities. Attempts at rehabilitation have frequently focused on restoration of damaged EM processes either through the use of repetitive drills or by teaching patients mnemonic strategies such as visual imagery or verbal elaboration. These retraining attempts have met with limited success: there is no evidence that exercising damaged neural or cognitive mechanisms leads to positive outcomes; and although patients have sometimes been able to acquire a few pieces of information

by using mnemonic techniques, they do not use the strategies spontaneously in everyday life.

On the other hand, rehabilitation strategies that have focused on providing compensatory devices designed to bypass problems in daily life have been somewhat more promising. External aids such as notebooks, diaries, alarm watches, and environmental labels have enabled some amnesic patients to function somewhat more independently, although use of such devices often requires considerable amounts of training and practice. The hand-held computer, potentially a powerful prosthetic for people with memory impairments, has yet to be extensively used for this purpose probably because of the problems in teaching amnesic individuals how to use such a device.

The finding that IM and procedural knowledge often remain intact even in cases of severe amnesia has recently prompted researchers to begin to explore ways in which these preserved processes might be exploited beneficially for rehabilitation purposes. Cuing techniques, which take advantage of amnesic patients' ability to respond normally to word stem or fragment cues, have been used successfully to teach individuals new factual information such as vocabulary as well as procedural tasks such as data entry and word processing. Continued research in this direction, paralleling more theoretically based research concerning preserved memory functions in amnesia, should enable further progress toward improving the ability of amnesic individuals to function effectively in their everyday lives.

Glossary

Amnesia Pathological memory loss resulting from brain injury, illness, or psychological disturbance.

Anterograde amnesia Impaired memory for facts or events encountered after the onset of amnesia (postmorbidity memory loss).

Confabulation Falsification of memory without the intent to mislead.

Consolidation Process by which information is assimilated and stabilized into memory. Consolidation includes both fast processes operating at the cellular level and slow processes operating at the systems level.

Declarative memory A form of memory characterized by the ability to consciously bring to mind facts and events. Declarative memory is dependent on the integrity of the limbic system. Episodic memory and semantic memory are both forms of declarative memory.

Episodic memory Memory for personally experienced events or 'episodes' that are specific in time and place.

Limbic system System of brain structures associated with memory function, including the medial temporal lobes, diencephalon, mammillary bodies, and fornix.

Medial temporal lobes Medial region of the temporal lobes associated with memory function. Subregions include the hippocampus, parahippocampal gyrus, entorhinal cortex, and perirhinal cortex.

Nondeclarative memory Memory expressed through behavioral performance without conscious memory content. Includes classical conditioning, skill learning, and repetition priming.

Retrograde amnesia Impaired memory for information acquired prior to the onset of amnesia (premorbid memory loss).

Semantic memory Memory for general knowledge (facts or concepts) that is impersonal and context-free.

The Amnesic Syndrome

Amnesia can be defined as a special case of memory loss that is distinct from ordinary forgetting. The amnesic syndrome is characterized by a profound disorder of memory in the context of preserved general intelligence and other cognitive abilities such as language, perception, and attention. Permanent amnesia can be differentiated from more common forms of memory loss, such as memory loss associated with aging or depression. In particular, amnesia is characterized by anterograde memory loss, in which patients cannot remember events that occur after the onset of amnesia. Retrograde amnesia, in which patients cannot remember experiences or information acquired before the onset of the illness, is also commonly observed, though the extent of retrograde amnesia is more variable. Occasionally patients present with focal retrograde amnesia, but this presentation has been argued to be psychogenic in nature.

The most widely studied clinical case of amnesia is patient H.M. In 1953, H.M. underwent surgery in which his medial temporal lobes (MTLs) were bilaterally resected to relieve medically intractable epileptic seizures. Though the surgery succeeded in alleviating his epileptic symptoms, H.M. immediately showed profound anterograde amnesia that persisted until his death in 2008. In the 55 years following his surgery, H.M. demonstrated a remarkable inability to learn and intentionally retrieve new information. His memory impairment was evident in many types of memory tests (e.g., cued recall, free recall, and recognition) across multiple domains of information (including verbal, visual, auditory, and somatosensory). In everyday

life, H.M. was unable to recall conversations that he had with a visitor 30 min ago, or the fact that he had a visitor at all. He could not acquire new information about salient life events occurring after his surgery, such as the death of his father, and he also had difficulty recalling premorbid memories, with most of his personal memories deriving from the age of 16 or earlier. Interestingly, despite these severe memory problems, H.M.'s IQ was above average (118 on the Wechsler Adult Intelligence Scale) and he performed normally on standard tests of perception, short-term memory, and language comprehension. The specificity of H.M.'s impairment to long-term memory provided strong evidence that the MTL is critical for normal human memory function.

While amnesia can also have a psychogenic origin, the focus of this article is on organic amnesia caused by nonprogressive brain damage to the MTL and related limbic system structures. The laterality of damage to the limbic system results in modality-specific memory impairments, with damage to left-lateralized limbic structures producing primarily impaired verbal memory (such as story recall and list learning) while damage to right-lateralized limbic structures produces impaired visual memory (such as memory for figures or designs) and sometimes, spatial memory. While left-sided lesions seem to produce more functionally significant memory problems in humans, likely due to the importance of verbal memory and language to human behavior, bilateral lesions are required for permanent global amnesia. A range of vascular, infectious, and traumatic processes can cause damage to the limbic system. The following section describes the most common etiologies of permanent amnesia.

Etiologies of Amnesia

Herpes Simplex Encephalitis

Herpes simplex encephalitis (HSE) is a viral infection that causes hemorrhagic lesions in the brain. Neural damage due to HSE typically occurs in MTL regions, including the hippocampus, entorhinal cortex, perirhinal cortex and parahippocampal cortex. Damage can also extend into the insular cortex, basal forebrain, and anterolateral and inferior temporal lobe regions. Anterograde amnesia is a prominent feature of HSE and can be accompanied by aphasia and agnosia when neural damage includes the anterolateral and inferior temporal lobes. In addition, lesions extending into lateral temporal regions can result in extensive retrograde amnesia.

Patient S.S. provides a striking demonstration of the memory impairments following HSE. Patient S.S. became densely amnesic in 1971 after developing HSE that caused bilateral lesions in anterolateral and medial portions of his temporal lobes, as well as lesions in his insula and putamen. S.S. has not been able to form any new declarative memories since the time of his illness. He cannot retain information regarding significant family matters or recent public events, and he cannot acquire new general knowledge such as vocabulary introduced into the English language since the onset of his illness. S.S. also has extensive retrograde amnesia for autobiographical and personal semantic information that includes most of his adult life. Despite these severe memory impairments, S.S. is of superior intelligence and performs well on tasks of short-term memory, language, executive function, and deductive reasoning skills.

Anoxia

Anoxic injury results from a loss of oxygen to the brain and can be caused by a variety of conditions such as cardiac arrest, respiratory distress, or carbon monoxide poisoning. Certain brain regions, such as the hippocampus, are particularly vulnerable to anoxic injury due to their physical location and biochemical makeup. Selective memory impairment following anoxia can vary from mild to severe, depending on the extent of MTL damage, and can include both anterograde and retrograde amnesia. Anoxic brain damage that extends outside the MTL to regions such as the basal ganglia, thalamus, white matter, or other neocortical regions can affect additional cognitive and perceptual abilities. In addition, anoxic injuries occurring shortly after birth can cause bilateral hippocampal atrophy leading to developmental amnesia that presents as impaired learning and retention in the face of preserved attention, reasoning, and visuospatial skills.

Stroke

Stroke can produce amnesia by blocking blood supply to various components of the limbic system, including limbic system white matter. Stroke involving the bilateral posterior cerebral artery (PCA) can cause lesions in the posterior hippocampus, parahippocampal gyrus, and occipitotemporal gyrus and can result in a dense amnesic syndrome. Anterograde amnesia following bilateral PCA stroke can include impairment in verbal recall and recognition as well as in visuospatial memory. Patients can also present with retrograde amnesia. Memory

problems can also occur following left-lateralized PCA lesions, and can affect verbal and visual information either transiently or permanently.

Stroke can also cause amnesia by damaging tissue in the thalamus. Strokes affecting blood supply to the anterior or medial regions of the thalamus most commonly occur due to small vessel occlusive disease or hypertensive hemorrhages and can damage the anterior thalamic nuclei as well as thalamo-frontal connections. Executive dysfunction frequently accompanies memory impairments, and patients often display worse performance on recall than on recognition tests. The extent and persistence of retrograde amnesia is variable.

Several features of stroke make it an important source of information about the nature of memory impairments in amnesia. First, there are usually no pre-illness neurological issues to complicate interpretation of the effects of stroke. Second, the abrupt onset of stroke avoids concerns about adaptive changes in the brain before initial assessment. Finally, stroke generates relatively discrete lesion boundaries without co-occurring diffuse injury, enabling regional effects to be mapped with greater specificity.

Wernicke–Korsakoff Syndrome

Wernicke–Korsakoff syndrome (WKS) is caused by thiamine deficiency and is most commonly observed as an effect of alcohol abuse in populations over 40 years of age. Because thiamine helps to produce energy needed for proper neuronal function, insufficient thiamine can cause neuronal damage or death. The thalamus and mammillary bodies are particularly sensitive to damage due to thiamine deficiency.

Diagnosis of WKS is given when an individual with a history of chronic, heavy drinking or malnutrition presents with anterograde amnesia. This diagnosis can be supported by neuroimaging or autopsy findings showing degeneration of the thalamus and mammillary bodies and loss of brain volume around the fourth ventricle. In the acute phase, patients exhibit a confused state, eye movement disturbances, and ataxia. In the chronic phase, patients exhibit dense anterograde amnesia that is attributed to neural damage in the anterior and dorsomedial nuclei of the thalamus and mammillothalamic tract. Confabulation and source memory errors can also occur in WKS and are thought to reflect additional frontal dysfunction. In addition to anterograde amnesia, many WKS patients also have profound retrograde amnesia that is characterized by a temporal gradient for autobiographical information (i.e., greater impairment for recent compared to remote personal memories). However, interpretation of retrograde amnesia is complicated by premorbid lifestyle characteristics and frontal dysfunction that may interfere with memory encoding and retrieval.

Anterior Communicating Artery Aneurysm

Rupture of an anterior communicating artery (ACoA) aneurysm can cause lesions in the basal forebrain, which are the origin of the cholinergic pathways to the hippocampus, the striatum, and the frontal lobes. Amnesia with ACoA aneurysm is likely due to disruption of hippocampal function, but controversy remains about the specific role of other lesioned regions. Lesions in the basal forebrain are usually bilateral

and if damage includes the basal forebrain, striatum, and frontal lobes, the resultant amnesia is severe and persistent.

Approximately 18% of ACoA aneurysm survivors will have some form of cognitive deficit, of which severe amnesia is the most common. Anterograde amnesia is characterized by delayed recall deficits for verbal and nonverbal material and memory recall is worse than recognition. Severe retrograde amnesia is also common, but is not universally observed. The clinical presentation of patients suffering from ACoA aneurysm can be complicated by significant executive deficits and prominent confabulation. Of all the etiologies of amnesia, patients with ACoA aneurysm are the most likely to be unaware of their memory deficits, which can cause safety and behavioral problems.

Information-Processing Descriptions of Amnesia

Though functional heterogeneity exists amongst the different etiologies of amnesia, comparison across cases with different lesion locations and associated deficits has enabled identification of the core information-processing deficits in amnesia. The following sections describe the core information-processing characteristics of anterograde and retrograde amnesia.

Anterograde Amnesia

Anterograde amnesia includes impaired memory for personally experienced events (episodic memory) as well as impersonal facts and concepts (semantic memory). Together, these forms of memory are categorized as declarative (explicit) memory and can be distinguished from nondeclarative (implicit) forms of memory that are largely preserved in amnesia. To demonstrate the distinction between impaired declarative and preserved nondeclarative memory in amnesia, consider the example of learning to ride a bicycle. While amnesic patients may not be able to recall specific instances when they have ridden a bicycle in the past (impaired declarative memory), they can nonetheless demonstrate the motoric skill of riding a bicycle (preserved nondeclarative memory). This example reflects one form of nondeclarative memory, procedural memory, that is intact in amnesia: amnesic patients are able to retrieve premorbidly learned motor skills and are able to acquire new ones, even if they are unable to retain declarative knowledge of having learned these skills. Other forms of nondeclarative memory that are preserved in amnesia include conditioning (provided that the conditioned stimulus and the unconditioned stimulus are overlapping) and perceptual and conceptual repetition priming. Repetition priming is the behavioral facilitation that occurs when processing a repeated compared to a novel stimulus, even without explicit awareness of the repetition. Perceptual repetition priming refers to facilitated processing of visual information, such as stimulus form, when visual information is repeated after an initial occurrence. Conceptual repetition priming refers to facilitated processing of stimulus meaning, independent from stimulus form, when analysis of stimulus meaning is repeated. The preservation of nondeclarative memory functions in amnesia is thought to reflect intact neural function in regions outside the limbic system, such as the basal ganglia and premotor/motor cortices

(motor learning), cerebellum (conditioning), and inferior and lateral temporal cortex (perceptual and conceptual priming). In the case of perceptual and conceptual priming, neocortical regions in inferior and lateral temporal cortex that store perceptual and conceptual representations are thought to be tuned with repetition such that previously accessed information can be more effectively activated and retrieved.

In contrast to largely preserved nondeclarative memory function, amnesic patients demonstrate profound declarative memory impairments on explicit memory tests requiring conscious retrieval of recent experiences. Explicit memory tests can take the form of recall or recognition. Although both recall and recognition tests require conscious retrieval of mnemonic information, they differ with respect to their processing demands and can be differentially impaired in amnesia.

According to dual-process models, recognition memory relies on two distinct processes: recollection and familiarity. Recollection refers to the effortful and intentional remembering of a prior encounter with its contextual source, whereas familiarity refers to the subjective feeling of knowing that an item was previously encountered without any knowledge of the context in which the item was acquired. Recollection and familiarity can be differentially impaired in amnesia depending on the locus of MTL damage. Amnesic patients with damage limited to the hippocampus have been described as having impaired recollection but preserved familiarity. Consistent with this theory, these patients perform poorly on free recall tasks but demonstrate intact performance on item recognition tasks. Recall deficits with hippocampal damage are thought to reflect impaired binding of contextual information into the memory trace, a process that is normally mediated by the hippocampus and makes recollection possible.

In contrast, when lesions extend into extrahippocampal regions of MTL, such as perirhinal cortex, patients demonstrate more severe declarative memory impairments that include both recollection and familiarity. These impairments are evident in both recall and recognition tests, though impairments in recall may be more severe than impairments in recognition. Extrahippocampal regions of MTL are thought to support memory for individual items without their accompanying episodic context.

While neuroimaging and neurophysiological studies provide convergent evidence for a division of labor in the MTL according to regions that support familiarity and those that support recollection, functional dissociations along these lines have not been consistently observed. An alternative proposal is that the hippocampus supports both recollection and familiarity (supporting both item recognition and recall) and that MTL subregions functionally dissociate according to whether they support stronger memories (hippocampus) or weaker memories (extrahippocampal regions of MTL). While the precise contributions of different MTL lesions to functional impairments in amnesia remain to be specified, episodic memory deficits can be considered to be a core characteristic of amnesia.

In addition to pervasive deficits in acquiring episodic information, new semantic learning can also be impaired in amnesia when MTL lesions are extensive. In such cases, patients demonstrate minimal ability to acquire new facts or concepts, particularly when this new information is difficult to incorporate into existing knowledge structures. For example,

patient H.M. was unable to acquire the meaning of new words that had entered into the vocabulary since the onset of his amnesia in 1953 (e.g., words such as 'granola' or 'jacuzzi').

The magnitude of semantic learning deficits in amnesia has been found to correspond to the amount of MTL damage. Patients with lesions limited to the hippocampus can acquire some degree of new semantic knowledge, including vocabulary words, indicating that new semantic learning can be supported by regions outside the hippocampus proper (e.g., perirhinal, parahippocampal, or lateral temporal cortex). Patients with larger MTL lesions extending into lateral temporal lobe have more severe impairments in semantic learning. Though these patients can acquire small amounts of new semantic knowledge with very extensive repetition, likely reflecting the ability of intact lateral temporal regions to gradually acquire new semantic knowledge after a great number of encoding episodes, such learning is typically very inflexible.

While the extent and location of lesions within the MTL greatly impacts the nature of anterograde memory impairments in amnesia, even more striking are the cognitive symptoms that occur when frontal deficits are superimposed on the core amnesia. Frontal lesions impair executive processes that contribute to memory, such as the ability to mentally manipulate or organize information to be encoded into memory and the ability to initiate and evaluate memory search. Executive deficits can lead to impairments in temporal or contextual aspects of memory and can lead to high levels of intrusions in recall tests or false endorsements in recognition tests. Rather than exhibiting a qualitatively different form of amnesia, patients with additional frontal lesions display a pattern of deficits consistent with a combination of a classic amnesic syndrome and additional problems associated with a frontal dysexecutive syndrome.

Retrograde Amnesia

Though many premorbid memories are preserved in amnesia, some degree of retrograde memory loss is often observed. Retrograde amnesia for events immediately preceding the onset of the brain lesion is particularly pronounced. According to Ribot's law, retrograde amnesia is characterized by a time gradient in which the memory impairment is inversely related to the age of the to-be-recalled event. By this view, memory is worse for more recent compared to more remote memories. While patients with MTL damage reliably demonstrate such a temporal gradient of retrograde memory loss for semantic information, with relative sparing of remote memory compared to recent memory, MTL damage does not spare remote memories in all cases, and patterns of retrograde amnesia appear to depend on the type of memory under investigation. In particular, when personal episodic (autobiographical) memories from different past time periods are probed (e.g., memory for events occurring during childhood, during early adulthood, and within the past 5 years), memory impairments can extend for decades and in some cases can include a patient's entire lifespan.

Temporally graded retrograde amnesia has been interpreted in terms of standard models of consolidation. In these models, memories are thought to depend on the MTL, and particularly the hippocampus, until they can be transferred to more stable cortical storage systems. The hippocampus plays a time-limited

role in memory and is crucial only for the initial consolidation of declarative memories. Thus, while MTL mechanisms are critical for the retrieval of recent memories that have yet to be consolidated, the MTL is no longer needed to retain and recover memories once consolidation is complete.

Observations of extensive temporal gradients of autobiographical memory loss are difficult to incorporate into consolidation theory, as the loss of such memories extends well beyond the time frame during which biological consolidation is likely to operate. An alternative theory, multiple trace theory, suggests that the MTL is always necessary for the retrieval of episodic memories, including both recent and remote autobiographical memories. According to multiple trace theory, older memories become more resistant to disruption because each time a memory is retrieved, a new memory trace is established that is linked to the older memory traces. Thus, older memories are represented by more and stronger traces and are more resistant to partial lesions of the MTL whereas newer memories are represented by fewer and weaker traces and are more vulnerable to damage. By this view, the extent of retrograde amnesia is determined by the amount of MTL damage as well as the number of traces by which a memory is represented. As such, very extensive MTL damage can affect autobiographical memories for all time periods.

Yet another pattern of remote memory loss is seen in patients whose lesions extend beyond the MTL into the anterolateral temporal lobes. In these cases, retrograde amnesia is characterized not only by extensive autobiographical memory loss, but also by severe semantic memory loss. The latter is thought to reflect damage to the neocortical sites where semantic information is stored. Impairments in semantic memory are often more prominent after lesions to the left temporal lobe, likely reflecting the role of the left hemisphere in verbal lexical-semantic processing.

Patients with frontal lobe damage can also present with extensive retrograde amnesia that may encompass both semantic and episodic memory. These retrograde memory impairments are particularly evident under high demands of self-initiated retrieval and likely reflect deficits in frontal executive processing. Confabulatory responses may also be prominent with frontal lobe damage, reflecting impaired monitoring of information retrieved from memory.

Theoretical and Clinical Implications

While memory deficits are the hallmark of amnesia, this article has described the important point that not all forms of memory are similarly impaired in amnesia. Memory impairments can include both retrograde and anterograde components but differ according to episodic and semantic demands and depend on lesion location and extent. Though structurally and functionally heterogeneous, amnesia provides an important window onto the multiple forms of memory supported by the human brain. The patterns of impaired and preserved function in amnesia clearly demonstrate that rather than being a unitary system, long-term memory comprises functionally and structurally distinct memory subsystems.

In addition to expanding our knowledge about long-term memory systems, studies of patients with amnesia have also

influenced our understanding of cognitive functions outside the memory domain. Emerging evidence indicates that amnesic patients have difficulty envisioning the future and are impaired at generating imaginary scenes. These results suggest that the brain regions involved in remembering the past overlap with those involved in thinking about novel future scenarios. It has been proposed that richly envisioning future scenarios requires flexible retrieval and recombination of details from the past, drawing on the same memory processes that are impaired in amnesia. The integrity of long-term memory mechanisms may also impact other related functions in amnesia, such as planning and problem solving.

While the theoretical advances provided by the study of amnesic patients are significant, caution must be taken when inferring strict one-to-one mappings of neural structure to cognitive function. In particular, the behavioral measurements indexed by standard neuropsychological tests may reflect contributions from multiple underlying cognitive processes or neural systems. Indeed, recent evidence raises questions about the independence between memory systems that has been inferred from the performance of amnesic patients on standard neuropsychological tests (such as implicit memory vs. explicit memory and short-term memory vs. long-term memory). For example, while standard neuropsychological measures suggest that memory impairments in amnesia are selective to long-term memory, a growing body of evidence suggests that short-term memory may also be impaired. In particular, recent behavioral studies of amnesic patients with damage to the MTL have demonstrated impairments in retaining relational information over delays as brief as one second. Together with recent functional neuroimaging data in humans that demonstrates delay-period activity in the MTL during short-term memory tasks, these results challenge traditional neuroanatomical dissociations between short-term memory and long-term memory and suggest that the mnemonic role of the MTL may extend beyond the long-term memory domain.

Though the nature of memory impairments in amnesia must be interpreted carefully, research into this topic will continue to enable greater clarification of how memory representations are formed in the human brain and how they contribute to behavior. In turn, such insights may serve as a foundation for improved diagnosis and more targeted treatment of memory disorders. In addition, improved understanding of how the brain supports memory can inform new rehabilitation techniques. Because pharmacological treatments for organic amnesia

are not widely tested or available, behavioral techniques currently offer the most promising method for helping amnesic patients manage and remediate their memory problems. Rehabilitative techniques that take advantage of learning mechanisms that are preserved in amnesia, such as repetitive training and implicit learning, can be effective in teaching amnesic patients new information. With such techniques, patients can be trained to use external memory aids such as personal digital assistants (PDAs) or paging devices. Such memory aids can provide useful reminders about important events, such as the need to take medications, providing functional support in everyday life.

Analogical Reasoning

D Gentner and L Smith, Northwestern University, Evanston, IL, USA

Glossary

Analog Situation or domain involved in analogical mapping; either the base (source) or target.

Base (or source) Analog from which inferences and explanatory structure are drawn; typically, the more familiar or concrete domain: for example, in the analogy 'An electric circuit is like a plumbing system,' the base is a *plumbing system*.

Candidate inference Fact posited about the target analog based on completing the common relational structure between base and target: for example, in the above analogy, a possible inference is 'Higher voltage leads to greater current in an electric circuit, just as higher pressure leads to greater water flow in a plumbing system.'

Conceptual metaphor System of words and phrases used conventionally to talk about one domain by analogy with another: for example, 'Love is a journey: The road is sometimes steep; You have to take the rough with the smooth, etc.'

Literal similarity Likeness based on overall similarity; applies when two situations are similar in their objects and entities and also in their relational structure: for example, one dishwasher tends to be literally similar to another (alike in both appearance and causal structure).

Relational similarity Likeness based on relations common to both domains or situations (whether or not the

objects in the two systems resemble each other): for example, an electrical circuit and a plumbing system can be relationally similar if they have a *common causal structure*.

Source (see base) structural alignment Identifying correspondences between two analogs, based on their common relational structure.

Structural consistency The property of having a clear set of matches between the two analogs. In a structurally consistent alignment, the parts of the two analogs are in one-to-one correspondence, and the analogy's inferences are clear.

Structural similarity (see Relational Similarity)

Surface similarity Likeness based only on similar objects and background context between two domains/situations, without a common relational structure: for example, a dishwasher may look like a clothes dryer, but their mechanical and causal relational structures are quite different.

Systematicity Preference for matching deep systems of connected relations, rather than smaller relational sets.

Target Analog one is drawing inferences about; typically the less familiar or more abstract domain: for example, in the analogy 'An electric circuit is like a plumbing system,' the target is *electric circuit*.

Introduction

Analogical reasoning – the ability to perceive and use relational similarity between two situations or events – is a fundamental aspect of human cognition. Indeed, some researchers suggest that it is the crucial cognitive mechanism that most distinguishes human cognition from that of other intelligent species. It is a core process in scientific discovery and problem-solving, as well as in categorization and decision-making.

Reasoning by analogy involves identifying a common relational system between two situations and generating further inferences driven by these commonalities. The commonalities may also include concrete property matches between the situations, but this is not necessary for analogy; what is necessary is overlap in relational structure. Although this may sound like a highly complex process, people routinely use analogy in everyday life. For example, people readily apply proverbs to situations based on purely relational matches. When you hear 'That's locking the barn door after the horse has gone,' you don't look for a barn; rather, you apply the relational pattern – *a precaution taken after the damage is done* – to some current situation. This kind of relational mapping is the essence of analogy.

In the most typical case of analogy, a familiar domain (the *base* or *source*) serves as a model by which one can comprehend

and draw new inferences about a less familiar domain (the *target*). Consider a rather timely example, used by Sterman and his colleagues at MIT to explain the behavior of atmospheric carbon dioxide; they describe the balance of carbon dioxide (CO₂) in the atmosphere by analogy with a bathtub:

The amount of water in a bathtub is determined by the rates of water flowing into the tub and water flowing out through the drain. As long as the inflow of water into the tub exceeds the outflow, the bathtub will continue to fill.

Likewise, the amount of carbon dioxide (CO₂) in the atmosphere is determined by the rates of CO₂ emissions and CO₂ removal.

In this analogy, the bathtub corresponds to the atmosphere. Water inflow corresponds to CO₂ emissions into the atmosphere and water outflow to CO₂ removal. This analogy invites the (correct) inference that as long as CO₂ emissions exceed removal, CO₂ levels in the atmosphere will continue to rise. This illustrates a typical feature of analogy: A process that cannot be seen becomes easier to grasp by virtue of an analogy with a familiar situation. This example also reveals the power of analogy to highlight a common relational pattern. Often, such a common pattern is given a linguistic label – in this case, a *stock-and-flow* system – to facilitate

remembering the abstraction and applying it to other situations. A student who grasps this analogy will find that this abstraction is useful in reasoning about other arenas, such as cash flow. Analogy is often the most effective way for people to learn a new relational abstraction; this makes it highly valuable in education.

Analogy is also frequently used in argumentation, where it allows the speaker to guide his or her audience toward a particular framing and set of inferences. For example, when a US district court judge in December 2002 ordered Microsoft to include Sun Microsystems' version of Java with the Windows operating system, a lively web discussion ensued, often involving analogy. One writer wrote: 'Please explain to me why Microsoft should be forced to include third party software in their OS? Every time I buy a six pack of coke, should a can of Pepsi be included?' and another wrote 'That would be like (my attorney) being forced to refer clients to his competition, since they didn't have as much business as him.' Many of these analogies were picked up and either extended or reversed. Defending the decision, another writer wrote 'If Ford had a monopoly on cars, they certainly would not be allowed to sell their cars with only Ford brand radios and tires ...'

As demonstrated in the above examples, analogies vary widely in their appearance, content, and usage. But they can all be characterized by a set of processes common to analogical reasoning of all types. These processes are:

- **Retrieval:** Given some current topic in working memory, a person may be reminded of a prior analogous situation in long-term memory.
- **Mapping:** Given two cases present in working memory (either through analogical retrieval or simply through encountering two cases together), mapping involves a process of aligning the representations and projecting inferences from one analog to the other.
- **Evaluation:** Once an analogical mapping has been done, the analogy and its inferences are judged.

We begin with mapping, the core process in analogical reasoning, and its subprocesses, reserving retrieval for later. The rationale for this is that, while analogical reasoning invariably involves a mapping process, it does not always require finding a second analog in memory. For example, when analogies are used in argumentation, both analogs are typically presented to the reasoner, who must then carry out a mapping and evaluate the analogy.

Mapping

Mapping is the core process of analogy, and has therefore been the main focus of analogy research. At a first level, the mapping process consists of finding how two situations are similar, and then bringing across further inferences from the better-known situation (the *base*, or *source*) to the less familiar one (the *target*). What distinguishes analogy from other kinds of similarity is that for two situations to be analogical, they must be similar in their relational structure. Analogy research has largely agreed on a set of principles laid out by Dedre Gentner in 1983, in a theory called structure mapping. According to structure-mapping theory, analogical mapping requires *aligning* the two situations based on their commonalities – particularly their common relational structure – and *projecting inferences* from the base to the target, according to this alignment.

Alignment

In an analogy, the two situations being compared can be aligned on the basis of common *relational structure*. For example, consider the simple perceptual analogy in Figure 1. These two scenes are analogous: they can be aligned – that is, the elements can be placed in one-to-one correspondence such that the same relational structure (Circle 1 > Circle 2 > Circle 3, which could be labeled *steadily decreasing size*) holds in both scenes. There is something satisfying about noticing structural alignments like this one. For example, in this case, despite the obvious object similarity between the two circles indicated by black arrows (both circles are the same size), when people are led to compare these two scenes (i.e., to engage in analogical mapping), they will match objects that occupy the same relational role in their respective figures: for example, the smallest, rightmost circles.

This same kind of alignment process occurs with a complex analogy like the bathtub example. Here too, people will align two domains based on their common relations. However, for scientific analogies, the matching relational structure will generally be governed by causal relations rather than spatial relations.

Even though most of us are not aware of how we process analogies, research suggests that there are some implicit principles that people follow during analogical mapping. First, we like our alignments to be structurally consistent. Two things are required for an alignment to be structurally consistent. First, each object in the base should match to one and only one thing in the target; this is known as *one-to-one correspondence*.

Figure 1 Perceptual analogy depicting *decreasing size*. The smallest circle in (a) could match either with the middle circle in (b) (an object match) or with the rightmost circle (the relational match). Adapted from Markman AB and Gentner D (1993) Structural alignment during similarity comparisons. *Cognitive Psychology* 25: 431–467.

For example, for the pair in Figure 1, people either map the smallest circle in 1A with the smallest circle in 1B (the relational match) or else with the middle circle (the object match) but not both. Second, if two relations are matched with one another, then their arguments must also be matched. We can see the principle of structural consistency at work in scientific analogies just as in simple spatial analogy above. For example, one-to-one correspondence holds in the bathtub analogy: water draining from the tub cannot correspond to both CO₂ emissions and CO₂ removal.

Further, when we align two situations, we do not simply find one pair of matching relations and stop there; rather, we prefer to match large, deep-connected systems. This preference is known as the *systematicity principle*: people prefer to align two domains based on large, connected relational systems, rather than just a single common relation. In the bathtub analogy, people generally prefer to align the entire stock-and-flow system that characterizes water flow and CO₂ flow, rather than simply noting that both involve the single relation of one thing flowing into another. Our desire for systematicity reflects an implicit preference for analogies that are highly informative and have inferential power.

Figure 2(a) provides a schematic depiction of structural alignment. Notice that this depiction shows a one-to-one correspondence between elements of the two domains – each element is mapped to (at most) one element in the other domain. Also, not only are relations matched but their corresponding arguments are matched as well. Finally, a large, inferentially rich relational pattern is matched, illustrating systematicity.

Inference

Analogies permit us to draw new *inferences* about the target. Indeed, one major reason we use analogy is to learn something new about the target domain by recruiting our knowledge of a relationally similar base domain. But this brings up a key question: How do we avoid drawing the many wrong (or even ridiculous) inferences that we might make if we simply mapped across whatever we know about the base to the target? Clearly, analogical reasoning would be useless if we had to spend time rejecting inferences such as *pouring Mr. Bubble into the atmosphere can make for an enjoyable evening*, which could be derived from the bathtub analogy. One key finding in analogy research is that people are highly selective in the inferences they make from analogies – we do not simply bring over everything we know about the base to the target.

According to the structure-mapping view, inference happens as a natural outcome of the structural alignment process. Once the base and target have been aligned and their common relational structure found, if there are additional parts of the relational pattern in the base that are not present in the target, then this missing pattern will be brought over as a candidate inference (Figure 2(b)). Thus, one way to think about inference generation is as a process of *relational pattern completion*. The requirement that candidate inferences be connected to the common relational pattern effectively filters which inferences will be considered. For example, in the bathtub analogy, *pouring in some Mr. Bubble makes for an enjoyable evening* is not connected to the common relational structure (as amplified below), so this inference would not normally be made.

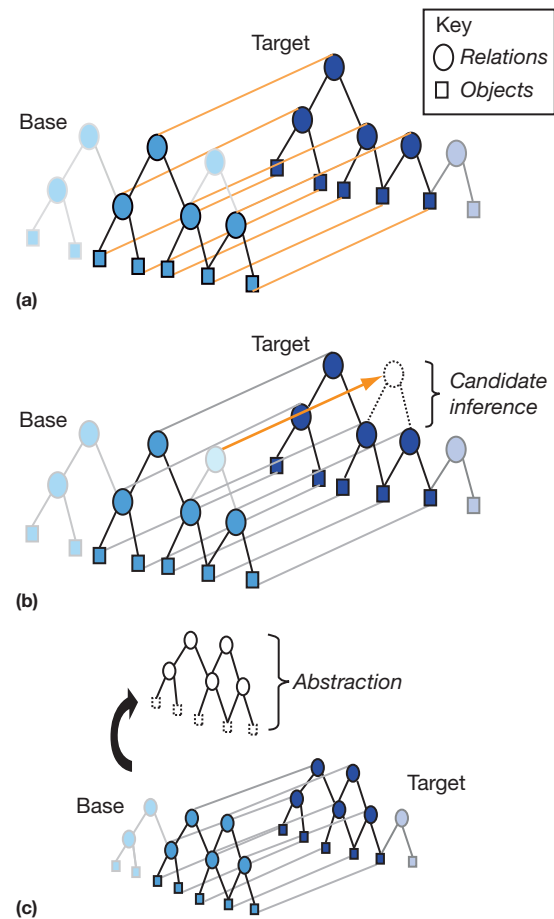

Figure 2 Analogy as structure mapping. (a) Initial alignment of common relational structure. Relations are matched between domains, and their arguments are also matched. (b) A frequent outcome of making an analogy is that candidate inferences are generated by completing the missing relational pattern in the target. (c) A possible outcome of structural alignment is abstraction of the common relational pattern.

Because inference and structural alignment are so tightly linked, perhaps it is not surprising that many of the constraints people impose on alignment they also use in inference. People prefer inferences that are consistent with the rest of the matching structure between the base and target. In addition, people prefer systematicity in inference: that is, people are more likely to project inferences that are connected to large relational patterns, rather than to project isolated parts of the base or inferences involving only a subset of the matching relational pattern. Clement and Gentner in a 1991 study found support for systematicity in inference: people were more likely to import a fact from the base to the target when it was connected to other facts shared with the target. In analogical matching and inference, people are not interested in isolated coincidental matches; rather, there is a tacit preference for deeply interconnected relational patterns.

Here is how you might generate an inference in the bathtub analogy. First, you align the known fact that *the amount of water entering and leaving the tub determines the total amount of water in the tub* with the known fact that *the amount of CO₂ entering and leaving the atmosphere determines the total amount of CO₂ in the*

atmosphere. You can then draw new inferences. For example, let us assume you know that the amount of water in the tub will decrease only if the amount of water draining is greater than the amount of water entering. You can carry this fact over to the target as an analogical inference: 'The amount of CO₂ in the atmosphere will decrease only if CO₂ removal exceeds CO₂ emissions.' This inference is warranted by its connection to the aligned relational structure.

As just discussed, one way in which analogy is useful is that it helps us learn new information about the target by suggesting inferences. Another benefit of analogy is *abstraction*: that is, we may derive a more general understanding based on abstracting the common relational pattern (Figure 2(c)). For example, on the basis of the bathtub analogy, a student might extract an abstract schema of a stock-and-flow system: as long as inflow exceeds outflow, the stock will increase; and as long as outflow exceeds inflow the stock will decrease. Once formed, this abstraction can serve as a general schema for other stock-and-flow systems, such as those that occur in economics or biology.

In addition to highlighting potential abstractions, analogies can also call attention to certain differences between the analogs. For example, a salient difference between the CO₂ system and the bathtub system is that the amount of water in a bathtub can change rather quickly by adjusting the inflow or outflow, whereas if you adjust CO₂ emissions and removal, it takes several decades to see a corresponding change in CO₂ levels in the atmosphere.

Evaluation

Once the common alignment and the inferences have been generated, the analogy and its inferences are evaluated. The criteria for evaluation can be grouped into three classes. The first factor is the *factual correctness* of the inferences generated by the analogy. If the analogy yields inferences that are untrue, the inferences and the analogy will in general be rejected, or at least revised. Of course, in some cases one cannot immediately identify whether an inference is true or not, as when making predictions about a future event, or when predicting a scientific outcome by analogy with another domain. A related factor in evaluating inferences is *adaptability*: how easy it is to modify a fact from the base to fit the target. People accept inferences that are highly adaptable to the target more readily than those that are less adaptable.

A second factor that people use in the evaluation of inferences is *goal relevance*. Goal relevance has been explored as a major factor in analogical reasoning in the theories of Keith Holyoak and colleagues. They emphasize that inferences that are relevant to the current goals of the reasoner are more likely to be projected during analogical inference, and are more important in evaluating the analogy. This constraint is particularly germane in problem-solving situations. During problem-solving, even if an analogy yields a reasonable inference, it is unlikely to be retained if it does not bear on the problem at hand. Spellman and Holyoak showed in a 1996 study that when two possible mappings are available for a given analogy, people will select the mapping whose inferences are relevant to their goals.

A third factor that may influence evaluation is how much new knowledge the analogy and its inferences can potentially

provide. The idea is that inferences that potentially yield a significant gain in new knowledge may be desirable (even if somewhat risky), especially when brainstorming or dealing with unfamiliar domains. The evaluation of inferences and of the whole analogy can mutually influence one another. Evaluation of particular inferences contributes to the larger evaluation of the analogy. If an analogy generates false inferences, we will generally reject or at least revise the analogy.

Analogical Retrieval

So far, we have been discussing a scenario in which two analogs are already present in working memory. However, sometimes only one analog is currently present, and we experience a reminding to something that may be similar or analogous (e.g., a previously solved problem). Thus, understanding the use of analogy in reasoning requires some account of how potential analogs are accessed in long-term memory – what leads people to think of analogies? While relational similarity exerts a strong influence on analogical mapping, it has much weaker effects on retrieval from memory. People often fail to retrieve potentially useful analogs, even if they share relational structure. In a classic 1980 study by Mary Gick and Keith Holyoak, participants were given a very difficult insight problem. When people simply read the problem and tried to solve it, only 10% succeeded. When another group was given a story with an analogous solution (but with different specific content) before receiving the insight problem, about 30% solved it – three times as many as without the analogy. Yet despite this impressive gain, the majority still typically failed to solve the problem. Although one might have suspected that they had simply forgotten or never encoded the analogous story, this was not the case. When people were given a hint to try using the prior story, the proportion solving the problem rose to around 90%. Thus, the solution rate tripled if people had heard an analogous story; and it tripled again if people were reminded of the prior analog. People's failure to access the prior analogous problem resulted not from forgetting it but from failure to be reminded of it by the current problem. This is an example of what Alfred North Whitehead called 'inert knowledge' – knowledge that is not accessed when needed.

Reminders to potential analogs are typically driven by surface similarities, such as similar objects and contexts, rather than by similarities in relational structure. Of course, it is important to bear in mind that in all these studies, some individuals show genuine relational transfer. It is not the case that relational reminders never occur; it's just that they are much rarer than surface reminders and overall similarity reminders. Gentner and colleagues have proposed two inter-related explanations for this. First, people often encode experiences in a content-specific manner, so that later reminders occur only for highly surface-similar experiences. Second, there is evidence that people's representations of relations are more context-specific than those of objects and entities. For example, Brian Ross gave people mathematical word problems to study, and later gave them new word problems. Most of their later reminders were to examples that were similar on the surface (e.g., both problems talked about mechanics), irrespective of whether the underlying mathematical principles matched.

Experts in a domain are more likely than novices to retrieve relationally similar examples, but even experts retrieve some examples that are similar only on the surface. However, as demonstrated by Laura Novick in 1988, experts reject misleading surface reminders more quickly than do novices. Thus, especially for novices, there is an unfortunate dissociation: while accuracy of transfer depends critically on the degree of relational pattern matching, memory retrieval depends largely on surface similarity between domains.

Factors that Influence Mapping

People's fluency in carrying out analogical mappings is influenced by three broad kinds of factors. First are factors internal to the analogical mapping itself, such as systematicity – whether the common relational system possesses a deeply connected structure – and transparency – the degree to which corresponding elements are similar. The second category includes characteristics of the reasoner, such as age and expertise. The third includes task factors such as processing load, time pressure, and context.

We have already discussed the importance of structural consistency and systematicity in analogical mapping, so we turn directly to transparency. *Transparency* depends chiefly on the degree of similarity between corresponding objects. A high-transparency analogy is one in which the objects that play the same roles in the common relational structure are highly similar (or identical), and the objects that play different roles are quite dissimilar. Such an analogy is generally both obvious and easy to align correctly. The most pronounced case of high transparency is *literal similarity*, in which both relations and objects match. As discussed above, literal-similarity matches are more reliably retrieved from memory than are purely relational analogies. To this, we can add that even in online processing, literal-similarity matches are processed faster than purely relational matches (in which the corresponding objects lack similarity). This fits with our intuitions: for example, it is easier to see how one tiger is like another than to see how a tiger is like an eagle (both are carnivores that hunt alone). However, although high-transparency matches are natural and easy to process, many useful explanatory analogies are of relatively low transparency – that is, the corresponding objects are not at all similar. The bathtub analogy discussed earlier is an example of a low-transparency analogy: the corresponding objects are very dissimilar, for example, water looks very different from CO₂ (and in any case, we never directly observe CO₂ molecules). Finally, as noted above, achieving a relational alignment is more difficult when noncorresponding objects are similar. Thus, the worst case of low transparency is *cross-mapped* analogy, in which similar objects play *different* roles within the relational structure, as exemplified below.

Both transparency and systematicity interact with individual characteristics of the reasoner, notably age and experience. For example, Gentner and Toupin gave children a simple story and asked them to reenact the story with new characters. Both 6- and 9-year-olds performed best when the corresponding characters were highly similar between the two stories (the literal-similarity condition – high transparency). They performed less well when corresponding characters were different

(medium transparency), and they performed worst when similar characters played different roles across the two stories (the cross-mapped condition – low transparency). Thus, both age groups were sensitive to the transparency of the correspondences. In addition, older children (but not younger children) benefited strongly from systematicity: when they were given a summary statement that provided the structure for the plot, their performance stayed high regardless of transparency. They were able to use the relational system provided by the plot description to maintain relational correspondences despite the tempting object matches.

Further studies have corroborated this finding that when relational similarity is pitted against object similarity as in the cross-mapped conditions mentioned above, younger children are highly influenced by object matches and less able to attend to relational matches than are older participants. This shift from a focus on objects to a focus on relations has been termed the *relational shift*. Although there is widespread agreement that such a shift occurs, developmental researchers differ on why. Gentner and colleagues have argued that the relational shift is driven primarily by gains in relational knowledge. An alternative view, proposed by Graeme Halford and colleagues, is that the shift results from a developmental increase in processing capacity; according to this view, processing relational matches requires more processing capacity than processing simple object matches. A third view, championed by Lindsey Richland and colleagues, explains the relational shift as stemming from maturational increases in inhibitory control, which permits the child to suppress object matches in favor of relational matches.

The third class of factors affecting analogical processing concerns task variables such as time pressure, processing load, and immediate context. One generalization that emerges from several studies is that making relational matches requires more time and processing resources than making object attribute matches. For example, a study by Robert Goldstone and Doug Medin found that when people are forced to answer quickly, they are strongly influenced by object matches (such as a black wing with a black wing), even in cases where they would choose a relational match (such as both wings same color with each analog) if given sufficient time.

Adult performance in mapping tasks is also influenced by immediately preceding experiences. For example, in the one-shot mapping task of Markman and Gentner, subjects are shown a pair of cross-mapped pictures, such as a truck towing a car and a car towing a boat (Figure 3). The experimenter points to the car in the first picture, and the subject indicates which object in the second picture 'goes with' it. Subjects often choose the object match (e.g., the other car). However, if they have previously rated the similarity of the pair, they are likely to choose the relational match (the boat). These findings suggest that carrying out a similarity comparison encourages structural alignment.

This one-shot mapping task has also been used to test whether processing load influences analogical processing. The experimenter pointed to the cross-mapped object in the first picture (the car), and subjects were instructed to point to the relational correspondence (the boat) in the second picture. Subjects made more object-mapping errors when given an extra processing load, such as having to count backward.

Figure 3 Sample cross-mapped pictures from the Markman and Gentner study. Carrying out a prior comparison increases the likelihood that adults will match the car in (a) with the boat in (b) based on their common relational role (both are the things being towed), rather than simply matching the two cars.

Neuropsychology of Analogical Reasoning

Recent studies have begun investigating the neural correlates of analogical processing. The studies so far converge on areas within the left prefrontal cortex as important in analogical reasoning. Of course, much remains to be discovered. We do not yet know the degree to which these prefrontal areas are specialized for analogy as compared to other higher order reasoning processes. We also do not yet know whether and to what degree other areas of the brain are involved in analogy, and whether this differs according to the type of analogy. Further studies exploring a greater range of analogical tasks and materials should give us a more complete picture.

Analogy in Naturalistic Settings

Analogy researchers note that analogy is a ubiquitous component of human thinking. However, much of the research focuses on analogy use in one very specific setting: the experimental psychology laboratory. Many studies of analogical reasoning in the laboratory have adopted an approach of explicitly providing participants with an analogy and eliciting particular responses from them (e.g., inference preference ratings, identifying correspondences). This method enables psychologists to closely observe phenomena tied to analogical mapping. However, this state of affairs suggests two questions: (1) To what degree do people spontaneously use analogies in

real-world contexts? and (2) Is this analogical reasoning guided by the same preferences (e.g., relational priority, systematicity) identified in the laboratory? For this discussion, we move out of the laboratory to review work on analogy in real-world settings, or analogy ‘in the wild.’

Dunbar and his colleagues have investigated the use of analogy in naturalistic environments in a variety of contexts. In one project, he studied the day-to-day processes of scientists in microbiology laboratories. Dunbar found that analogical thinking was a key component of all aspects of scientific reasoning, ranging from hypothesis generation to experimental design, data interpretation and explanation. Analogy is also a key component of the way scientists reason about unexpected findings. Interestingly, Dunbar observed that many of the analogies scientists made were of high overall similarity, sharing not only causal structure but also many superficial features. For example, a scientist working on a novel type of bacterium might hypothesize that its genetic sequence is like that of a highly similar species. These studies suggest that people frequently make analogies that reveal deep relational similarities, but that superficial similarity between domains aids in the noticing of these analogies, as many theories of analogy would predict.

However, scientists do sometimes use the kind of dramatic analogy that constitutes a true leap in understanding. For example, Robert Boyle likened molecular motion to leaves being swirled around by the wind; and Johannes Kepler likened the course of the planets around the sun to the course of a boat steering in a current (the gravitational attraction). Historical analyses have documented many cases like these, in which scientists have used analogies based on relational patterns that share little or no superficial similarity. These types of analogies often occur in connection with larger discoveries and shifts of paradigms, such as Rutherford’s analogy likening the structure of an atom to that of the solar system, which displaced the then-dominant plum-pudding model.

One interesting case of everyday analogy is the use of conceptual metaphors, as discussed by George Lakoff, Mark Johnson, and colleagues. For example, statements like ‘Their marriage is going over some serious bumps in the road’ or ‘They’re just coasting along without putting in energy’ would be part of the ‘love is a journey’ conceptual metaphor. Often, the same base term can be conventionally used with many different targets; for example, we can liken progress in a career, in college, or even in a specific project to a journey, as in ‘she’s zipping along on her paper, way ahead of the other students.’ Many of these metaphoric systems behave like extended analogies, as illustrated by the journey example. Another frequently used example is the conventional mapping from space to time, as in ‘The holidays will soon be here’ and ‘Exams will come after the holidays this year.’ We also find extended analogical metaphors in the introduction of new technical concepts, such as (*computer*) *virus*, and accompanying ideas such as *antibodies* against such viruses.

Another everyday use of analogy is in humor. For example, Benjamin Franklin stated, “A countryman between two lawyers is like a fish between two cats.” A more elaborate example comes from Louis Menand, writing in the *New Yorker* of February 23, 2009: “Postmodernism is the Swiss Army knife of critical concepts. It’s definitely overloaded, and it can do almost any job you need done.” Research by Jeff Loewenstein and Chip Heath in

2009 has shown that many jokes (as well as many children's stories and advertisements) follow a three-step *repetition-break plot structure*: two closely similar stories are given, followed by the *break* – a sudden change from the parallel plot structure. This kind of structure will be familiar to anyone who has heard a 'three guys walk into a bar' joke; the first two, closely similar, stories set up an aligned structure, and the humor comes from the surprise when the third story 'breaks' that structure.

Analogical Reasoning Without Awareness

Analogical reasoning has typically been considered a high-level reasoning process; for this reason, analogy has traditionally been thought of as a deliberate, conscious activity. Much of the research on analogy accords with this assumption: experimental work tends to focus on the deliberate use of analogy, where learners either discover or are given an analogy, use it to derive new inferences, and accept only those inferences that they consider structurally sound, plausible, and goal-relevant. However, research in the past decade has demonstrated that not all analogical reasoning is deliberate. Isabelle Blanchette and Kevin Dunbar first demonstrated the *analogical insertion effect*, in which analogical inferences are integrated unknowingly into mental representations of the target domain. In their studies, participants read descriptions of a target issue (e.g., legalizing marijuana) and then were given an analogy to another situation (e.g., ending Prohibition). On a subsequent recognition test, these participants often misidentified analogical inferences as facts actually presented about the target: that is, they mistakenly 'recognized' assertions about marijuana repeal as part of the passage, when what they had actually read was the analogous assertions about alcohol and Prohibition.

The studies just described demonstrate that analogical inferences can be drawn without the reasoner's full awareness. However, in both of these studies, the participants were explicitly told about the analogy between the two domains. This invites the question of whether analogical inference can occur without explicit awareness of the analogy. Recent research by Samuel Day and Dedre Gentner shows that the answer is yes. In their study, people read a series of brief passages and then answered questions about one of the later passages. Unbeknownst to the participants, the later passage was analogous to a prior passage, of which there were two versions. The results revealed that participants spontaneously made analogical inferences from whichever version of the early passage they had received, without recognition of having done so. These results show that information from a single analogous instance can influence the way in which another situation is understood or remembered without an individual's awareness. This suggests the intriguing possibility that analogy may be a process by which people implicitly understand and structure everyday experiences, and form abstract schemas over similar experiences.

Conclusion

Analogy is at the core of higher-order cognition. As Douglas Hofstadter puts it, "Analogy is the engine of cognition." Analogical thinking enters into creative discovery, problem-solving, categorization, and learning and transfer. This realization has

led to a surge in research activity over the last three decades, resulting in great gains in our understanding of analogical processing. But there remain many open questions. We need a better understanding of how analogy operates in everyday learning and reasoning. What determines when people will spontaneously compare things, and how much they will profit from the comparison? Are spontaneous, nonaware analogies common, and if so what are their effects? When and how do people filter out bad analogies? Another area that is being actively explored is the neural underpinnings of analogical processing, as discussed above. There has also been recent interest in further specifying the development of analogical ability in children, and also in understanding the role of analogy in children's everyday learning across a variety of domains, from language acquisition to category formation. Finally, we are just beginning to explore analogical processing in other species. Cross-species comparisons will help to delineate the cognitive components of analogical ability.

Anger

J R Averill, University of Massachusetts, Amherst, MA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Aggression The intentional infliction of harm on others, against their wishes and not for their own good.

Anger An emotional state that involves both an attribution of blame for some perceived wrong and an impulse to correct the wrong or prevent its recurrence.

Category mistake The logical fallacy of assuming that what is true of one category (e.g., aggression) is also true of a related category (e.g., anger); category mistakes are particularly common when the relation between the categories is one of class inclusion, part-whole, or cause-effect.

Catharsis A purgation ('cleansing') or clarification of emotion; used to explain the relief sometimes associated with vicarious emotional experiences, for example, during theatrical performances (Aristotle) and psychotherapy (Freud).

Crime of passion Legal terminology for homicide committed while in an emotional state, typically anger; also termed voluntary manslaughter.

Emotional state A short-term disposition to respond based on an evaluative judgment (e.g., that something is good or bad, challenging or threatening, just or unjust); as traditionally conceived, emotional states differ from other short-term dispositions in that the relevant evaluation is nondeliberate and the ensuing response seems to be beyond personal control (a passion rather than an action).

Hate A long-term disposition to respond with hostility. While anger is typically accompanied by physiological arousal and precipitous action, hate is primarily a way of thinking. Hate can foster anger; conversely, unresolved anger can culminate in hate. But hate can also serve as an antidote to one's own anger for, under normal conditions, those whom we hate cannot hurt us.

Social constructionism The view that most emotions, anger included, are not an intrinsic part of human nature (i.e., genetically determined) but, rather, are constructed from elementary processes in conformance with social norms (beliefs and rules).

Anger and aggression are often discussed under one heading, a fact that has distorted discussions of both. Anger need not be, and typically is not, manifested in aggression; conversely, aggression is frequently manifested for reasons that have little to do with anger. This article focuses on anger as an emotion; the orientation is social-psychological. Psychologically, anger is an accusation of wrongdoing, an attribution of blame, and a determination to correct the perceived wrong; socially, anger functions as a kind of informal judiciary that helps regulate interpersonal relationships.

Generic and Specific Uses of the Concept of Anger

The concept of anger is often used in two distinct ways: first, as a generic term to cover a wide range of related emotional responses, such as envy, jealousy, fury, frustration, annoyance, contempt, and the like; and second, as a specific emotion on a par with other emotions in the same general category (e.g., anger vs. envy). Linguistically, when a single term is used to refer to phenomena at two different levels of generality, the term so used is known as a synecdoche. 'Anger' is often used as a synecdoche, both in everyday speech and psychological theory.

It is important to distinguish the generic and specific uses of the concept of anger, for what is true of a category at one level of generality need not be true at another (higher or lower) level. To conflate levels of generality is to commit a 'category mistake.' Category mistakes are particularly common when

synecdoches are involved, for the use of the same term makes it easy to traverse between levels of generality without recognizing the shift in meaning.

Consider, first, the meaning of anger as a generic category. What do members of the category (e.g., envy, jealousy, and fury, as well as anger as a specific emotion) have in common? On some occasions, at least, all are associated with aggressive behavior. In its generic sense, then, anger may be used to refer to almost any aggressive emotional response. Angry aggression in this sense is typically contrasted with instrumental aggression, that is, aggression deliberately used as a means for achieving some extrinsic reward (as in a robbery).

Now, consider anger as a specific emotion. How does anger in a narrow sense differ from other members of the general category of anger-like emotions, such as envy, jealousy, and fury? As is explained more fully below, anger as a specific emotion involves an attribution of blame for wrongdoing and a desire for reparation. Only rarely is anger in this sense accompanied by aggression, at least by physical aggression. The main objective of anger is not to harm the instigator, but to correct the perceived wrong and prevent recurrence.

Category mistakes can proceed from the top-down (generic to specific categories) or from the bottom-up (specific to generic categories). An example of a top-down mistake is the common assumption that because anger (in the generic sense) connotes aggression, then anger (in the specific sense) must also involve a tendency toward aggression, even if that tendency is repressed, bottled up, disguised, or otherwise made unobservable. An example of a bottom-up mistake is the

inclination on the part of perpetrators to excuse aggression of all sorts, from child abuse to urban riots, with the plea: 'It wasn't my fault; he/she/they made me angry.'

The following discussion focuses on anger as a specific emotion. No attempt is made to review the vast amount of research related to aggression in general. Considerable advances have been made in understanding the biological (evolutionary) and physiological bases of aggressive behavior; as important as that understanding may be, it is only tangentially related to anger as a social-psychological phenomenon. On the other hand, data relevant to anger come from a wide range of sources, including historical (ethical) teachings, legal proceedings, surveys of everyday experience, experimental studies, cross-cultural research, and clinical practice.

Anger in Historical Perspective

Historically, and today, anger appears on nearly every list of 'basic' emotions. Often, this is taken to mean that anger is somehow prior to society, for example, that anger is a relic of biological evolution. Anger, however, does not arise from the depths of some presocial self. It embodies a history of social meanings. From early infancy, we are emotional apprentices, first to our parents, and then to teachers, ministers, artists, entertainers, and other formal agents of cultural transmission. The apprenticeship continues on a less formal basis throughout life as we interact with family, friends, and acquaintances in everyday, face-to-face encounters. In the process, we learn the beliefs and rules that help constitute our emotions, and the skills to enact them properly. Subsequently, we may refine and transform what we have acquired, but we can never completely escape the vestiges of our cultural heritage.

Western culture has been greatly influenced by the confluence of two main streams of thought, Greco-Roman philosophy and Judeo-Christian theology. Each stream has contributed its share to current conceptions of anger. A little later, we will consider briefly the views of three early representatives of these traditions, namely, Aristotle, Seneca, and Lactantius. But first, a bit of etymology may be helpful.

Anger is an emotion. On that, everyone would agree. But what is an emotion? On that, few psychologists agree. For most of Western history, from the time of the ancient Greeks until about the middle of the eighteenth century, what we now call emotions were commonly referred to as passions. As traditionally conceived, a passion is anything a person (or physical object) 'suffers'; this would include, in the case of humans, both emotions and diseases. Hence, from the same root (the Greek, *pathē*, and the Latin, *pati*, *passiones*), we get such emotion-related terms as passion, pathos, and sympathy and such disease-related terms as patient, pathogen, and pathology.

Aristotle considered that the passions formed one of ten fundamental categories of being. Actions – things a person does deliberately and with forethought – formed another distinct category. This distinction between passions and actions is embedded in our ordinary language, as when we say of a person that he was 'gripped,' 'seized,' and 'overcome' by emotion. Anger, in particular, is often depicted as a 'wild beast' that must be 'tamed,' or as an 'inner force' that will 'explode' if not adequately 'vented.' Such conventional ways of speaking

help constitute the way we think and feel. But linguistic conventions can mislead as well as inform.

When addressing the practical concerns of rhetoricians, as opposed to the theoretical concerns of metaphysicians, Aristotle defined anger "as an impulse, accompanied by pain, to a conspicuous revenge for a conspicuous slight directed without justification towards what concerns oneself or towards what concerns one's friends" (*Rhetoric*, 1378a30). Two aspects of this definition are especially noteworthy. First, the 'slight' (by which Aristotle meant any show of contempt, spite, or insolence, especially by a friend or inferior) had to be 'without justification.' A reprove that is deserved is not an adequate provocation to anger, no matter how upsetting it might be. Second, the revenge must be 'conspicuous'; otherwise the offender will not realize that he or she is being punished for the slight. To these two points, we should add a third important feature of Aristotle's analysis, namely, the response must be appropriate to the provocation and the situation, being neither too weak nor too strong.

Aristotle's analysis contains a paradox. If anger is a passion, how can it be so finely tuned to the social context, in both initiation and expression? One way to resolve this paradox is to deny that anger, at least under ordinary circumstances, is beyond personal control: to assert, in effect, that the classification of anger as a passion is based more on metaphor than on fact. More will be said about this possibility later. Another possible resolution is to regard anger as a primitive reaction to painful stimuli, an impulse that is regulated but not constituted by social norms. This is the position of many current psychological theories of anger and aggression. It was also the position taken by Aristotle, who believed that the physiological changes that accompany anger (e.g., a 'boiling of blood about the heart') can impel a person to act in a nondeliberate and irrational manner.

Aristotle's answer, however, hardly seems adequate. The physiological changes that accompany a brisk walk, say, exceed those that accompany most episodes of anger, and yet a brisk walk does not lead a person to act irrationally. Conversely, some of the worst deeds committed in the name of anger are done in a cold and calculated manner, with no more than usual physiological involvement.

The Roman philosopher and statesman Seneca (4 BC–AD 65) wrote the first full work devoted entirely to anger. As a follower of Stoicism, Seneca defined passion as a form of false judgment, the mental analogue of a physical disease. (After all, who would deliberately, 'in his right mind,' make a false judgment?) This definition of passion led Seneca to reject the notion that anger is necessarily tied to one's bodily condition or that it could be anything but a human emotion. A false judgment, no less than a true judgment, is born of reason, no matter how ill-begotten the false judgment might be. Seneca also rejected the Aristotelian notion that anger, properly directed and in moderation, can be considered good. If on occasion a false judgment produces a beneficial outcome, it is a fortunate happenstance. Whatever good is done in anger, according to Seneca, can be done even better and with greater surety, following rational deliberation. In a manner prescient of current cognitive therapies, Seneca offered advice on how to reinterpret events so that they are no longer judged offensive, or, when that is not possible because the offense is too egregious, to correct the wrong in a rational and deliberate manner.

Stoicism was the dominant philosophy of the Roman Empire, and views such as those expressed by Seneca were very influential – in theory, if not in practice. And although it might at first seem like a relatively minor footnote to the history of thought, Seneca's treatment of anger also posed a major challenge to the ascendancy of Christianity. Jehovah of the Old Testament is often depicted as wrathful, vengeful, and punishing. The biblical Christ, too, was not without anger, as when he drove the moneychangers from the temple. How could an all-knowing, all-powerful, and all-loving God be susceptible to anger, if anger is indeed a passion (whether conceived as a form of false judgment or a physiologically based impulse)?

This question was addressed by Lactantius, a Roman convert to Christianity and confidant to the Emperor Constantine (fourth century AD). Lactantius criticized the notion that anger involves a desire for revenge. Rather, anger in the strict sense (i.e., righteous or just anger) is a mental act motivated to restrain offenses. Such anger is proper to God and necessary to humankind, according to Lactantius, for no one who is good and just can fail to be moved at the sight of evil. We therefore rise to punishment, not for the sake of revenge, but in order that morals be preserved and license suppressed. Of course, Lactantius recognized that angry people sometimes do more harm than good. That, however, is a feature of 'unjust' anger, a debasement of true anger that (in a manner similar to Aristotle) he attributed to interference from bodily reactions.

The views of Aristotle, Seneca, and Lactantius, although presented here in the most cursory manner, highlight some of the issues and controversies that still divide contemporary theories of anger.

Is anger a passion or an action? In terms of the language we use to describe anger in everyday discourse, it is clearly a passion. On this point, Aristotle, Seneca, and Lactantius would agree; however, the reasons they give for this classification are very different, a fact that might call into question the nature of the classification itself. Indeed, Lactantius comes close to denying that anger is a passion, at least when he speaks of divine or (in humans) righteous anger. Perhaps the closest modern analog of Lactantius's divine anger (a fully rational, disembodied anger) can be found in the area of Artificial Intelligence. Computers can be programmed to simulate righteous anger, that is, to evaluate 'offenses,' interrupt ongoing activity, and take corrective measures. We need not postulate special circuitry, no less some primitive anger 'instinct' or 'drive' on the part of the computer. All that is required is the programming of appropriate rules.

What is the role of physiological arousal in anger? To the extent that anger leads to vigorous action, it may be accompanied by noticeable bodily changes. There is also evidence that the physiological changes associated with anger are somewhat different from those typically associated, say, with fear. (Anger shows a norepinephrine-like pattern; fear, an epinephrine-like pattern.) Moreover, research suggests that when a person is physiologically aroused, for whatever reason, and regardless of the patterning of the arousal, he or she may be more prone to anger or to any other emotion appropriate to the situation than would otherwise be the case. Thus, the potential importance of physiological arousal during anger should not be underestimated, but neither should it be overestimated.

Physiological arousal is neither a necessary nor a sufficient condition for anger. Fundamentally, anger is to be understood primarily in cognitive rather than physiological terms. This fact was recognized by Aristotle and even more unequivocally by Seneca and Lactantius.

What is the function of anger? When appropriately experienced and expressed, anger serves an important social function, namely, the restraint of offense (Aristotle, Lactantius); indeed, when faced with adequate provocation, anger is not only appropriate, but it is also a God-given duty (Lactantius). Needless to say, anger can be, and too often is, used for selfish and even antisocial ends (Seneca). But a phenomenon must be understood in terms of its normative application, not its misapplication, although the latter may be more dramatic and in need of attention.

To conclude this section, we might ask with regard to historical teachings in general: Does anger exist outside of a particular sociohistorical context, or is it a product of that context? Theorists who adopt the first alternative are sometimes referred to as 'naturalists,' for they believe that anger is an inherent part of human nature. Those who favor the second alternative are known as 'social constructionists,' for they believe that anger is constituted, not just regulated, by social beliefs and rules. For social constructionists, views such as those presented by Aristotle, Seneca, and Lactantius are of more than historical interest; they help form the cultural matrix within which anger is constituted.

Anger in Courts of Law

In contemporary society, the law of homicide both embodies and promotes social norms with respect to anger. In Anglo-American common law, two grades of criminal homicide are generally recognized, murder and manslaughter, and each of these may be divided into two subcategories, first and second degree murder, and voluntary and involuntary manslaughter. Murder is homicide committed with 'malice aforethought,' that is, deliberately and with the intent of gain (cf. instrumental aggression). Second degree murder differs from first degree murder in the presence of mitigating circumstances. Manslaughter is a lesser crime than murder. Voluntary manslaughter is the technical name for a 'crime of passion,' that is, homicide committed during emotion, typically anger. It is 'voluntary' because the angry person wants to attack the victim. Involuntary manslaughter is accidental, but nevertheless culpable homicide, for example, due to negligence.

As just noted, anger serves to mitigate a charge of homicide from murder to voluntary manslaughter. This is no trivial matter. A conviction for murder can mean a life sentence or even the death penalty. By contrast, voluntary manslaughter carries a much lighter sentence – typically little more than a few years in prison, and often probation. Why should this disparity exist? And how does a jury decide whether a defendant was truly angry at the time of the crime?

The law stipulates four major criteria for deciding whether a person was truly angry at the time of a killing: adequacy of provocation, heat of passion, insufficient cooling time, and a causal connection between the provocation and the crime. 'Heat of passion' is a vague reference to the behavior of the

individual at the time of the homicide; and 'causal connection' refers to the fact that the aggression must be a direct response to the provocation. The other two criteria – the adequacy of provocation and insufficient cooling time – are the most interesting from an analytical point of view, for they are judged by the so-called 'reasonable-man test.' This test stipulates that the provocation be sufficient to arouse an ordinary member of the community to anger so intense that it might lead to homicide and, again according to community standards, that there be insufficient time for the anger to dissipate before the homicide is committed.

The reasonable-man test provides ostensibly objective criteria (community standards) against which the feelings and reactions of the defendant can be compared. If there is a match, the defendant may be considered to have been in an angry state; if there is no match, the defendant is not judged to have been angry, regardless of his or her feelings at the time. Put differently, the reasonable-man test objectifies anger; no longer does anger refer simply to a state of mind of the defendant, but to an objectively existing state of affairs to which the individual may or may not have attained. The so-called 'reasonable-man' is, after all, no actually existing person, but is, rather, an idealized embodiment of the norms of the community.

The above considerations suggest that the attribution of anger in courts of law is a kind of social subterfuge. The crime of passion is still a crime, but one that is to some degree excusable. The angry person was, after all, doing his duty by correcting some wrong as defined by community standards. He is therefore given a two-way excuse. First, the victim is, in a sense, put on trial along with the defendant; and if the victim (instigator) was sufficiently guilty (had committed a provocation egregious enough to be judged 'adequate'), then he or she must share the blame for having provoked the incident. Second, as anger is classified as a passion, the defendant cannot be held fully responsible for behavior that was presumably beyond personal control.

Anger in Everyday Affairs

Crimes of passion present a misleading picture of anger in one very important respect – they are crimes. The presumed 'reasonable-man' has proven himself to be unreasonable in his resort to excessive violence. To what extent can we generalize from crimes of passion to anger in everyday affairs?

Anger is a very common emotion. When asked to keep diary records, most people report becoming mildly angry once or twice a day, and seriously angry once or twice a week. The most frequent targets of anger are friends and loved ones; the most common instigations involve some perceived misconduct, for example, an intentional wrongdoing or avoidable accident; and the motivation of the angry person is to correct or prevent recurrence of the 'wrong,' not to hurt the instigator.

Anger may be expressed in a great variety of ways, depending on the person and situation. Common responses include talking the incident over with the instigator, verbal reprimands, withdrawal of privileges, brooding, and so on. At higher levels of intensity, an angry episode may include such behaviors as shouting, slamming doors, and stomping out. Only rarely does anger result in direct physical aggression

against the instigator, at least among adults. In fact, being unusually kind to or solicitous of the instigator – a 'contrary reaction' – is more common than direct physical aggression.

Needless to say, it is easy to think of episodes of anger that do not conform to the above pattern. For example, on occasion we all have become angry at an inanimate object, as when our car stalls in the middle of an intersection; in such instances, however, we typically imbue the object with human qualities (the car had no 'right' to stall). Overwhelmingly, anger is an interpersonal emotion; it is directed at persons or other entities (the self, human institutions) that in some way can be held accountable for their actions.

Few people find pleasure in their own anger; to be the target of another person's anger is even more unpleasant. Nevertheless, surveys indicate that the consequences of most everyday episodes of anger are evaluated positively. Even instigators (the 'wrongdoers') report that, in the majority of cases, they gain from being the target of anger, for example, by coming to realize their own faults or by gaining a better understanding of the angry person's point of view.

An important caveat must be added to this last observation: The more aggressive the response, the less likely it is that anger will have a positive outcome. Rather than being a typical manifestation of anger, aggression reflects a failure of anger to achieve its objective, which is to correct the wrong, not to hurt the target.

Rules of Anger

On the basis of historical teachings, legal procedures, and everyday experience, it is possible to infer the norms that help determine the way anger is experienced and expressed. Some general rules of anger are presented in [Table 1](#).

All theorists recognize the importance of rules for the experience and expression of emotion. There is a crucial difference among theorists, however, in the way the rules are presumed to work. Naturalists assume that anger is an inherent part of human nature and that rules function only to regulate how the emotion is experienced. Social constructionists, by contrast, believe that the rules and associated beliefs not only regulate but also help constitute anger as a distinct emotion. There are other differences among these positions as well. For example, naturalists search for the origins of anger in biological evolution, whereas social constructionists look toward history; naturalists see an essential link between anger and aggression, whereas social constructionists believe that aggression is only one of many ways in which anger may be expressed; and naturalists regard anger as universal, whereas social constructionists consider anger to be culturally specific.

The Utku Eskimos supposedly do not have a name for, nor do they express an emotion equivalent to, anger. Social constructionists take such data as support for their contention that anger is not a biologically based, universal phenomenon; naturalists, on the other hand, argue that the Utku simply suppress their anger, or express it in subtle and indirect ways, in order to preserve harmonious social relationships. There is no easy way to resolve these divergent interpretations, for the issue depends partly on how anger is defined, for example, as a general category or as a specific emotion (cf. the earlier

Table 1 Some rules of anger as inferred from historical teachings, legal procedures, and self-reports of everyday experiences

1. A person has the right (duty) to become angry at intentional wrongdoing or at unintentional misdeeds if those misdeeds are correctable (e.g., due to negligence, carelessness, or oversight)
2. Anger should be directed only at persons and, by extension, other entities (one's self, human institutions) that can be held responsible for their actions
3. Anger should not be displaced on an innocent third party, nor should it be directed at the target for reasons other than the instigation
4. The aim of anger should be to correct the situation, restore equity, and/or prevent recurrence, not to inflict injury or pain on the target, or to achieve selfish ends through intimidation
5. The angry response should be proportional to the instigation; that is, it should not exceed what is necessary to correct the situation, restore equity, or prevent the instigation from happening again
6. Anger should follow closely upon the provocation and not endure longer than is needed to correct the situation (typically a few hours or days, at most)
7. Anger should involve commitment and resolve; that is, a person should not become angry unless appropriate follow-through is intended, circumstances permitting

Source: Averill JR (1993) Illusions of anger. In: Felson RB and Tedeschi JT (eds.) *Aggression and Violence: A Social Interactionist Perspective*. Washington, DC: American Psychological Association, with permission from American Psychological Association.

discussion of anger as a synecdoche). However, this much can be said: as cross-cultural research continues to reveal the great diversity of ways that human societies have developed to deal with potential frustrations and interpersonal conflicts, the case for the universality of anger as a specific emotion becomes increasingly problematic.

Consider *liget*, a fundamental emotion among the Ilongot, a headhunting people indigenous to the Philippines. Like anger, *liget* can be occasioned by insults, slights, and other affronts to the self, and the violation of social customs. Unlike anger, the most dramatic manifestation of *liget* is cutting off the head of another person; the identity of the victim is largely irrelevant – a man, woman, child, anyone will do, but preferably a stranger. The taking of a head helps establish one's place as an equal and honored member of Ilongot society, and hence may be an occasion for celebration. *Liget* also finds expression in a variety of ways other than headhunting. For example, male *liget* is implicated in both courtship and childbirth; 'concentrated' in the sperm, it helps make babies. *Liget* also stimulates work and provides the strength and courage to overcome obstacles. From these few remarks, it is evident that *liget* is constituted by different rules and beliefs than is anger. A crazed American might cut off the head of another, but only a well-socialized Ilongot could experience *liget*. Moreover, if a crazed American did cut off the head of another, we would not attribute the response to anger – neither in a court of law (cf. previous discussion of crimes of passion) nor in everyday affairs.

In short, the rules presented in Table 1 may seem self-evident, but that is not because they are universally held. Rather, they are culturally based norms that, when internalized, become part of our 'second nature.' Other cultures have different norms, different emotions, different 'second natures.'

Anger and the Social Order

We question the sincerity and even the character (or mental health) of a person who claims to be angry but who declines to take action, circumstances permitting (see Rule #7, Table 1). This link between anger and action is not due simply to the fact that anger is a reaction to unpleasant events. Of greater importance is the fact that anger involves a commitment to the shared values that make social life possible. The demand for

action is thus a social as well as a psychological imperative. In traditional moral teachings, the failure to become angry under appropriate circumstances was regarded to be as sinful as excessive or unjustified anger; in the words of the seventeenth century divine, Thomas Fuller, "anger is one of the sinews of the soul; he that wants it hath a maimed mind." A modern extension of this traditional teaching can be found in the popularity of 'assertiveness training.'

In most everyday episodes, the transgressions that provoke anger are relatively minor – breaking a promise, ignoring a responsibility, being inconsiderate and the like. This fact tends to obscure the role that anger plays in maintaining the social order. No matter how trifling our everyday promises, responsibilities, and considerations may seem to be, they are the threads from which the fabric of society is woven. If they are too frequently broken without mend, society unravels. In a very real sense, then, the many small mendings that are the everyday experiences of anger, each minor in its own right, help sustain a way of life.

Anger can be a tool for social change as well as maintenance. There may come a time when we commit ourselves to values other than those embraced by the larger society. In a fight for civil rights and equality, for example, we may turn our anger on people and institutions to whom we previously held fealty. But the new norms we now seek to establish are, typically, old norms applied to new circumstances or extended to new groups (e.g., women, minorities). Even as a tool for radical social change, anger tends to be conservative of the norms it embodies.

Anger in Health and Disease

Anger has implications for the health of the individual as well as society. Evidence for an etiological role of anger is best documented in the case of coronary heart disease and stroke. Chronically experienced anger that goes unexpressed, or that is expressed too vehemently, appears to be especially damaging to the cardiovascular system, increasing the risk of both coronary heart disease and stroke.

Unexpressed or repressed anger has also been postulated as a cause of depression. The concept of repression owes much to Freud and psychoanalysis, although it is not tied to any one theoretical position. The notion of repressed anger has even

passed into the legal system (thus extending the 'insufficient cooling time' criterion for crimes of passion). The basic idea is that, due to situational or personal constraints, anger is too threatening for the individual to even admit experiencing. Banned from consciousness, the anger nevertheless finds outlet in a disguised and maladaptive fashion.

Depression can have many causes, both physiological and psychological. It need not, and typically does not, have anything to do with repressed anger. There are occasions, however, when depressive-like symptoms can take on some of the qualities of an angry response. Consider the case of a woman who is so fatigued that she finds it difficult to get out of bed in the morning, feels despondent through most of the day, and is haunted by frequent thoughts of suicide. Life becomes a burden both to her and to those around her. Now add the following considerations: the woman's husband treats her with neglect; she sincerely believes that she has no right to be angry with her husband, for his neglect of her is somehow deserved; nevertheless, in subtle ways her behavior causes considerable inconvenience to her husband; and, finally, she derives barely concealed satisfaction from her husband's discomfort. In such a case, we might well speak of the woman's depression as being a manifestation of 'repressed' anger. That, however, is a metaphorical way of speaking, for the woman's behavior follows only some, but not all, of the standard norms for anger. A more parsimonious explanation might be that the woman has acquired, in this situation, at least, a set of idiosyncratic beliefs and rules that help constitute an emotion that resembles both anger (retaliation for a perceived wrong) and depression (fatigue, despondency, self-reproach).

Recall the emotion of *liget* described earlier. It bears some semblance to anger within our own culture, but it is constituted by different norms and hence represents a different emotion. Norms of emotion can vary within, as well as between, cultures. There exist subcultures of increasingly smaller scope, down to the level of the family and ultimately the individual. An emotion that is the product of personal (idiosyncratic) norms is particularly subject to misinterpretation because usual forms of consensual validation are lacking. But nothing is gained by way of clarity, and much may be lost, if we label the nonconforming emotion by some common name ('anger,' say, or 'depression') and attribute its idiosyncrasy to repression.

Less often recognized than its pathogenic effects, anger can also have ameliorative effects on the course of disease. For example, patients suffering from serious diseases such as cancer have a better prognosis if they become angry at their condition than if they become merely frightened or depressed. Although the underlying mechanisms are not clear, a possible explanation is that the angry person is more likely to 'fight' the illness, for example, by taking an active role in his or her treatment.

Catharsis

The idea of repression is closely tied to that of catharsis. During psychoanalytic therapy (what Freud originally called the 'cathartic method'), presumably repressed impulses are brought to consciousness and expressed in an adaptive fashion. Using a rather graphic metaphor, Freud compared catharsis to the draining of pus from an infected wound. Continuing

with the example of depression, let us suppose the woman described earlier turns to psychotherapy for help. During treatment, she may come to recognize on a conscious level the unfairness of her treatment, and, blaming her husband rather than herself, she may resolve to do something to change the situation. From a psychoanalytic perspective, it might be said that her depression 'lifts' as her repressed anger is 'released.' An alternative explanation is that one kind of emotional response (an ill-defined anger/depression combination) has been replaced by a more adaptive response (normative anger).

A good deal of experimental research has been devoted to the possible cathartic effects of emotional expression, especially with respect to anger and aggression. On the whole, the results have not been kind to the catharsis hypothesis. More often than not, the expression of anger on one occasion facilitates, and, on subsequent occasions, encourages its expression. This is opposite to the mitigating effect predicted by the catharsis hypothesis. In the case of anger and aggression, as in so many other areas, practice makes perfect or, at least, easier.

When Anger Turns to Hate

In popular conception, anger and hate are closely allied conditions. In actuality, the matter is not so simple. As mentioned earlier, anger is more likely to be directed at friends and loved ones than at strangers and enemies. One reason is opportunity: close contact with friends and loved ones offers frequent occasions for anger. Another reason is that friends and loved ones can hurt us in ways that strangers and enemies cannot; a breach of trust, for example, can only occur where trust exists. Most importantly, if we want a relationship to continue, perceived wrongs must be set right, and anger is one way of achieving that end. It is primarily when anger proves ineffective, or is pursued for selfish ends, that it may turn to hatred on the part of the target as well as the angry person.

Put differently, unresolved anger may cool and solidify into an enduring animosity, which predisposes an individual to a variety of different emotions depending on the fortunes of the hated person; thus, we may feel sorrow at the success of our enemies and joy (*schadenfreude*) at their failures, as well as anger at their presumed transgressions. We may even hate persons or entire groups who have never done us any wrong, as in prejudice. While normative anger is focused on the misdeeds of others, real or imagined, and attempts at repair, hatred has an inner dynamic that is more purely destructive of the self as well as of others. In his novel *Demian*, Hermann Hesse observed: "If you hate a person, you hate something in him that is part of yourself. What isn't part of ourselves doesn't disturb us." That is both an overgeneralization (not all hatreds fit the pattern) and an understatement (something similar could be said of other sentiments; e.g., if you love a person, you love something in him that is part of yourself). Keeping these qualifications in mind, Hesse's observation contains a truth about hatred that is worth remembering.

Gender Differences

A common stereotype is that women are less capable of anger than are men. This stereotype is also sometimes used to explain

the greater frequency of depression diagnosed among women than men (cf. previous discussion of repressed anger). However, surveys of the everyday experience of anger suggest that women become angry as often, as intensely, and as effectively as men. Gender differences in anger, to the extent that they exist, must be sought on a more subtle plane than suggested by the stereotype.

In the conduct of interpersonal relations, men tend to place greater emphasis on competition and individual rights, whereas women tend to place greater emphasis on cooperation and affiliation. Men also tend to be physically more aggressive than women. Such differences in orientation and response style cannot but have reverberations on the way anger is experienced and expressed. Some of the things that a man finds offensive may not offend a woman, and vice versa; and when angry, a man may do and say things that a woman typically would not (e.g., men are more likely than women to engage in physical violence when angry, and women are more likely than men to cry). But as important as such differences may be, they should not be interpreted to mean that anger is less appropriate to women than to men, or that women are less capable of anger than are men. 'Different' does not necessarily imply 'more' or 'less.' Women are as sensitive as men to unfair treatment; and in response to provocations that they deem adequate, women are as likely as men to make their feelings known clearly and effectively.

Wrongful Anger

The rules presented in [Table 1](#) suggest that anger, properly constituted, serves to correct socially recognized wrongs, and that the anger should not exceed what is necessary to achieve that end. And, as described earlier, the majority of episodes fit that description. However, the rules of anger are easily broken, either unintentionally or willfully, with consequences that are harmful to the self and to interpersonal relationships.

When the rules are violated, we may speak of wrongful anger (provided the violation is not so egregious as to preclude the response from being classified as anger altogether). Three types of wrongful anger have already been discussed in passing, namely, anger that goes unexpressed, resulting in continued provocation and unrelieved tension; anger that is expressed indirectly or in accordance with idiosyncratic rules; and anger that is expressed intemperately, resulting in unwarranted violence. To these, we could add anger that is unduly prolonged, is displaced on innocent third parties, is oft-repeated without adequate follow-through, and so forth.

The rules of anger may be violated for many reasons, some of which antedate the angry episode – for example, inadequate socialization, neurological dysfunction, and inordinate stress or fatigue. Extraneous stimuli in the immediate situation can also lead to inappropriate anger. According to Berkowitz's neoassociationistic theory of anger and aggression, aversive stimuli of any kind (which would include aspects of most provocations to anger) tend to automatically elicit aggressive thoughts, feelings, and behavioral inclinations, either innately or through prior experience. These tendencies are especially likely to find expression if other aggressive cues are present (e.g., a weapon) or customary restraints are inhibited (e.g., through the use of alcohol). By contrast, the present article

has focused on higher order sociocognitive mechanisms by which anger may serve as a rationale for aggression, before, during, and after the fact, regardless of what other precipitating factors may be involved. The two types of mechanisms (socio-cognitive and neoassociationistic) are not mutually exclusive; indeed, they tend to complement one another. For a more complete discussion of how anger can go awry, the reader should consult the article on aggression in this Encyclopedia.

Regardless of the precipitating factors, with a better understanding of what constitutes an adequate provocation and with the acquisition of effective coping skills, aggressive tendencies can be typically curbed. But the outcome of anger – whether constructive or destructive – does not depend exclusively on the behavior of the angry person. Anger is more like a dialog than a soliloquy; put differently, there are 'rules of engagement' for the target as well as for the angry person. The most beneficial response for a target (assuming the anger is justified) is an explanation to correct any misunderstanding, an apology if no misunderstanding exists, and a resolve to prevent recurrence. Too often, unfortunately, anger provokes anger, conflict escalates, attitudes harden, and resentments build; eventually, all goodwill may be squeezed from the relationship (see earlier discussion of when anger turns to hate).

When goodwill is absent, the rules of anger may be violated 'wantonly,' so to speak. That is, anger may be used deliberately (if not consciously) to achieve ends that are only tangentially related to the instigation. The concept of anger, it will be recalled, has exculpatory implications, and this could be in two ways: firstly, as anger is commonly interpreted as a passion rather than an action, the angry person presumably cannot control his or her own behavior; secondly, if the anger is accepted as justified, the blame for initiating the incident is shifted from the angry person to the instigator. Not surprisingly, perpetrators and their apologists often seek to excuse vicious behavior – child abuse, spouse battering, mugging and robbery, gang warfare, urban riots, etc. – by attributing it to anger. And in a multitude of more minor ways, we all sometimes resort to anger to intimidate and coerce others in the pursuit of selfish ends.

Wrongful anger is unwittingly fostered by the misguided advice, often found in popular psychology books, that it is healthy to 'let your anger out.' If a response is inappropriate to begin with, letting it out in the name of anger is doubly inappropriate, for a response cannot be labeled as anger without endorsing, no matter how unwittingly, its exculpatory implications. It would be far better to heed the warning of Aristotle: "Anyone can get angry – that is easy; ... but to do this to the right person, to the right extent, at the right time, with the right motive, and in the right way, that is not for everyone nor is it easy; wherefore goodness is both rare and laudable and noble" (*Nicomachean Ethics*, 1109a25).

Glossary

Associative learning Making the psychological connection between contiguous events in the environment.

Categorization Placing different objects or events into separate classes or categories.

Conceptualization The process of forming an abstract or generic idea from particular instances.

Discrimination Responding differently to two or more stimuli differing in one or more respects.

Generalization Transferring a learned response from one stimulus to another.

Matching-to-sample Experimental procedure for studying memory in which reward is given for responding to a stimulus if it is the same as a prior sample stimulus.

Memory Control of current behavior by past stimulation.

Metacognition Thinking about one's own cognitive states and processes.

Numerical processing Set of abilities related to understanding and manipulating numbers, such as: using symbols to denote quantities; discriminating, ordering, and comparing different quantities; and, combining quantities in order to perform arithmetic operations.

Reinforcer Any consequence of a behavior that increases the probability that the organism will repeat that behavior.

Time-out A brief period of time during which there is no stimulation; time-out is a form of punishment that is used to decrease the probability that the organism will repeat a behavior.

The Science of Animal Cognition

For centuries, it was believed that a clear discontinuity held between the cognitive capabilities of humans and animals. Philosophers and other thinkers tended to be quite skeptical of animals' mental abilities. For example, the great French philosopher René Descartes deemed animals to be mere machines whose actions could be explained without invoking any cognitive processes whatsoever. In his *Letter to the Marquess of Newcastle*, Descartes proposed that "the reason why animals do not speak as we do is not that they lack the organs but that they have no thoughts." Approximately 50 years later, the great British philosopher John Locke, in *An Essay Concerning Human Understanding*, joined Descartes in disparaging the cognitive capacities of animals: "the having of general ideas is that which puts a perfect distinction betwixt man and brutes, and is an excellency which the faculties of brutes do by no means attain to."

All that changed some 200 years later when Charles Darwin advanced his revolutionary ideas about the evolution of species. In *The Descent of Man*, Darwin went beyond suggesting the evolution of physical traits to proposing the evolution of the mind as well. For Darwin, there was "no fundamental difference between man and the higher mammals in their mental faculties" (p. 66). Human and animal intelligence differ only in degree, not in kind, Darwin argued; so, there should be no sharp schism between human and animal mind. The human mind might be the final step in the evolution of intellectual functions, but the roots of human mental processes should be observable in animals as well.

Darwin's unsettling ideas had actually been presaged by other philosophers and psychologists. In his *Principles of Psychology*, Herbert Spencer suggested that the mind could be understood only by examining how it had evolved. According to Spencer, mental capacities could be represented along a continuum with no great gaps: a continuous progression

from simple associative learning to complex forms of abstraction and reasoning.

The ideas of Darwin and Spencer on the evolution of the mind were staunchly defended by Thomas Huxley, who wrote in 1874 that: "the doctrine of continuity is too well established for it to be permissible to suppose that any complex natural phenomenon comes into existence suddenly and without being preceded by simpler modifications; and very strong arguments would be needed to show that such complex phenomena as those of consciousness first made their appearance in man."

These principles of evolutionary biology clearly clashed with Cartesian philosophy. The gradual evolution of cognition was a direct consequence of this new biological vantage point. Critically, within that new paradigm, it was entirely plausible to believe that mental capabilities could be observed in organisms other than humans.

Once the hypothesis of mental continuity was enunciated, evidence to support it was needed. Darwin himself amassed a large collection of supportive anecdotes: stories told by naturalists, zookeepers, and pet owners attesting to how smart animals really were. For example:

Dr. Hayes, in his work on *The Open Polar Sea*, repeatedly remarks that his dogs, instead of continuing to draw the sledges in a compact body, diverged and separated when they came to thin ice, so that their weight might be more evenly distributed. This was often the first warning which the travelers received that the ice was becoming thin and dangerous.

Darwin was alert to the hazards of relying on anecdotal evidence alone; such observations lacked the information needed to pinpoint the mechanisms responsible for the animals' behavior. Relevant to the prior example, Darwin wondered about the origins of the dogs' behavior: "now, did the dogs act thus from the experience of each individual, or from the example of the older and wiser dogs, or from an inherited habit, that is from instinct?"

Any bona fide scientific analysis of animal cognition requires careful recording of the relevant behaviors as well as precise knowledge and control of the variables influencing or determining that behavior. Darwin's disciple, George Romanes, advocated for an objective analysis of the mind in his book *Animal Intelligence*: "We can only infer the existence and the nature of thoughts and feelings from the activities of the organisms which appear to exhibit them." (p. 1). Yet, despite his advocacy for and his interest in documenting mental continuity across species, Romanes' work too was simply a compilation, albeit extensive and thorough, of still more informal observations and anecdotes.

The true transition to the scientific study of animal cognition began with C. Lloyd Morgan. In his *Introduction to Comparative Psychology*, Morgan emphasized the importance of distinguishing between an animal's behavior and the interpretation of that behavior. In order to properly interpret an organism's behavior, high standards of objectivity are needed. As well, systematic experimental studies are required in order to reach incisive conclusions as to the origins of behavior, which he himself undertook with baby chicks whose developmental history could be known and carefully controlled. Finally, circumspection was to be one of Morgan's enduring contributions. Morgan's famous canon urged researchers to be cautious in advocating advanced cognitive interpretations when the behavior in question might be more parsimoniously explained by simpler behavioral processes.

These then were the forebears of the science of comparative cognition. Following the methods of natural science, research in comparative cognition today seeks to discover the extent to which our mental capacities are similar to those of other animals and to answer many longstanding questions. Are animals intelligent? Is human intelligence superior to animal intelligence? What are the cognitive and neurobiological mechanisms of intelligent action?

In this article, we will consider a few particularly prominent and promising areas of research in animal cognition: numerical processing, memory and planning, conceptualization, and metacognition. This sampling of topics, issues, methods, and findings should provide readers with a good taste of the current state of the science of animal cognition. A broader compilation of animal cognition studies can be found in *Comparative Cognition* edited by Wasserman and Zentall.

Numerical Processing

Number is an important property of objects in the external world. Critically, numerical processing can be considered to be mediated by an abstract cognitive process, because behavioral control by number must be made irrespective of the specific physical features of the items to be evaluated; 2, 5, or 8 items are 2, 5, or 8 regardless of whether the items are apples, pebbles, or geckos. Traditionally, it has been believed that linguistic competence is necessary for numerical processing. Although it is the case that a verbal system does mediate several numerical and mathematical operations, considerable evidence has been obtained documenting numerical processing by animals and infants lacking language; this evidence suggests

that common preverbal processes underlie numerical and mathematical competencies in humans and animals.

Basic numerical abilities comprise: learning and using symbols to denote specific quantities; discriminating, ordering, and comparing different quantities; and, combining quantities so that basic arithmetic operations, such as addition and subtraction, can be accomplished.

The Japanese primatologist Tetsuro Matsuzawa taught a 5-year-old chimpanzee, Ai, to use Arabic numerals to denote the number of items in a display. Ai was first presented with either 1 or 2 items in a display window and then required to choose either the '1' or the '2' key on a numeric keyboard. As Ai mastered the lower numbers, higher numbers of items were progressively introduced, up to a maximum of 6. Regardless of the items being colors, objects, or symbols, Ai's accuracy exceeded 90%. Nevertheless, Ai had greater difficulty reporting the numbers when they were close to one another (e.g., it was easier for Ai to distinguish 2 from 5 than to distinguish 2 from 3) and when the numbers were at the higher end of the scale (e.g., Ai was more accurate at identifying 2 and 3 than at identifying 5 and 6, even when the disparity between them was in both cases 1 item). It seems that, as quantities increase, the discrepancies between them become less obvious and, in turn, the discrimination between them becomes more challenging.

Interestingly, Ai's behavior is not an isolated curiosity. Humans too find it easier to distinguish between 2 and 14 items than between 4 and 5 items. This finding is called the numerical distance effect. As well, humans can rapidly distinguish between 2 and 3 items, but we cannot so rapidly say if there are 14 or 15 items, in this case showing what is called the numerical magnitude effect. The numerical magnitude effect has also been found in monkeys, rats, and pigeons.

Recent research has found that rhesus monkeys can learn to choose the smaller of two simultaneously presented sets of items when such nonnumerical factors as area and density are controlled. Monkeys can also choose the larger of two quantities even when the items are sequentially presented, as when the items fall one by one into an opaque container. In addition, Brannon and her colleagues have found that monkeys' accuracy rises as the disparity between the amounts to be evaluated increases. Indeed, the monkeys' performance is affected by the ratio of the values being compared. As predicted by Weber's law, the larger the amounts, the greater the difference between them must be in order to be distinguishable. This relationship was true for human college students as well.

These and other observations have led researchers to propose that humans and animals share a system that calculates inexact, but approximate representations of quantity. For example, when having to choose among different waiting lines, we tend to select the shortest. We rarely do so by precisely counting the people in line, but rather do so by a process of rough estimation; we use an approximate preverbal number system. It is not difficult to imagine that animals in the wild benefit from the ability to distinguish between trees containing 5 and 15 fruits or predators attacking in groups of 2 or 4. Small or large quantities can surely make a difference and numerosity judgments in these situations seem to be similarly performed by verbal and nonverbal organisms.

Estimating and representing numerical values appears to be necessary for the next step in numerical reasoning: interrelating quantities so that operations like adding, subtracting, multiplying, and dividing can be accomplished. Can animals perform these basic arithmetic operations? Studies using a preferential looking paradigm have suggested that preverbal human infants and monkeys can understand simple arithmetical operations, such as adding and subtracting a small number of visually presented objects.

For example, when monkeys watched as two eggplants were placed behind a screen, they looked longer when the screen was removed and only one eggplant was present than when two eggplants were present. Monkeys may have spent more time looking at the incorrect outcome because it surprisingly violated the rules of arithmetic. But, the results of such studies may be explained in terms of the infants' and monkeys' understanding of object permanence: organisms can keep track of occluded objects and when one object unexpectedly appears or disappears, they are surprised; no real arithmetic ability is required in that case.

More compelling evidence of addition in monkeys has been found by Brannon and Cantlon. They presented animals with two sets of dots on two sequential screens. Then, on a third screen, the monkeys had to choose from two sets: one containing the number of dots equal to the sum of the two sets and a second containing a different number of dots (see [Figure 1](#)). Monkeys learned to choose the array that roughly corresponded to the arithmetic sum of the two sets of dots and they readily transferred this behavior to novel combinations. Some problems proved to be more difficult than others. For example, monkeys were faster and more accurate when, after being presented with a set of 2 dots and a second set of 6 dots, they had to choose between 8 and 14 dots compared to when they had to choose between 8 and 10 dots. The closer the two possible answers, the more difficult the task.

When humans were given the same nonverbal task, their pattern of performance was strikingly similar. Although humans were generally more proficient than monkeys, both

Figure 1 A monkey performing the addition task designed by Brannon and Cantlon. The monkey had to choose from two sets of dots: one set containing the same number of dots as the sum of two previously presented sets and a second set containing a different number of dots. Photograph courtesy of Elizabeth Brannon, Duke University.

species' reaction times and accuracies were affected by the ratio between the numerical values of the choice arrays: the larger the numerical difference between the correct and the incorrect choices, the better the performance. These results further suggest that humans and animals share an approximate calculation system that does not involve verbal processing.

Research in numerical processing thus shows that animals possess the evolutionary precursors to advanced mathematical abilities: animals can identify and name quantities, compare and discriminate different quantities, and even manipulate those quantities to perform simple additive operations.

Memory

There is no question that animals can learn new information. Pavlov's classical conditioning experiments showed that, after presenting dogs with a sound followed by food, the mere presentation of the sound alone would make the dogs salivate, a response that was initially elicited only by food. We can infer that the dogs learned that the sound predicted food. And, if animals can learn, then that implies they remember the events they experienced in the past. So, the fact that the dogs came to salivate to the sound suggests that they remembered the pairing of sounds with food.

Unlike humans, animals cannot verbally express their recollections; but, there are other ways we can study their memory. One popular procedure is delayed matching-to-sample. In the basic task, a sample stimulus (a colored light or a picture) is presented for a few seconds. Then, the sample is removed and a delay ensues. After this delay (which can range from seconds to minutes), the sample is again presented along with one or more comparison stimuli. The animal's task is to pick the choice stimulus that matches the sample. Monkeys and pigeons successfully perform this task. Moreover, their accuracy generally decreases as the delay increases, which is true for humans as well. Further, animals can perform this matching task even when new sample and comparison stimuli are presented to them, showing effective transfer to a novel situation.

Human memory studies have traditionally involved learning and retrieval of lists of items. People are given lists of items and they must later recall as many items as possible. In this situation, the first and the last items in the list tend to be better recalled – primacy and recency, respectively. Animals too show these serial position effects.

The memory of pigeons, monkeys, and humans for lists of visual items has been directly compared after different delays between the last item and the recognition test. All three species show the same pattern: strong recency, but no primacy at the shortest delays; the classic U-shaped serial position function at intermediate delays; and, strong primacy, but no recency at the longest delays. Thus, the same mechanisms may mediate the serial memory performance of all three species.

Although similarities between species abound, there are disparities too. Sometimes, animals can be even more proficient than humans! One noteworthy example comes from Tetsuro Matsuzawa's laboratory in Inuyama, Japan. Chimpanzees were first taught to contact each of the numerals from 1 to 9 in order when they appeared in random locations on a computer touchscreen. Even when the sequence lacked some

Figure 2 A chimpanzee performing the memory task designed by Matsuzawa and his colleagues. On the left, the chimpanzee is touching in sequential order the numerals from 1 to 9 located randomly on the screen. On the right, after brief presentation, the numerals were covered by white squares; here too, the chimpanzee has to touch each of the squares in the correct sequence. This procedure is detailed in Inoue S and Matsuzawa T (2007) Working memory of numerals in chimpanzees. *Current Biology* 17: R1004–R1005. Photographs courtesy of Tetsuro Matsuzawa, Primate Research Institute, Kyoto University.

of the numbers (e.g., 1-3-4-6-8-9), the chimpanzees could still respond in sequential order from the smallest to the largest. Humans could also do this, of course. But, a critical variation was later introduced. The numerals were presented for a very short duration (from 650 to 210 ms) and then they were replaced by white squares (see Figure 2). Now, subjects had to remember which numeral appeared in which location and then touch each of them in the correct sequence. Humans' performance plummeted, but chimpanzees' performance remained high. The chimpanzees could retain an accurate image of the very brief visual scene, an ability that surpasses our own perceptual memory capacity. This eidetic (or photographic) memory can sometimes be seen in young children, but very rarely in adults. This striking developmental disparity was also seen in chimpanzees; the young animals were the best performers in this task.

Despite these remarkable illustrations of animal memory, some memory capacities have been deemed to be uniquely human. Episodic memory refers to the ability to remember specific events in time and space, thereby involving: the content of an experience (what), its place of occurrence (where), and its time of occurrence (when).

Many mammals and birds are food-hoarding animals; they cache food in specific places for future use. Food hoarding implies that: (1) food has to be stored and concealed and (2) actual consumption is deferred for hours, days, weeks, or months. Successful hoarding appears to require animals to use past spatial and temporal information to retrieve food later.

In a series of experiments with scrub jays, Nicola Clayton and her colleagues allowed animals to store and recover worms and peanuts. Fresh worms are the scrub jays' preferred food. But, the worms do not last very long; after a few days, they degrade and become unpalatable. Peanuts are less appetizing, but they are nonperishable; so, they can be consumed at any time. The jays were trained in the laboratory to cache worms on one side of a distinctive tray and to cache peanuts on the other side (Figure 3 shows a scrub jay caching food from a tray). Critically, the jays were allowed to retrieve their caches either 4 or 124 h later. After 4 h, the birds tended to inspect the side of the tray where the worms should be; but, after 124 h, the birds tended to inspect the side where the peanuts should be. No olfactory or visual food cues were available; the jays had to rely on their memory at the time of cache recovery.

Figure 3 A scrub jay caching worms and nuts in the compartments of a sand-filled ice-cube tray. Photograph courtesy of Nicola S. Clayton, University of Cambridge.

Evidently, the jays can remember: (1) whether peanuts or worms had been cached – what; (2) on which side of the tray each of the food items had been stored – where; and (3), whether a short or a long time had elapsed since the food items had been cached – when. Thus, the cache and retrieval behaviors of the scrub jays meet the criteria for episodic memory.

Many researchers believe that such successful and elaborate food caching suggests that animals plan for the future. However, in order to speak of planning, current behavior must be based on its future consequences and must be independent of the animal's prevailing motivation. Clayton and her colleagues asked if scrub jays could anticipate their future need states and act accordingly. The researchers placed the jays into two different compartments on alternate mornings for 6 days. In one compartment, food was always there in the morning; in the other compartment, the bowl was empty. Following 6 days of exposure to the two compartments, the jays were unexpectedly given a bowl of cacheable pine nuts after the evening meal; they were also given free access to the two different compartments in which the caching trays had been placed. The jays could either eat the pine nuts or store them in one or the other of the two compartments. The birds opted to store the food, but not randomly; they presumably anticipated their future needs and cached more food in the compartment in which food was not going to be available in the morning. Thus, it seems that scrub jays can plan for a future motivational state.

Conceptualization

It is generally admitted that the higher animals possess memory, attention, association, and even some imagination and reason. If these powers are capable of improvement, there seems no great improbability in more complex faculties, such as the higher forms of abstraction, ... having been evolved through the development and combination of the simpler ones.

Darwin's speculation that higher-order cognitive capabilities are the evolutionary outgrowth of more primitive cognitive capacities, has bolstered the search for evidence of abstract concept learning in animals. Over the last quarter century, the extent to which animals, especially those phylogenetically distant from humans, can learn abstract concepts and, particularly, understand the relations of sameness and differentness, has become a focal concern of this work.

Animals must possess at least some primitive sense of sameness and differentness. Animals are comfortable with members of their own species, but they flee from members of alien species. Plus, animals behave consistently in familiar situations, but they change their actions when something unusual transpires. For example, when uninformative stimuli repeatedly occur, a wide range of animals cease responding to them. This phenomenon of habituation requires the animal to perceive a particular stimulus as the *same* as one presented before. By contrast, when a second novel stimulus is introduced along with the habituated stimulus, the organism starts responding again – dishabituation. Now, the organism detects something *different* in the situation and its behavior changes accordingly.

We also know that behaviors which are associated with some stimuli in some contexts generalize to other stimuli in other contexts. Indeed, generalization and its counterpart, discrimination, are the foundations of categorization, another familiar instance of conceptual behavior. When an organism makes the same response 'car' to discriminably different cars, it is generalizing among all cars; when an organism makes the same response 'flower' to discriminably different flowers, it is generalizing among all flowers; at the same time, it is discriminating flowers from cars. Categorization thus involves generalization within a class, but discrimination between classes. If sameness within a category and differentness between categories are not perceived, then each event would have to be treated as entirely unique; animals would need to learn the appropriate response each time that each event is encountered, an excruciatingly demanding and inefficient chore.

Pigeons can learn to respond to photographs that contain a human being and not to respond to similar photographs in which human beings are absent. Even when people in the pictures differ in age, size, race, sex, clothing, and posture, pigeons learn to respond to the photographs when they portray people with a high level of accuracy.

Pigeons can also learn categorization tasks which are even more similar to the real-world situations that confront humans. Wasserman and his colleagues wanted to see if pigeons could report which stimuli belonged to which of four different categories of objects: cats, flowers, cars, and chairs. One image at a time from each category was presented on a viewing screen. Four report keys were also available, each

Figure 4 Illustration of one trial of the categorization task designed by Wasserman and his colleagues. In this case, a stimulus from the flower category is presented on the screen. The four report keys correspond to each of the four experimental categories; cats, flowers, cars, and chairs. For each of the categories, the pigeons had to choose the appropriate key. Text labels are included for explanatory purposes; they did not appear on the screen.

corresponding to a different category; these four different keys effectively served as four different 'words' for the pigeons (see Figure 4). Pigeons learned to select the appropriate key for the different categories. After learning, the birds were given novel items from the training categories to see if they would exhibit reliable transfer from the training stimuli, the critical test to document concept learning. The pigeons passed the test; they successfully used the four report keys to classify the novel items from the four trained categories.

It should be noted that items belonging to such categories as cats, flowers, cars, or chairs share a number of physical properties; so, it is generally accepted that perceptual similarity guides classification learning in animals, as it does in humans. A higher level of conceptualization is represented by relational concepts, which do not depend on perceptual similarity, but require learning about the relations between or among two or more stimuli. Here, the absolute properties of the stimuli must be transcended and knowledge of universal applicability must be extracted.

In order to speak of a true same–different concept, relational learning and generalization to novel situations must be demonstrated. Habituation and categorization suggest that abstract conceptualization may be within animals' capabilities, but more explicit evidence is required. Initial efforts to teach pigeons to report whether 2 items – the smallest number that is possible to make a same–different discrimination – are the same as or different from one another were not successful. But, perhaps it would be easier for pigeons to learn same–different discriminations with displays of items containing more than two stimuli.

Therefore, Wasserman and his colleagues trained pigeons to peck one button when a stimulus array comprised 16 identical icons and to peck a second button when a stimulus array comprised 16 nonidentical icons (Figure 5, top). Now, pigeons readily learned the discrimination to high levels of accuracy and, critically, they later transferred the discrimination with little decrement to both identical and nonidentical arrays constructed from novel visual items.

Figure 5 Examples of 16-item same and different arrays used in Wasserman and colleagues' research on same-different discrimination. The top panel shows orderly arrays, whereas the bottom panel shows disorderly arrays. Pigeons are highly adept at discriminating both orderly and disorderly arrays.

One characteristic of the same and different arrays depicted in **Figure 5** is that they differed in their spatial orderliness; the same arrays entailed clear horizontal and vertical regularities that the different arrays lacked. Pigeons could have been performing a perceptual rather than a conceptual discrimination. Remember Morgan's canon of parsimony?

Nonetheless, when pigeons were trained to discriminate 16-icon Same from 16-icon Different arrays in which the items were randomly placed on the screen, the birds readily acquired the discrimination and showed excellent transfer to new arrays (**Figure 5**, bottom). Moreover, randomly rotating the items in an array did not adversely affect pigeons' discrimination behavior. Finally, when pigeons were shown successive lists of same and different items on a one-at-a-time basis – thereby making spatial orderliness an unusable cue for solving the discrimination – the pigeons still exhibited robust discrimination learning and transfer performance. This pattern of results discredits simple perceptual accounts and strongly suggests that pigeons in these studies had acquired a same-different concept. Even Morgan would have been convinced.

To discriminate collections of same and different items involves understanding what are called first-order relations. Can animals go to the next level and learn higher-order relational concepts? Can they understand, not only that several identical apples are the same and that several identical balls are the same, but also that the relation between the apples and the balls is sameness? Judging relations between relations is basic to analogical reasoning; many authors have proposed that analogical competence is the very essence of human intelligence.

In an analogical or relational matching-to-sample task, the animal is given a sample stimulus set (either two or more

identical items on some trials and two or more nonidentical items on other trials), and two choice stimulus sets (one containing two or more identical items and the other containing two or more nonidentical items). Critically, none of the items in the sample is presented in the choice sets; so, if the sample is AA, then the choices can be BB or CD. To be successful, the animal must select the set of choice alternatives that instantiates the same relation as the sample set. Given that there is no overlap between the sample and choice items, only attention to the matching relations (same sample to same choice and different sample to different choice) can yield successful performance.

When baboons were given a relational matching-to-sample task in which the sample and choice arrays contained 16 items, they successfully learned to choose the 16-item choice array instantiating the same relation as sample array. Accuracy was high when sample arrays containing novel items were presented, thereby attesting to the generality of the relational matching concept; but, when the number of items in the sample arrays was reduced from 16 to 12 to 8 to 4 to 2, baboons' accuracy systematically fell to chance level. For the baboons, the task proved too taxing when too little pictorial information was available. Similar results have been reported with pigeons.

In contrast to baboons and pigeons, chimpanzees solve relational matching-to-sample problems even when only 2 items are presented in the sample and the choice arrays. The first chimpanzee to exhibit a variety of analogical behaviors was Sarah, who could evaluate, complete, and even create analogies.

Sarah initially learned to use one plastic token for the concept 'same' and another plastic token for the concept 'different.' In a set of later experiments, Sarah was given four geometric forms on a display board in a 2×2 format. The 2 items on the left represented one relation and the 2 items on the right represented another relation. Sarah had to choose the correct plastic token (one for 'same' and one for 'different') and place it in the middle of the board to indicate whether the relations between the set on the left and the set on the right were same (thus representing an analogy) or different. Sarah chose correctly about 80% of the time.

In other experiments, Sarah was given 2 items on the left side and only 1 item on the right side. The token for 'same' was placed in the middle of the board and Sarah now had to choose, from two alternatives, the item that completed the analogy. Sarah chose the correct option most of the time. She even did so when items representing functional relations were presented. For example, when shown a lock and a key on the left side, and a can on the right side, Sarah would choose the can opener to complete the analogy.

Another set of studies explored whether Sarah could also construct analogies. She was given an empty board and 4 or 5 items that could be used to create a valid analogy. This task was especially challenging because Sarah had to find unspecified relations among the items and arrange them on the board so that they would represent a proper analogical relationship. When only 4 items were available, Sarah created a valid analogy 76% of the times. Her performance dropped when 5 items were available, but it was still above chance level.

Premack and his colleagues have contended that language training and/or prior experience with arbitrary symbols for the

abstract concepts of same and different are needed for animals to exhibit analogical reasoning. Such training may have allowed Sarah to display analogical abilities that had been believed to be uniquely human. Language or symbol systems may facilitate relational and analogical behavior because they provide a way for animals to represent abstract relations so that these relations can be encoded and manipulated.

However, the research described above with baboons and pigeons suggests that language or symbol training may not be necessary for disclosing this cognitive capacity. Perhaps critically, both baboons and pigeons had been trained to discriminate same from different collections of items before training on the relational matching-to-sample task. That prior learning of first-order relations may have provided the scaffolding required to process second-order relations.

We conclude from all of this research that animals either have a rudimentary capacity for analogical reasoning or they at least possess the basic mechanisms that evolved into this capacity. These observations have important evolutionary implications. Higher-level cognition was once believed to be the unique province of human beings; but, we now know that chimpanzees, baboons, and pigeons show similar intellectual abilities, at least in their basic form. The roots of abstract thought may thus lie deep in our animal ancestry.

Metacognition

Demonstrations of numerical and basic mathematical abilities, different types of memory, as well as abstraction and analogical reasoning clearly document that animals possess a broad range of cognitive abilities. But, do animals know what they know? This question is not a tricky word play, but the core matter of research in the growing field of metacognition. Metacognition in humans is said to be associated with conscious awareness of one's own cognitive states. People know whether they can retrieve a specific memory, whether they can ascertain if they have enough information to make a decision, and whether they can assess the amount of knowledge they have about a certain topic; in short, people can think about their own cognitive states and processes.

In the last decade, several researchers have studied metacognition in animals as well. Metacognition in animals is plausible. Imagine this common scene: you are walking through a park and you encounter a woman walking her dog; the dog sees you and then it starts looking back and forth to his owner, as if deciding 'should I stay or should I go?' Or we see a hesitant squirrel at the base of a wall apparently deciding if the wall is low enough for her to jump up and land on it safely. When animals do not know what to do, they might defer their actions and seek help or information. These behaviors may be the result of a metacognitive process; but, do they really require metacognition? Do animals have access to their own cognitive states and can they use those states to control their behavior?

First attempts to address animal metacognition used what has been dubbed the uncertainty paradigm, in which animals must learn to discriminate between categories of stimuli, for example, between high-pitch and low-pitch sounds or between pixel-dense and pixel-sparse visual images by choosing one

of two different responses for each of the categories. Animals receive food reward for a correct response and a time-out period for an incorrect response. When the stimuli are near the extreme values, the task is easy; but, the task becomes increasingly difficult the closer values are to the middle of the continuum.

In addition to the two category responses, animals are also given a third option – the uncertainty response – that avoids the target discrimination altogether and takes the animal to another easier task and a smaller amount of food than if they had chosen the correct response for the training categories. If animals can monitor their knowledge, then they might choose the uncertainty response when the values to be discriminated are highly similar and failure is likely. And, so they do. Dolphins and monkeys choose the two category responses when the task is easy, but they choose the third uncertainty response when the task is more difficult.

Nevertheless, the uncertainty response paradigm has raised several concerns, because alternative explanations based on simple associative learning can explain animals' apparently metacognitive behavior. For example, animals may have learned to select the uncertainty response for a particular range of stimuli (the difficult ones near the middle of the continuum) because of the reinforcement history with those stimuli (animals are consistently rewarded if they choose the uncertainty response, but they are inconsistently rewarded if they choose the category responses), not because of a subjective feeling of uncertainty.

In order to avoid this problem, other paradigms have been devised. As we saw earlier, animals have excellent memories for rich and varied information; but, as in the case of humans, these memories may fade or become difficult to retrieve over time. One interesting possibility is to see if animals can report their having good or poor memory for an event that happened some time ago.

Hampton trained rhesus monkeys on a matching-to-sample task in which a delay was introduced between offset of the sample image and the testing stimuli, with the sample presented along with three distractors. On some trials, an intermediate choice was introduced at the end of the delay interval which allowed the monkeys to either accept the memory test and receive a preferred reward if they were successful or to decline the memory test and receive a guaranteed, but less desirable reward (see method in [Figure 6](#)). On other trials, at the end of the delay interval, only the option to take the test was given, so that the monkeys had to take the memory test. If monkeys have metamemory, then when given the option to accept or to decline the test, they should accept the test if their memory is strong, but they should decline the test if their memory is weak.

As a consequence, the monkeys should be more accurate on those trials in which they are given the choice. They should accept the test on choice-test trials when they know that their memory is good. But, the forced-test trials will also include cases in which the monkeys' memory is poor, thereby, lowering their overall accuracy. Monkeys' performance accorded with this prediction; they were more accurate on trials in which they accepted the test than on trials in which taking test was the only option, suggesting that the monkeys could distinguish between their different memory states. Similar results have been found with rats.

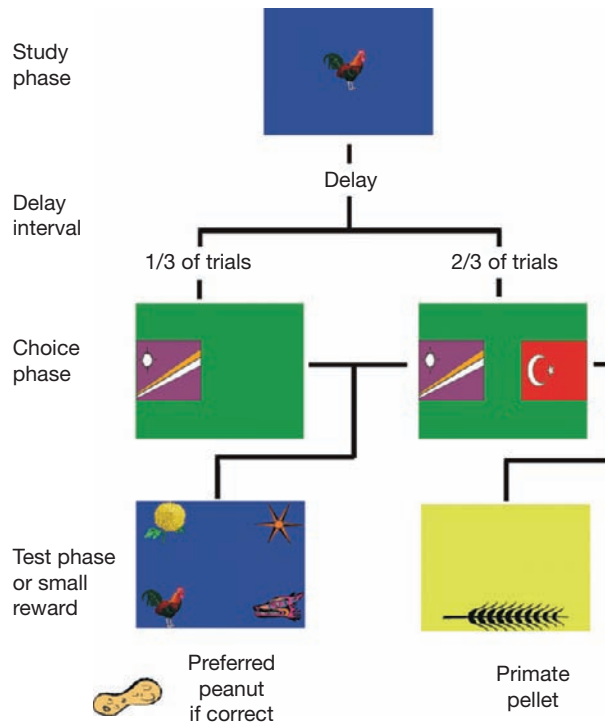

Figure 6 Method for assessing monkeys' metamemory designed by Hampton. Colored panels represent what the monkeys saw on the computer monitor. At the start of each trial, monkeys studied a randomly selected image. After a delay period, on two-thirds of trials, monkeys could choose between taking a memory test (right, left-hand stimulus) or declining the test (right, right-hand stimulus). On the remaining third of the trials, monkeys were forced to take the test (left). From Hampton RR (2001) Rhesus monkeys know when they remember. *Proceedings of the National Academy of Sciences* 98: 5359–5362. Work in the US public domain.

Monkeys' confidence in their memory has also been evaluated by allowing them to gamble. Monkeys viewed a series of six pictures, one by one; after the last picture, nine pictures simultaneously appeared on the screen, only one of which had been presented in the prior series. The monkeys' task was to select this picture. But now, before feedback was provided, the monkeys were given a choice of 2 icons, representing a high-risk option and a low-risk option. A high-risk choice resulted in the gain of three tokens (that could be later exchanged for food) if the monkeys' response in the picture memory test had been correct, but a loss of three tokens if the monkeys' response had been incorrect. A low-risk choice resulted in a sure gain of one token.

The rationale was that a monkey showing metacognitive capabilities should make a high-risk bet when confident about its prior response, but it should make a low-risk bet when unsure about its prior response. In fact, monkeys chose the high-risk button more often on correct trials than on incorrect trials, suggesting that they knew whether they had responded correctly before the presentation of any feedback. Moreover, monkeys generalized the use of the high- and low-risk options to a variety of different perceptual discrimination and memory tasks. This flexibility further helps to discount any specific

associations between the presented stimuli and the alleged metacognitive responses.

Animals can certainly exhibit complex behaviors in these metacognitive tasks; nevertheless, some researchers believe that it is premature to conclude that those behaviors are the result of access to and evaluation of internal cognitive states. Meta-memory tasks, the gambling paradigm, and other studies do suggest that animals can adaptively regulate their behavior under conditions of uncertainty and respond in accord with the knowledge they possess. But, that behavioral regulation may be achieved by means other than metacognitive processes. For example, animals may use their latency to respond as a cue for subsequent behavior (humans also take into account their speed of coming up with an answer to decide whether or not they really know). Although metacognition is a plausible mechanism for the animals' behavioral regulation, it is not yet clear whether it is the only possible mechanism. Again, Morgan's Canon comes into play.

Final Comments

Considerable recent research documents many animals' ability to remember the past, to respond effectively in the present, and to plan for the future. Research also suggests that animals may be able to take into account their current state of knowledge to control their own behavior in an adaptive way. Finally, animals can master numerical and abstract concepts, perform basic arithmetic operations, and even exhibit behaviors which suggest that they possess the roots of analogical reasoning.

Dumb beasts? Hardly! Animals of many different species are sensitive to the rich mosaic of events and relationships that are woven into the causal fabric of the environment. How could it be otherwise? Animals evolved under most of the same constraints and contingencies as the human species. To study animal cognition is to study the mechanisms and functions of cognition without the complexities of language or the biases of anthropomorphism. Doing so not only enriches our understanding of cognition in animals, but it also places human cognition into a more complete evolutionary perspective.

Glossary

Construct A working concept.

Nosology Branch of medicine dealing with the systematic classification of diseases.

Operationalization The process of defining a variable or variables into measurable factors.

Psychotic Group of psychiatric symptoms that include hallucinations, delusions, and odd behavior that reflect an impaired contact with reality.

Reliability The extent to which a test or criterion repeatedly yields consistent results when assessed by independent raters or in retesting.

Validity The extent to which a test or criterion measures or predicts what it is supposed to.

Introduction

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders – Text Revision* (DSM-IV-TR) defines antisocial personality disorder (ASPD) and narcissistic personality disorder (NPD) as persistent maladaptive personality styles that cause distress to a person or interfere with his/her social and/or occupational functioning. ASPD occurs in ~5% of men and 2% of women in the general population and is characterized by a disregard for the rights of others often exemplified by criminal behavior and a lack of remorse. NPD occurs in ~8% of men and 5% of women in the general population and is characterized by a grandiose sense of self and pathological self-centeredness. Antisocial PD and NPD are included in Cluster B in the DSM-IV-TR, which groups PDs according to shared descriptive features. Cluster B is marked by erratic and dramatic behavior and also includes borderline and histrionic PDs. Antisocial and NPD often cooccur with one another reaching 20% and 50% comorbidity in clinical samples and impact not just the individual with these conditions but also the people in their social/occupational circle and the greater society through associated aggressive and criminal behavior.

Conceptualizations of ASPD and NPD

The DSM-IV-TR characterizes ASPD as a ‘pervasive disregard and violation of the rights of others.’ While this current description emphasizes a behavioral disposition toward breaking society’s rules, a discussion of ASPD cannot be complete without addressing psychopathy, a clinical construct that emphasizes not just antisocial behaviors but also interpersonal features such as manipulativeness, glibness, and pathological lying as well as affective features including lack of empathy and callousness, lack of remorse, shallow affect, and failure to accept responsibility. Although not equivalent to DSM-IV’s ASPD definition, the concept of psychopathy has influenced to varying degrees the operationalization of ASPD throughout DSM history. At times, the term psychopathy has been used interchangeably with ASPD, but it has nonetheless been de-emphasized from

the official nosology. As a construct, psychopathy is reemerging in psychopathology research and clinical applications and it is likely to influence future DSM definitions of ASPD.

Descriptions of clinical phenomena that encompass modern conceptualizations of ASPD and psychopathy date from the early nineteenth century when psychiatry pioneers in Europe like Phillipe Pinel and J. C. Pritchard described patients with a conspicuous absence of overt psychotic symptoms, neuroses, or other ‘mental defectiveness’ who habitually violated societal rules displaying *moral insanity* (Pritchard) or *manie sans delire* (insanity without delirium, Pinel). In addition to the consistent antisocial behavior and apparent lack of other psychiatric symptoms, these early descriptions remarked on personality characteristics such as deceitfulness and lack of guilt, which are part of the ASPD construct today. The term *psychopathic inferiority* was first introduced by the German psychiatrist Julius L. A. Koch (1891) to encompass ‘character disorders’ (what we currently would consider PDs) and emphasized their organic etiology. Unfortunately, this broad application of the term ‘psychopathic’ expanded, and it often applied to various conditions ranging from what were considered sexual deviations of various kinds (including homosexuality) to substance abuse. Starting in 1904, Emil Kraepelin refined the concept to include conditions characterized by poor impulse control and severe antisocial behavior (sexual criminals, fire-setters, swindlers). By 1915, Kraepelin had described various ‘psychopathic personalities,’ which included the callous, aggressive, and alienated features of modern conceptualizations of ASPD. Nonetheless, despite refining by Kraepelin, the disorder remained undefined and the term ‘psychopathic’ was used to describe a multitude of unrelated conditions. The issue was further complicated with the introduction of the term ‘sociopathic’ by Karl Birnbaum (1909) to emphasize the view that criminality was mainly the product of social factors.

This confused state of affairs remained when in 1941 Hervey Cleckley published his influential monograph ‘The Mask of Sanity.’ Based on his extensive clinical observations, Cleckley provided a series of illustrative case examples along with 16 diagnostic criteria to operationalize the term ‘psychopathy.’ Cleckley’s criteria described psychopathic

persons in terms of maladaptive behavioral attributes such as unreliability, inadequately motivated antisocial behavior (e.g., robbery committed by someone with significant financial support), as well as affective features including pathological egocentricity, lack of remorse or shame, and untruthfulness. Notably, Cleckley's criteria also included healthy mental and interpersonal characteristics such as superficial charm, average to high intelligence, lack of delusions or signs of irrational thinking, and importantly, 'absence of nervousness or psychoneurotic manifestations.' Cleckley's book became (and remains) a cornerstone for research in the field. Based on it, David Lykken (1957) conducted a seminal psychophysiological investigation supporting the hypothesis that psychopathic behavior may result from impaired affective responses to fear and anxiety. Lykken's findings have been widely replicated and form the basis of his influential 'fearlessness' theory on the etiology of psychopathy.

In 1952, the first edition of the DSM used the term 'sociopathic personality disturbance: antisocial reaction' to refer to persons who habitually violated societal rules, were irresponsible, did not benefit from experience or punishment, were frequently 'callous and hedonistic,' and rationalized their misbehavior. However, under the same diagnostic rubric of 'sociopathic personality disturbance,' the diagnosis of 'dyssocial reaction' was also included to account for people who engaged in antisocial behavior but were able to maintain meaningful relationships with others. As could be expected, the inclusion of two versions of the antisocial personality diagnosis did not help clarify the classification of the syndrome. In response, DSM-II, in 1968, attempted to reduce confusion by discarding the 'dyssocial reaction' category and, in a marked departure from DSM-I, stressed that the diagnosis should not be based solely on a history of offending. Also, other personality characteristics including low frustration to tolerance and selfishness (common to Cleckley's psychopathy criteria) were added in the DSM-II and the name of the disorder was changed to antisocial personality.

As the use of the DSM-II became widespread, it became evident that a narrative description of disorders resulted in poor reliability for some of them, including ASPD. To remedy this, the development of DSM-III included clinical field trials of the proposed diagnostic criteria for each disorder to determine their validity and reliability. The final criteria for ASPD were heavily influenced by the work of Lee Robins (1966), who conducted research on the development of 'sociopathy.' Robins obtained archival clinical data of children and adolescents who had been referred to a clinic for juvenile delinquents from the early 1920s to 1930s and contacted 524 of them 30 years after their original referral. Although Robins initially included some of Cleckley's symptoms (e.g., lack of guilt about crimes), her criteria for the diagnosis of sociopathy heavily favored a behavioral approach to classification (e.g., repeated arrests, large numbers of sexual partners, substance abuse). At around the same time that the DSM-III field trials were being conducted, Robert Hare was developing a structured interview assessment of psychopathy in prison samples based on Cleckley's criteria. The result was the Psychopathy Checklist (1980), which used a clinician rated interview and a review of file information to rate interpersonal, affective, and behavioral indices to arrive at a diagnosis. Since its emergence, the Hare

PCL and its revised version (PCL-R, 1991) have become the gold standard of psychopathy assessment in forensic settings.

Despite its eventual importance, the first version of the PCL was too late to influence the diagnostic criteria for ASPD in the DSM-III, also published in 1980. In the DSM-III, the diagnosis gained its current name (antisocial personality disorder), and it again departed from its predecessor by exclusively relying on behavioral criteria and specifically *including* disregard for social norms and laws as a diagnostic criterion. To meet diagnosis, a person would have to persistently display at least four out of nine symptoms during adulthood and have a history of severe conduct problems before the age of 15. These changes resulted in increased interrater reliability, but many researchers pointed out that it came at the cost of lowered validity. A person could display an inability to sustain consistent work behavior and/or function as a parent, have divorces, and be impulsive, but *not* have any of the personality/affective traits of psychopathy (callousness, lack of guilt), and still receive a diagnosis of ASPD. To address these criticisms, the item 'lacks remorse' was added in the DSM-III-R in 1987. However, criticism continued because the added symptom was not necessary for diagnosis and various researchers suggested that some ASPD symptoms specified on the DSM-III-R (e.g., not maintaining a monogamous relationship for more than a year) were not good indicators of the traits underlying the syndrome.

The current diagnostic criteria for ASPD in the DSM-IV-TR still have not resolved the identity of this disorder as one marked more by behavioral antisocial acts or by personality features reflected in the psychopathy construct. This controversy has continued as the current field trials for the next edition of the DSM are underway and is reportedly one of the reasons that contributed to the recent decision by the American Psychiatric Association to delay the publication of DSM-V until 2013.

In comparison to the development of the ASPD concept, the evolution of the NPD construct has been less controversial. Diagnoses related to pathological narcissism have a relatively long history in psychiatry. In 1898, Havelock Ellis used the term 'narcissism' to describe a sexual perversion in which the self becomes the object of sexual desire. Throughout the twentieth century, the concept evolved with pathological egocentricity at its core and heavy influence from Sigmund Freud's psychoanalytic theory. Various writers including Sigmund Freud (1914), Ernest Jones (1955), and particularly Heinz Kohut and Otto Kernberg through the 1960s and 1970s contributed to the literature that speculated about the disorder's etiology, described its symptomatology, and proscribed its treatment. Although there were some differences between theorists (notably between Kohut and Kernberg) regarding the etiology of the disorder, all conceptions of NPD were remarkably similar in describing it as being characterized by grandiosity that masked underlying feelings of inferiority and fueled by an excessive need for admiration.

Although descriptions of the disorder date back to the late nineteenth and early twentieth centuries, NPD was introduced into the official psychiatric nosology in the DSM-III in 1980. The original description of the disorder was very similar to the current one and included grandiosity, feelings of uniqueness, entitlement, exploitativeness, lack of empathy, and idealization/devaluation of self and others. Since then, the criteria for the diagnosis have undergone only a few changes.

Specifically, a symptom of preoccupation with envy was added in DSM-III-R while the symptom of idealization/devaluation of self and others was removed, and then, in DSM-IV, a symptom tapping arrogance and haughtiness was added while the symptom of feeling rage, shame, or humiliation in response to criticism was removed. Although the symptom of anger in response to criticism was ultimately removed from the diagnostic criteria, the text of the DSM-IV-TR explains that rage and defiant counterattack in response to criticism are often an associated feature of NPD. Importantly, aggression in response to criticism has been well documented in clinical and laboratory settings among NPD patients and nonclinical populations with high narcissistic traits. Therefore, proneness to anger and aggression in response to perceived insult remains an important part of the narcissism construct and it may be a contributor to irritability and aggression, which characterize ASPD.

Although an initial comparison of the DSM-IV-TR's description of the essential features for NPD (grandiosity, need for admiration, and lack of empathy) and ASPD (pervasive disregard and violation of the rights of others) may not readily reveal an obvious overlap, it can be argued that, someone who engages in repeated deceit, assaults, and violations of norms while showing no remorse (characteristic of ASPD) is likely to be entitled, exploitative, unempathic, and arrogant (characteristic of NPD). Support for this view comes from various studies that have found a moderate to strong correlation between ASPD and NPD. In fact, the diagnostic overlap between the disorders was evident during the field trials to develop the current DSM diagnostic criteria for ASPD. Affective symptoms such as 'lacks empathy,' and 'inflated, arrogant self-appraisal' (from a 10-item version of the PCL) provided incremental validity for ASPD, but were not included in the official list of diagnostic criteria due to concerns that it would make the differentiation between ASPD and NPD difficult. These findings suggest that personality aspects that are central to NPD (and psychopathy) are an important aspect of ASPD and will likely influence future diagnostic criteria for the disorder.

Comorbidity

ASPD, Psychopathy, and Overt Criminality

Both ASPD and psychopathy are associated with aspects of criminality, including interpersonal violence, substance abuse (both intake and illegal trade), nonviolent crimes, and recidivism. However, the *type* of criminal behavior displayed by people with ASPD versus those with psychopathy may be an important factor that distinguishes these two syndromes. Studies with prison populations have found that up to 50–70% of people in prison meet ASPD diagnostic criteria, while only 25–30% meet psychopathy diagnostic criteria. However, within 3 years of release from prison, 80% of psychopathic offenders violate the terms of parole compared to only 25% of their nonpsychopathic counterparts. More worrisome are findings that psychopathic offenders are four times more likely than nonpsychopathic offenders to recidivate violently, and according to an FBI report, almost half of persons who kill law enforcement officers are psychopathic. These findings suggest that psychopathic offenders are at higher risk for recidivism, in particular, for violent offenses.

The literature categorizes criminal acts as 'proactive' or 'instrumental' to indicate a level of planning and/or emotional coldness (e.g., planned homicide to steal drugs from dealer) versus 'reactive' to indicate impulsivity and higher affective reactivity (e.g., assaulting a stranger after a perceived insult or argument). Starting in adolescence, a trend emerges for psychopathic individuals to engage in violent, planned criminal behavior whereas persons with ASPD are more likely to engage in unplanned, impulsive criminal behavior. This trend continues throughout adulthood and extends to a variety of crimes ranging from petty crimes to sexual homicide. This is not to imply that persons with ASPD do not engage in proactive criminal behaviors or that psychopaths are not reactively hostile. Rather, psychopathic individuals appear to have a proclivity for violence and are more likely to have planned their actions and/or not be emotionally aroused (e.g., angry) before committing a crime than people with ASPD. Notably, investigators examining the relationship between facets of psychopathy and criminality have found that interpersonal/affective traits of the disorder appear to be uniquely associated with the instrumentality and planning of crime, while the impulsive/social deviance traits are not. On the other hand, the social deviance traits of psychopathy are more strongly related to ASPD and play an important role in the maintenance of antisocial behavior: they predict violent and nonviolent recidivism and, among adults, they predict violent sexual offense recidivism.

Other factors such as intelligence may also play a role in the type of crimes in which people with ASPD or psychopaths engage. Low scores on measures of verbal ability have been associated with ASPD and the social deviance aspect of psychopathy but not with the interpersonal affective traits of psychopathy. Therefore, in the case of people with ASPD, their lower cognitive ability and aggressive and impulsive nature makes them likely to repeatedly engage in opportunistic, unplanned crimes, often 'in the heat of the moment' or under the influence of substances. On the other hand, higher verbal ability, superficial charm, and conning manipulateness of psychopathic individuals allow them to better plan crimes and put them in close contact with victims they may not know. It should be noted that crimes cannot always be clearly divided into planned/instrumental or impulsive/reactive and the majority of crimes have both elements. Research indicates that while psychopaths may be *more likely* to commit proactive/instrumental crimes, *the majority* of the crimes they commit have been categorized as 'impulsively instrumental,' leading some researchers to propose that psychopaths may be able to restrain their violent impulses but are unwilling to do so.

NPD and Antisocial Behavior

As mentioned earlier, ASPD and NPD have features in common and it is therefore not surprising that narcissistic traits and NPD have been associated with antisocial and aggressive behavior. A large part of the evidence supporting a relationship between narcissistic traits and aggression comes from social and personality psychology laboratory studies showing that highly narcissistic individuals (though not necessarily diagnosed with NPD) react aggressively toward people who they think have criticized them. The same relationship between narcissism and aggression has been observed in clinical settings

with NPD patients and persons with 'subclinical' NPD. For example, studies examining domestic violence have reported a strong association between NPD, high narcissistic traits, and sexual coercion (among both genders), child abuse, and violence against women. Importantly, as the levels of narcissism increase, so do the levels of violence. Therefore, the data appear to show a pattern in which narcissistic traits and NPD are clearly related to violence and as narcissistic traits are more elevated (e.g., among psychopaths), the relationship to aggression is more robust and crosses the threshold from reactive to include proactive or predatory aggression.

Comorbidity with Other PDs

Epidemiological data show that nearly two-thirds of people with NPD also meet criteria for another PD at some point in their lifetime. The highest comorbidity is found for other Cluster B PDs, particularly ASPD and borderline PD. Men with NPD are significantly more likely than women with NPD to have ASPD and the converse is true for borderline PD. Histrionic PD occurs in 10% of people with NPD regardless of gender. The next most common lifetime comorbidity for NPD is with Cluster A PDs, which are marked by odd or eccentric behavior. Schizotypal and paranoid are the Cluster A PDs that occur most frequently with NPD and neither of them shows a gender difference in the comorbidity rate. Finally, Cluster C PDs are characterized by anxiety and are found at some point in the lifetime of almost one-quarter of people with NPD regardless of gender. The comorbidity rate with Cluster C PDs is driven primarily by NPD's association with obsessive-compulsive PD. Antisocial PD is fairly similar to NPD in its pattern of comorbidity with other PDs. Like NPD, ASPD has its highest comorbidity with other Cluster B PDs, and ASPD also has substantial comorbidity with paranoid PD from Cluster A and obsessive-compulsive PD from Cluster C.

Comorbidity with Other Disorders

The rate of comorbid PDs among individuals with NPD is rivaled by a similarly high rate of substance use disorders (SUDs). One-half of those with NPD have an alcohol use disorder and one-quarter have a drug use disorder within their lifetime. Men with NPD show double the rate of alcohol and drug use disorders as women with NPD mirroring the gender difference found in the comorbidity of ASPD with NPD. Mood disorders such as major depression and bipolar I and anxiety disorders such as specific phobia and posttraumatic stress disorder are found in 20–25% of those with NPD at some point in their lifetime. Gender differences in the comorbidity rates for these mood and anxiety disorders are similar to those for borderline PD, with women with NPD showing greater rates of all but bipolar I as compared to men with NPD.

An extensive literature documents the high comorbidity between ASPD and SUDs, with some research showing that those with ASPD have an 11-fold increase in risk for an alcohol use disorder and a 14-fold increase in risk for a drug use disorder during their lifetime. There is a large literature on subtypes of alcoholism that consistently identifies two subtypes, one characterized by comorbid ASPD, more severe substance use

history, and higher likelihood of illicit drug use problems. According to research examining the structure of mental disorders, ASPD is part of an externalizing spectrum along with SUDs and behavioral disorders such as attention-deficit hyperactivity disorder. Antisocial PD's significant comorbidity with SUDs and other behavioral disorders stems from their association to a common factor labeled 'externalizing.' This externalizing factor is proving useful in the search for etiological influences (e.g., specific genes) that relate to multiple disorders in the spectrum, including ASPD.

Relationship to Normal Personality Traits

Personality Trait Dimensions Associated with NPD and ASPD

Currently, there is a movement to conceptualize PDs as extreme, aberrant configurations of otherwise normal personality traits. Most personality trait models coalesce around a hierarchical structure of three to five 'broad-band' personality domains comprised of a number of lower-order personality traits. One of the most widely used models is the five-factor model (FFM) of personality. Briefly, the FFM is composed of five broad-band factors: openness (intellectual curiosity vs. conventionality); conscientiousness (orderliness/planning vs. disinhibition); extraversion (outgoing/sociable vs. introverted/quiet); agreeableness (trusting/empathic vs. arrogant/aggressive); and neuroticism (emotionally stable/easy going vs. stress reactive/prone to negative emotions). Various researchers have mapped PDs along these dimensions in an effort to understand the personality traits that contribute to the disorders.

In the case of NPD, studies using dimensional measures of narcissism and the personality profiles of NPD patients have found that the disorder appears to be characterized by low self-reported agreeableness and neuroticism coupled with high extraversion. More detailed examinations of components of the narcissism construct such as leadership, exploitativeness, arrogance, self-absorption, and entitlement are associated with high levels of FFM facets of assertiveness/dominance of others but low gregariousness/affiliation. Therefore, the FFM profile of narcissistic individuals is consistent with the clinical picture of a person who is aggressive and demands attention and/or submission from others but without a desire to establish personal relationships with them. With regard to the relationship between NPD, narcissism, and the broad-band dimension of conscientiousness, findings have been mixed. However, recent studies have found a positive relationship between the motivational dimension of sensitivity to reward and NPD, as well as narcissistic traits. In addition, clinical cases show that persons with NPD endorse high levels of reward driven traits such as achievement striving, but they also score low in deliberation (both facets are subsumed under conscientiousness). This combination of motivational and personality traits contextualizes the clinical picture of persons who might view themselves as capable and diligent but at the same time are careless or impulsive in their approach and indeed aggressive or impatient when frustrated.

Interestingly, studies have shown that the aforementioned FFM features associated with NPD have some parallel relationships to ASPD and psychopathy and could explain their high rates of comorbidity. Specifically, low agreeableness

is common to the three disorders and may be the most relevant factor influencing their characteristic aggressiveness, mistrust of others, arrogance, and lack of empathy. Low agreeableness has also been found to account for much of the covariance between the interpersonal/affective and the social deviance facets of psychopathy. Antisocial PD and the social deviance traits of psychopathy are positively associated with neuroticism from the FFM, particularly the angry hostility, impulsiveness, and vulnerability (to stress) facets. On the other hand, the interpersonal/affective factors of psychopathy have been found to be unrelated or negatively related to neuroticism though positively related to extraversion particularly to the excitement-seeking and assertiveness facets. Finally, various studies have found a strong and negative association between all facets of conscientiousness, ASPD, and the social deviance aspects of psychopathy, completing the clinical picture of people who are unscrupulous, aimless, disorganized, and careless. The interpersonal/affective traits of psychopathy have also been negatively related to conscientiousness; however, the association tends to be lower than the one for psychopathy's social deviance traits and ASPD. This attenuated relationship between conscientiousness and the interpersonal/affective traits of psychopathy may be the result of poor insight conferred by inflated self-esteem. Among the facets subsumed under conscientiousness are competence (self-competence vs. ineptness) and dutifulness (ethical/scrupulous vs. lax/casual). Therefore, psychopaths' arrogance may lead them to report being competent while at the same time endorsing a nonchalant attitude toward responsibilities and ethics.

NPD Subtypes, ASPD, and Psychopathy

The above description of NPD presents a paradoxical picture of persons who may demand attention and recognition yet dislike being with others they deem inferior. Also, although some aspects of narcissism (e.g., vanity, arrogance) are negatively related to omnibus measures of emotional reactivity (neuroticism), the entitled and exploitative aspects of the disorder are positively related to it. In addition, as mentioned above, persons with NPD may have high conscientious traits such as achievement striving and competence but low deliberation and therefore poor control of impulses including their well-documented aggressive reactions. This 'narcissistic paradox' has been widely noted in the clinical literature and has led some writers to propose that there may be subtypes of narcissism: grandiose (or overt) and vulnerable (or covert). Both subtypes of narcissism have been related to undercontrol of aggressive and erotic impulses, insistence on self-expression even at the expense of others, and unrealistic and entitled expectations. However, grandiose narcissism is positively related to personality traits measuring social poise, self-assurance, and well-being, whereas, vulnerable narcissism is negatively related to these traits. Vulnerable narcissism has also been related to hypersensitivity and fear of social scrutiny, whereas grandiose narcissism is related to exhibitionism and attention seeking.

The duality of the narcissistic paradox is similar to the one observed with psychopathy and ASPD. Psychopathy, particularly its interpersonal/affective traits, is associated with high levels of assertiveness and excitement-seeking but low levels of stress reactivity (similar to grandiose narcissists),

whereas ASPD and the social deviance factor of psychopathy are associated with high levels of both excitement-seeking and stress reactivity (similar to vulnerable narcissists). Given the similarities in personality factors associated with NPD, ASPD, and psychopathy, recent theoretical proposals have posited that grandiose narcissism may be related to the interpersonal aspects of psychopathy while vulnerable narcissism may be related to the social deviance/ASPD aspects of the disorder. These proposals would be in line with earlier theories (e.g., Kernberg) suggesting that there is a pathological egocentric core to psychopathy and ASPD. Though provocative, these proposals require further exploration.

Etiological Influences: Genes and Environment

Twin studies are a primary methodology for estimating the extent to which genetic and environmental factors are associated with individual differences in a behavior or trait. The comparison of monozygotic (MZ) twins who share all of their genes to dizygotic (DZ) or fraternal twins who share, on average, half of their segregating genes allows for estimates of the amount of variability in a behavior or trait that is associated with genetic factors, shared environmental factors (things that are common to individuals who live together and serve to make them more alike), and nonshared environmental factors (experiences that are not shared among relatives which serve to make them different from one another). Research on the etiology of NPD is lacking relative to the voluminous literature on the etiology of ASPD. This is apparent when examining research on genetic and environmental influence.

Only a handful of twin studies have examined NPD or its dimensional representations. These studies based on a Norwegian twin sample suggest that 60–80% of the individual differences in NPD diagnoses or symptom counts are associated with genetic factors. The remaining variance is accounted for by nonshared environmental factors. Studies examining a dimensional representation of narcissism using the Dimensional Assessment of Personality Pathology in a large Canadian twin sample have found a similar pattern as found for NPD but with a more equal distribution of variance across genetic and nonshared environmental factors. Like NPD, ASPD is influenced by genetic and nonshared environmental factors, but many twin studies also indicate a small influence of shared environment on ASPD. Juvenile forms of antisocial behavior such as conduct disorder and delinquency show larger estimates of shared environmental influence that decreases in magnitude as people age.

A natural question given the comorbidity between ASPD and NPD is whether comorbidity arises from common genetic and/or environmental factors. This question has been addressed in two reports on a large Norwegian twin sample and the results suggest that a common set of genetic factors contributes to the association between NPD and ASPD (and histrionic and borderline PD). The data are inconsistent on whether a common set of nonshared environmental factors contribute to the disorders. Other research has shown ASPD to be part of an externalizing spectrum of disorders that also includes SUDs, attention-deficit hyperactivity disorder, and constraint (a personality dimension reflecting risk taking, adherence to

traditional values, and behavioral control). The externalizing spectrum has a common genetic etiology contributing to the various disorders as well as some disorder-specific genetic factors. Future research will need to assess the extent to which NPD fits within the externalizing spectrum.

Twin studies are useful in providing information on how much of the variability in a behavior or trait is associated with genetic or environmental factors, but they have not typically provided information on the specific genes and environmental factors involved. Recent developments in data analytic techniques are beginning to spur research on the interplay between genes and environment, but NPD has not been the focus of that research. Nor has NPD received attention in molecular genetic studies aimed at identifying specific genetic variants associated with the disorder. A growing body of work is beginning to show that there are gene \times environment interactions at work for antisocial behavior and ASPD. Adoption data, which provide a direct test of shared environment, show that conduct disorder symptoms are more frequent among adoptees whose biological parent had ASPD *and* whose adoptive environment was disadvantaged (e.g., presence of mental illness in adoptive parent). Research has also identified peer group as an important environmental factor in the development of persistent antisocial behavior. Finally, numerous studies have examined associations of genetic variants with ASPD and have found some support for genes related to the dopamine neurotransmitter system and to monoamine oxidase.

Treatment

The treatment of NPD has received much attention in the psychoanalytic literature with case studies of difficult to treat patients and outlines of psychoanalytic treatments for the disorder. Studies of clinical samples have shown that NPD is associated with impairments in interpersonal relationships and epidemiological studies have shown that impairments appear to be worse for men than for women. In addition, the presence of NPD can hinder treatment of other disorders such as SUDs and depression. Despite the evidence that NPD is a real phenomenon that impairs relationships and can negatively impact clinical practices, there are very few published studies of effective cognitive/behavioral treatments for NPD. Given this lack of attention, it is not surprising that there are no published reports on the empirical effectiveness of treatments for NPD using well-controlled clinical trials.

Psychopathy and ASPD have long been considered difficult to treat conditions. In fact, many PDs are difficult to treat because the conditions are ego syntonic, which means the person lacks insight into the fact that their personality is the root of their distress or functional impairment. The research on ASPD suggests that it might be more amenable to treatment than was first thought, but that the type of treatment makes a difference. Randomized control trials suggest that behavior-based treatments can be effective for reducing related problems such as substance use, whereas treatments that depend on the formation of a strong therapeutic alliance are less effective for people with ASPD. In the case of psychopathy, some researchers have presented evidence that treatment may actually make the disorder worse. Other researchers are less

pessimistic and claim that, like ASPD, some of their behaviors may be moderated while other researchers suggest that persons with psychopathy may only be managed or 'contained' (i.e., imprisoned and/or closely supervised). There is agreement, however, that the main reason for inconclusive or even contradictory findings in the area is the dearth of rigorous studies. In short, it is not clear that the symptoms of ASPD or psychopathy themselves are highly amenable to treatment of any kind once the disorder is present, and this has led some to advocate for early identification of severely antisocial youth as targets for intervention.

Summary

Narcissistic and antisocial PDs are persistent, maladaptive personality styles that interfere with a person's functioning. The DSM-IV-TR defines NPD as characterized by a grandiose sense of self and pathological self-centeredness. Antisocial PD is characterized by a disregard for the rights of others often exemplified by criminal behavior and a lack of remorse. Narcissistic PD occurs in ~8% of men and 5% of women while ASPD occurs in ~5% of men and 2% of women in the general population. Narcissistic PD and ASPD are included in Cluster B in the DSM-IV-TR which groups PDs marked by erratic and dramatic behavior. Narcissistic PD and ASPD are related to psychopathy, a disorder that embodies a particularly virulent combination of traits from both NPD and ASPD. Research has shown that NPD and ASPD have similar relationships to many normal range personality dimensions, which might help explain the high comorbidity among the disorders. Both NPD and ASPD are also comorbid with other disorders such as depression and SUDs. The effects of NPD and ASPD extend beyond the individuals with the diagnoses to people in their social/occupational circle and the greater society through associated aggressive and criminal behavior. The causes of NPD and ASPD include both genetic and environmental influences, and some evidence suggests that the disorders may be underlied by common sets of genes and environment. Like many PDs, both ASPD and NPD are often difficult to treat because individuals with the disorders often lack insight into their personality dysfunction.

Glossary

Anxiety An emotional state characterized by verbal reports of distress (e.g., apprehension, worry), physiological arousal (e.g., increased heart rate), behavioral activation (e.g., avoidance), and/or disruption of cognitive processing (e.g., hyperawareness). Anxiety is associated with more cognitive symptoms and less visceral activation, and cues for its manifestation are more diffuse and changeable, relative to fear, as the focus of anxiety is on objects/events that are more physically removed in space and/or time.

Fear An emotional state involving verbal reports, physiological arousal, overt behavior, and/or cognitive disruption similar to that of anxiety. Fear, however, involves greater mobilization for physical action, as the threat typically is related to specific objects or situations that are immediately present.

Panic Sudden onset of a discrete period of intense fear, typically involving feelings of terror and often accompanied by a sense of imminent doom. Physiological (e.g., hyperventilation) and/or cognitive (e.g., feelings of unreality) symptoms are involved. Panic attacks can either be associated with specific situations or are manifested with no known situational trigger; they can be either expected or unexpected, or situationally predisposed.

Phobia Extreme and persistent fear and/or anxiety of specific object(s) or a situation(s) that is out of proportion to any actual danger involved, typically provokes an immediate response, is recognized by the person affected as excessive, involves avoidance or considerable discomfort, and results in interference with life activities or great suffering.

What Is Anxiety and What Is Fear?

Use and Origins of the Words *Fear* and *Anxiety*

The importance of anxiety and fear in the human experience is reflected by the rich vocabulary that describes these emotions. A few of the many words used in everyday language to describe fear and anxiety include agitation, apprehension, concern, dread, edginess, fright, horror, jitters, nervousness, restlessness, scare, tension, terror, uneasiness, wariness, and worry. Historically, the word *fear* evolved from the Old English word *faer*, which meant peril or calamity but later came to mean a feeling of uneasiness caused by possible danger. The word *anxiety* originated from the Latin word *anxius*, which means troubled in mind, solicitous, or uneasy.

While the terms *anxiety* and *fear* are used interchangeably in much of the literature, recent theorizing suggests important differences between them. Fear, being an evolved basic emotion, typically is in response to a more immediate threat, and so is more highly associated with psychophysiological activation. Anxiety, on the other hand, primarily is a fear reaction to distal or non-present threat, and so is more cognitive in nature.

Fear and Anxiety in Discrete and Dimensional Models of Emotion

Discrete models of emotion propose the existence of a finite number of basic, fundamentally different emotions. Izard, for example, proposes ten fundamental emotions including anger, fear, sadness/distress, contempt, disgust, guilt, shame/shyness, joy, interest/excitement, and surprise. These basic emotions are considered innate and are thought to motivate adaptive action. For example, in fear, the corresponding 'flight' or 'fight' action

tendencies help motivate the organism to avoid or escape or fight to survive a dangerous situation. Individual emotions may combine with one another to produce a large variety of affective states. Fear typically is regarded as a basic emotion while anxiety is viewed as a blend of emotions.

Dimensional models generally assert that all emotions can be classified in terms of their relationship to two or three major orthogonal, bipolar dimensions of affect. The two dimensions proposed by Watson and Tellegen are positive affect (feeling active, elated, vs. dull, sleepy) and negative affect (feeling distressed, nervous vs. calm, relaxed). These dimensions are usually depicted visually as two axes intersecting at a 90° angle within a circumplex. In Watson and Tellegen's model, anxiety is associated with heightened negative affect.

Lang's bioinformational model proposes three rather than two orthogonal, bipolar dimensions: (1) a valence dimension, pleasantness-unpleasantness (feeling happy, content vs. afraid, sad), (2) an activity dimension, arousal-calm (feeling excited, tense vs. relaxed, sleepy), and (3) a control dimension, dominance-submissiveness (feeling in control, dominant vs. submissive, guided). These dimensions are visualized as three axes intersecting at 90° angles in three-dimensional space. According to this model, anxiety involves the experience of unpleasantness, arousal, and lack of control.

Components of Anxiety and Fear

Some psychological perspectives have regarded fear and anxiety as amorphous entities *inside* an individual. Critics have labeled these as *lump* theories. The lump perspectives have been criticized as being unscientific and nonconducive to empirical verification. More recently, fear and anxiety have been regarded as

comprised of verbal reports of distress (with underlying cognitive activity), physiological arousal, and overt behaviors. These three systems are fear and anxiety themselves and comprise their structure.

In many cases, verbal report is the most salient of anxiety/fear responses. The verbal report component is quite complicated in that people can not only describe private, internal states, such as feelings and thoughts, but can also report on their overt behaviors and physiological responses. Accuracy and reliability of reporting are an issue, due to the effects of social desirability and acquiescence, reactive effects of measurement, bias, and faking.

Behaviors associated with fear and anxiety are often motoric and observable. In fact, actual avoidance of an object or situation has long been a hallmark of phobia. Escape is a related behavior, but instead of avoiding the object or situation altogether, the individual confronts it, but leaves prematurely. While avoidance and escape behaviors are the most classic overt behaviors relevant to fear and anxiety, Marks has identified a total of four types of overt behaviors associated with fear and anxiety:

1. withdrawal (avoidance, escape),
2. immobility (freezing, unresponsiveness),
3. submission (vulnerable posturing, appeasement),
4. aggression (verbal attack, threats).

Immobility often is seen in the animal kingdom as an adaptive response to threatening situations, such as when predators are nearby and neither escape nor aggression would be prudent. Immobility can either be attentive, in which an animal freezes, or tonic, in which an organism is unresponsive, perhaps appearing dead. Immobility may be less common in human beings, but can be seen in extreme reactions to major stressors. For example, victims of brutal attacks have reported reacting by being paralyzed and unable to respond during the event. Individuals with height anxiety typically report feeling 'frozen' in place, which is adaptive to their fear as they are less likely to fall.

In submission, organisms attempt to deflect attacks on themselves (or their young) or try to appease a threatening organism. In human beings, appeasement can be observed in a variety of social encounters, such as in situations in which individuals with less status attempt to placate higher status persons by avoiding eye contact or making self-deprecating remarks.

Aggression is less commonly associated with fear or anxiety. Nevertheless, *fight* is one option in the fight or flight reaction. Sometimes, colorful aggressive displays, like the threatening rustling of plumage in some peacocks are involved in such reactions. Responding to threat with fear- or anxiety-associated aggression can be adaptive, discouraging attack by others.

Anxiety and fear are associated with changes in various bodily organs and systems. Of greatest interest in this area has been the nervous system, particularly the autonomic nervous system. The parasympathetic and sympathetic nervous systems (divisions of the autonomic nervous system) are associated with changes in physiological function related to anxiety and fear.

In fear/anxiety responses, cardiovascular and other systems are activated. The heart rate is increased. Blood flow to the

extremities is decreased because of the constriction of peripheral blood vessels. In order to aid in defense, blood pressure increases to allow blood to be directed to the large skeletal muscles. Blood is stored in the torso so that it is readily available for vital organs. Skeletal muscles prepare to contract and so generate electrical activity. Muscles of the face change, which may be evident in facial expression. Sweat gland activity increases to prepare the organism to cool itself after exertion. The skin surface becomes cooler because of decreased blood flow to the skin. Breathing becomes more rapid to supply the blood with increased oxygen. An increase in the release of glucose into the bloodstream prepares the muscles and organs for response. Pupils dilate and hearing becomes more acute.

This mobilization of the organism for action is not the only aspect of fear. A unique diphasic response, specific to blood, injury, and/or illness stimuli, ultimately decreases heart rate and blood pressure, sometimes causing the organism to faint. This response is usually triggered by the sight of injections, blood, or injury. Blood flow is reduced, presumably to lessen the danger of shock if an injury were actually to occur, thereby rendering an organism more likely to survive.

Relationship of Anxiety and Fear to Courage

Courage is persistence in the face of fear and anxiety. To carry on with behavior despite both responding physiologically and acknowledging fear or anxiety verbally is to act courageously. For example, rescuing a child from a burning building would constitute courageous behavior for a passerby. It is also courageous behavior, however, for someone with an intense fear of public speaking to give a speech to an audience. Repeated and successful practice of courageous behavior leads to a decrease in verbal reports of fear and psychophysiological responsivity, which can lead to a state of fearlessness.

Individuals 'deficient' in fear and anxiety are not necessarily seeking treatment, but can suffer negative consequences. Marks and Nesse describe this phenomenon as 'hypophobia,' and explain that it is more beneficial to be appropriately cautious than to take risks. When a potentially harmful situation is encountered, anxiety can be beneficial and used in a way to warn and prepare for the possible threat. Hypophobic individuals may not experience as much fear and anxiety as the average person, which means they are at a higher risk of engaging in risky and possibly injurious behavior.

Measuring Fear and Anxiety

Assessing fear and anxiety can follow the three systems model, in which the focus of measurement is what a person says (e.g., expressing oneself in speech or writing by saying 'I'm afraid'), what a person does (e.g., avoiding a feared situation), and how their body responds (e.g., muscle tension). Interestingly, these systems appear to operate somewhat independently of one another. This phenomenon is known as *desynchrony* or *discordance*; anxiety or fear is present in one or more systems, but to a lesser or greater degree in others. For example, some people appear outwardly calm while making a speech and do not avoid or escape, but their hearts pound and they later report having been terrified. People who are highly fearful, however, typically show consistency in fear across the three systems.

Anxiety can be measured in response to a specific situation at a discrete time, or can be assessed as a more general response tendency. Spielberger has characterized anxiety as being either state or trait in nature. State anxiety is a transitory emotional condition characterized by feelings of tension and apprehension which fluctuate over time as a function of environmental stressors and the individual's coping response to them. Trait anxiety is a relatively stable personality attribute that is an individual difference in proneness to experience stressors as distressing.

In assessment, the question arises as to which of the three response systems is the 'gold standard.' No one system has precedence over the others, nor is any one considered the most important, although self-reporting is the most commonly used approach, as a matter of convenience. Nevertheless, ideally the use of methods to assess each of the categories of self-report, psychophysiological response, and overt behavior is applied for the most comprehensive approach.

Self-reports are what people indicate through spoken, written, or other symbolic communication. Methodologies such as questionnaires and interviews are commonly used self-report assessment strategies. Questionnaires that directly prompt the individual to indicate the presence and intensity of anxiety/fear typically use numerical ratings. Some nonverbal assessment methods involve presentation of symbolic stimuli and require an individual to select stimuli that match internal feeling states. For example, the Self-Assessment Mannikin prompts individuals to rate dimensions using an abstract stick figure, changing characteristics of the mouth (for smiling or frowning), bodily activity (to indicate arousal), and body size (to report on feelings of dominance).

Another self-report methodology, interviews, can be used to collect information about anxiety and fear and can have the advantage of allowing a trained interviewer to use judgment in assigning ratings to compensate for interviewee biases such as over-reporting or minimizing. The interview format can be unstructured and general, such as open-ended interviews conducted by most mental health professionals in purely clinical settings. Structured interview protocols can be utilized to assess broadly (e.g., Anxiety Disorders Interview Schedule) or in highly specific areas (e.g., Dental Fear Interview).

Overt motoric behaviors are typically evaluated by observation. Observation of behavior can take place in the clinic, laboratory, or natural environment. Self-monitoring is often used with clinical patients, asking them to record event frequency, context, and associated thoughts and feelings (e.g., recording when panic attacks occur and in what situations). Monitoring can also be done by parents, partners, and others. In clinical settings, role plays can be used to emulate actual situations so that behavioral responses of patients can be observed.

It is possible to utilize trained personnel for standardized observations, such as monitoring of facial expressions or assessment of social skills. A standardized strategy for observing behavior in clinical and research settings is the behavioral assessment test (BAT). In this method, the individual being assessed is asked to confront a fear/anxiety-eliciting stimulus in a standardized format (e.g., how long a person can carry on a speech). It is also possible to observe more subtle behaviors (e.g., stammering during a speech), which can be quantified.

Typically, measures involve approach (e.g., how close a person can get to a snake in a BAT for snake phobia) or endurance (e.g., how long an individual can stay seated in a dental chair in a BAT for dental phobia).

Psychophysiological data most often are collected in the laboratory or clinic, but can be acquired in the natural environment using ambulatory monitoring equipment. Typically, psychophysiological levels are measured at resting baselines and then compared to precisely timed events that provoke fear and/or anxiety. The most frequently utilized measures of physiological arousal in fear and anxiety research are cardiovascular. Of these, heart rate has been the most often selected index. Another commonly used physiological measure is electromyography, the assessment of skeletal muscle activity. By measuring electrical activity from a muscle, it is possible to infer muscular tension. Assessment of electrodermal activity is yet another type of psychophysiological measurement; it focuses on sweat gland activity in the skin, using measures of skin conductance and resistance. An increase in perspiration will be reflected in a decrease in resistance and an increase in conductance. Other ways of measuring psychophysiological fear and anxiety reactions include endocrinological measures. Research has examined changes in catecholamine levels before, during, and after stress in both normal and anxious subjects. Endocrinological studies have also investigated changes in epinephrine, norepinephrine, and adrenocortical functioning.

Across the three systems, specialized instruments allow evaluation of aspects of anxiety and fear that would ordinarily be impossible to measure accurately or at all. Instruments are commonly used to measure psychophysiological responses as well as to record speed and accuracy of cognitive processing. Moreover, brain imaging techniques that allow measurement of very basic physiological processes are available now. Novel assessment methods have been introduced to accurately record cognitive processes. These techniques can be used to assess responses to stimuli that are within the consciousness (supraliminal) or outside the awareness (subliminal). Assessing cognitive processes in fear/anxiety research has focused on attention and memory, assessing reaction time, processing time for complex tasks, accuracy of recall and recognition, comprehension of ambiguous stimuli, and effects of interfering probe stimuli, among others.

What Makes Human Beings Anxious and/or Fearful?

Anxiety and Fear as Normal, Adaptive Emotional States

Fear and anxiety are normal responses in everyday life that are an important part of being human. Fear and anxiety can be adaptive reactions to realistic threats or to the possibility of some negative event(s). In dangerous situations, fear can mobilize people to respond rapidly and efficiently. Without this capacity, human beings would not have been able to survive when faced by the dangers present in the natural environment. Cannon's emergency action tendencies of 'fight' or 'flight' represent the organism's alarm reaction to life-threatening emergencies. With regard to anxiety, the ability to anticipate possible negative futures and to prepare to deal with them is adaptive as well.

Fear and anxiety continue to have adaptive value in everyday life. Without some minimal amount of fear and anxiety,

people might become careless and lack the motivation to accomplish things that need to be done. People might drive recklessly on the highway, approach dangerous animals, neglect work, or not plan for the future. According to the Yerkes–Dodson law, human and animal performance generally improves with increases in arousal until some optimal level is reached, at which point further increases in arousal hinder performance. With too little arousal, a pilot may become inattentive and make a critical mistake; with too much activation, the pilot may become paralyzed with fear and unable to respond effectively to danger.

People do not always avoid situations which provoke fear and anxiety and at times may actively seek out dangerous activities. Many sky divers, mountain climbers, and race car drivers enjoy the challenge of mastering danger. Most people enjoy some sort of danger vicariously such as by viewing horror movies, or reading suspense novels. Some individuals also enjoy the fear involved in riding roller coasters and going to Halloween ‘haunted houses.’

Pathological Fears and Anxieties

While a bit of fear and anxiety can keep people alert and ready for action, excessive amounts are disruptive and even paralyzing. It is important to clarify the relationship of normal fears and anxieties to pathological states, diagnostically known as anxiety disorders. The immediate context is particularly important with fear, as when there is danger present, even high levels of fear may be appropriately activating, to remove the individual from threat. Without such danger, however, higher degrees of fear likely interfere with functioning. Similarly, some lower levels of transient anxiety may be a cue for individuals to plan ahead and overcome procrastination, while excess worrying probably interferes with performance.

As illustrated in [Figure 1](#), fears and anxieties exist along a continuum of severity, ranging from fearlessness at one end to typical levels of anxiety and fear to their pathological manifestations in anxiety disorders at the other end. Inherent in this model is the idea that normal anxieties and fears are continuous with psychopathological states. The anxiety disorders are not disease states completely unlike that found in ‘normal’ individuals. They are, however, quite extreme and persistent versions of emotional states experienced by almost all people.

Anxiety and fear are considered pathological when they are out of proportion to the actual threat present, interfere with one’s daily activities, involve maladaptive behavior such as avoidance or escape, and are recognized by the individual as excessive or unreasonable. The prevalence of anxiety disorders

surpasses that of any other category of mental health problems in the general population. Additionally, substance abuse, especially alcohol abuse, is common among individuals suffering from anxiety disorders and sometimes reflects an attempt at self-medication.

Situations Eliciting Anxiety and Fear

A considerable amount of research has been directed at identifying the objects and situations that evoke fear in human beings. New fears and anxieties emerge or are lessened periodically. Only in the last several decades have there been concerns about terror attacks and AIDS; concerns about contracting certain diseases which were common prior to and early in the 20th century are considerably less now due to availability of certain medications. The specific focus of fear and anxiety are, in part, culturally and otherwise environmentally determined. It may be more common to fear violence, for example, in high-crime areas in certain cities and in war-torn lands, given the greater vulnerability and probability associated with attack. Nevertheless, work by Arrindell and others has made it possible to categorize anxieties and fears of adults into the following five basic dimensions:

1. social situations,
2. environmental and/or agoraphobic situations,
3. blood, bodily injury, illness, and death,
4. sexual and aggressive scenes,
5. small animals.

Fear and Anxiety Across the Lifespan

While fears and anxieties can develop at any time of life, some have greater incidence in particular developmental stages. Fears identified as being common in infancy typically include fear of heights, loss of physical support, loud noises, and other sudden, intense, unexpected stimuli from the environment. A fear of strangers typically develops between 6 and 12 months. Stranger fear appears to be different from distress associated with separation from parents. Fear of strangers can emerge as early as 4 months and peaks between 13 and 18 months. A program of research by Kagan and colleagues on temperament evident in infancy suggests that some human beings are constitutionally predisposed to being anxious and/or fearful, inhibited, and physiologically reactive, which may have long-lasting implications.

Common fears of children 1–3 years old include fear of toilet training activities, injury, loud noises, animals, dark rooms, masks, and novel stimuli. During preschool, kindergarten, and

Figure 1 Continuum of severity for anxiety/fear.

first grade, prominent fears include fear of separation from parents, animals, darkness, bodily harm, thunder, lightning, sleeping or staying alone, and supernatural beings. Older elementary school children frequently experience fears and anxieties related to test taking, grades, physical appearance, injury, illness, death, and natural phenomena such as thunder and tornadoes. Most fears and anxieties of adolescents are focused on personal adequacy, school events, physical health, sexual matters, and political and economic concerns. In general, over the course of childhood, fears and anxieties change from having a formless and imaginary quality to being specific and reality-based.

Many fears and anxieties are common in the general population. The five most common fears among adults, in developed Western societies, in order of prevalence, are:

1. snakes (most common),
2. heights,
3. storms,
4. flying in an airplane,
5. dental treatment.

What human beings fear and find anxiety-provoking changes across the lifespan. During the course of development, virtually all children display a large number of fears (e.g., of injections, doctors, darkness, strangers), most of which are transitory or short-lived. Fears of snakes, animals, heights, storms, enclosures, and social situations are frequently acquired during childhood and adolescence, but appear to be more long lasting, as their prevalence remains relatively high throughout adulthood and into old age. Fears which reach their peak of prevalence at the upper end of the lifespan include fear of crowds, death, injury, illness, and separation. Fears and anxieties in older adults are complicated by frequent coexistence with other disorders such as depression and dementia. Symptoms of anxiety, including worry, are similar in younger and older adults, although there may be some unique considerations in the elderly, such as the greater likelihood of medical illnesses. While some anxiety disorders decrease in prevalence in older adults, phobic disorders and generalized anxiety disorder are relatively frequently manifested.

Sex and Gender Differences

Studies consistently have shown that, in most domains (with social fears a notable exception), men generally report less fear and anxiety, while women report more such distress. This sex difference appears during childhood, and is seen throughout life. What males and females fear and find anxiety-provoking also seem to differ. Women express more environmental and agoraphobic fears, distress about small animals, and concern about sexual and aggressive scenes than men. Fear of social situations, as well as fear of bodily injury, death, and illness appears to be more equivalent. During childhood, girls report more fears and anxieties related to animals and physical injury and illness, while boys report more fears and anxieties related to economic and academic failure.

Variables other than biological sex may account for many of the differences observed between females and males regarding the prevalence of fears, anxieties, and anxiety disorders. While

there is more generalized anxious response in women relative to men, with females reporting higher and males reporting lower levels of anxiety, the response of females may be healthier for them, consistent with the literature on the benefits of emotional expression. Craske suggests sex differences in anxiety may be related to four main issues: gender role expectations (females allowed greater social latitude to report fear), life events (females have more negative events than males), physiology (males more physically reactive to acute stress, females more reactive to contextual cues), and cognition (females more likely to worry). Wilson and Daly contest that males are socio-biologically developed to be competitive risk takers, especially when there is a good chance of success. This predisposition to risk taking may result in either less fear and anxiety, or perhaps less *reporting* of fear and anxiety.

Cultural Considerations

Fear and anxiety are emotional states that are experienced by people across the world, although their environmental content, context, and manifestation vary widely. Traditional Aboriginals in Australia, for example, prefer open areas that are not closed in, and some may react quite negatively to being shut in a room. This reaction may be related to thousands of years of nomadic existence, in which closed in shelters were uncommon. As another example, Chinese males in Southeast Asia may suffer from *koro*, the fear of the penis retracting into the abdomen and death occurring as a result. This phenomenon results in acute panic and various devices may be employed to prevent retraction of the penis. Occasionally this disorder is seen among women as well; they fear retraction of the nipples, the breasts, or the labia. In this culture, male genitals are considered to be vital for life and excessive sexual activity is believed to be unhealthy. Therefore, it is not surprising to find that patients who experience *koro* may relate the cause to past sexual transgression.

Fright-related disorders are interesting phenomena that have been observed in many different cultures. In Iranian society, a variety of problems ranging from physical illness to psychotic episodes may be explained as being caused by a prior startle or fright experienced by the individual. Similarly, in some Hispanic cultures, *susto* is a condition that is caused by a sudden fright, the *evil eye*, or the casting of a spell and is characterized by a state of anxiety, fearfulness, or illness. The result of these beliefs may lead to what is termed *Voodoo Death*. The victim of the *curse* or *evil eye* can be in a state of autonomic hyperarousal for an extended period of time, which presumably may lead to damage of the internal organs and eventually death.

While these culture-specific conditions differ across the globe, the prevalence rates of many classic anxiety disorders are relatively similar. Nevertheless, there are differences between ethnic and racial groups within nations and geographic areas. For example, there is a higher rate of phobic disorders among African Americans than Caucasians in the United States. This distinction may be due to the stress of being in a minority group that has experienced prejudice and which has higher proportions of low socioeconomic status relative to the general population, placing them at higher risk for stress and negative life events.

Comparisons Across Species

Fear and anxiety responses have been instrumental in the survival of both human beings and other species throughout the course of evolution. Humans and animals have often experienced similar hazards to their existence and, through natural selection, have come to share many similar, adaptive fears. For example, human infants, like the young of other land-dwelling species such as cats, goats, and monkeys, display an adaptive fear of heights and withdraw from a visual cliff. Aquatic species such as ducks show no such fear. Similarly, novel objects, foods, and situations elicit adaptive approach-avoidance behaviors in humans and other species such as birds and primates; such behaviors are beneficial to organisms in that the unfamiliar carries with it the possibility of both danger and opportunity. Other fears common to both humans and many other species include fear of too much or too little light or space, fear of sudden touch, seizure, proximity, or movement, and fear elicited by visual and auditory alarm cues from members of the same species.

Theories of the Development and Maintenance of Anxiety and Fear

Origins of Angst

For centuries, philosophers and clinicians have pondered the cause(s) of diffuse and objectless anxiety. Kierkegaard used the German word *angst* to describe this experience. For Kierkegaard, *angst* results from the distinctively human, self-conscious capacity to discern the *possibility of freedom* and the ultimate threat of nonbeing. Kierkegaard thought that the achievement of selfhood was possible only if one was able to recognize and confront anxiety and to move ahead and actualize one's possibilities despite it.

Psychodynamic Models

Early theories of anxiety and fear arose from psychodynamic traditions. Freud used the word *angst* (anxiety) to refer to vague, objectless anxiety and the word *furcht* (fear) to label such distress when it was focused on an object. Freud viewed anxiety as the reaction to and signal of unconscious memories of real or imagined threats to the child. Anxiety is related to fantasized situations that were perceived as real and dangerous to the child, who felt helpless in the face of them. The generation of anxiety acts as a signal to elicit the psychological defense mechanisms, which, if adequate, reduce anxiety and allow for a high level of functioning. If the defenses are not adequate, phobic or compulsive symptoms symbolically related to the unconscious source of anxiety may arise.

Learning Theories

Although the capacity to experience fear is innate, most fears and anxieties are learned through association. Fear and anxiety may develop through classical conditioning. In this type of learning, an unconditioned stimulus (UCS), such as pain, is the original source of fear (unconditioned response). After pairing the UCS with a new, previously neutral stimulus, this

second stimulus becomes the conditioned stimulus (CS). The CS then can elicit a fear response (conditioned response) without the UCS being present. Watson and Raynor demonstrated this process in their case of little Albert. Albert, a young child, initially showed no fear of rats. He was, however, frightened by loud noises (UCS). Watson and Raynor repeatedly exposed little Albert to a loud noise (UCS) while viewing a rat (CS). Little Albert soon developed a conditioned fear to rats. This fear generalized to other objects that resembled rats, such as rabbits and other soft, furry animals.

An early adaptation to classical fear conditioning theory was the avoidance learning model, which hypothesized that fears fail to decrease or remit completely if the individual learns to avoid the stimulus. Mowrer stated that the learned fear of the CS was acquired according to classical conditioning principles, and that the motor response of avoidance was learned by instrumental conditioning. As it involves both classical conditioning and instrumental conditioning, it is known as the 'two-factor theory.' It purported to explain why phobias do not resolve even with repeated exposure. Mowrer reasoned that the motor response was first made to escape a negative situation, but on subsequent trials, the behavior was an avoidance response motivated by fear, and maintained by fear reduction. Despite the fact that the two-factor theory has not fared well when subjected to rigorous empirical investigation, it has made significant contributions toward the understanding of the maintenance of fear and anxiety.

Other mechanisms have been introduced to resolve the limitations of conditioning theories to account for the development and maintenance of anxieties and fears.

Vicarious Learning Through Observation and Direct Instruction

Vicarious learning has been extensively studied, and undoubtedly can play a major role in the acquisition of anxiety and fear. Such learning through observation, hearing accounts of fearful situations, or someone telling another person that an event (e.g., dental care) is *scary* can be linked to learned sensitivity of bodily sensations (e.g., suffocation cues related to panic attacks) and social phobias (e.g., socially anxious parents fearing and avoiding social situations, thereby serving as a model for their children's social behaviors). Although vicarious learning certainly does not always lead to phobic responses, or even anxiety or fear, it may serve as a specific type of psychological vulnerability for the development of anxiety disorders.

Cognitive-Behavioral and Cognitive Theories

Cognitive-behavioral and cognitive formulations of fear and anxiety have grown in influence within the scientific literature. Barlow regards panic as a critical component to anxiety disorders, with biological diathesis and psychological vulnerability potentially predisposing individuals to develop problems with anxiety. Barlow's work suggests anxiety, fear, and panic may be described as cued or uncued, expected or unexpected. Panic is considered cued when the individual is able to identify an external or internal event that precipitates it; panic is considered uncued when the individual is not able to identify a trigger. If a panic attack is anticipated, then it is expected; otherwise, it is unexpected. Thus, panic attacks fall into one

of four categories: cued and expected, cued and unexpected, uncued and expected, uncued and unexpected. For example, a panic attack is both cued and expected when a person with a snake phobia encounters a snake. Spontaneous panic that comes 'out of the blue' is uncued and unexpected. In this conceptualization, fear is largely cued, while anxiety is uncued.

Research suggests there are three particular categories of anxiety/fear-linked cognitive bias. Specifically, individuals experiencing anxiety (1) attend selectively to threat-related information, (2) show facilitated memory for threat-related information, and (3) demonstrate an interpretive bias favoring more threatening meanings of ambiguous information. In terms of the content of thinking, anxiety has been found to include negative self-talk, low self-efficacy, and self-abnegation.

Beck's cognitive theory depicts a three stage approach in responding to anxiety and fear: (1) registration of the threat, (2) activation of an automatic response to the threat, and (3) the subsequent evocation of secondary, elaborative checking. Further, this theory emphasizes that beliefs and cognitive processing of errors play an important role in producing and sustaining negative emotional states. For example, an anxious individual may believe that 'others are critical' and subsequently feel anxious when meeting new people. This individual will be quick to attend to threatening information in a social situation (e.g., frowns), will likely remember and ruminate about the most negative aspects of the situation (e.g., mispronouncing someone's name), and interpret ambiguous information negatively (e.g., someone ending a conversation is an indication of dislike rather than some more neutral explanation).

Metacognitive theory is a branch of cognitive psychology which emphasizes thinking about the manner in which individuals' process cognition, or 'thinking about thinking.' Instead of focusing on maladaptive beliefs, this theory places importance on awareness and control over cognitive (and emotional) processes, as well as overarching beliefs and appraisals of specific situations. Therefore, as described by Wells, an individual with generalized anxiety disorder may utilize various types of worrying as a means of appraising a situation and coping with it.

Network Models

As discussed earlier, Lang has forwarded a bioinformational model of emotion, differentiating the dimensions of valence, arousal, and control. In this theory, anxiety and other emotions are represented in memory via stimulus characteristics (e.g., hearing a dental drill sound), response propositions (e.g., gripping the arms of a dental chair), and meaning elements (e.g., being in a dental office for root canal therapy versus attending for routine care). Lang's theory may best be considered in the context of a defensive motivational system, in which the behavioral reactions of anxiety and fear are reflected in defensive immobility (freezing, hypervigilance response) and defensive action (flight-or-fight response). In Lang's recent research, there has been a focus on these responses, specifically the phenomenon of a startle potential. A noticeably stronger startle response is the result of the activation of the defensive motivational system, resulting from high arousal and a high level of unpleasantness.

Evolutionary Significance and Biologically Prepared Stimuli

Encounters with environmental stressors that cause fear and anxiety have been present throughout the history of humankind. Early encounters included contact with feared beasts that have shaped humans' reactionary responses. It has been proposed that animal fear originates in a predatory defense system that allows animals, including humans, to avoid or escape potentially dangerous animals such as poisonous snakes.

The evolutionary significance of fear and anxiety is directly linked to the biological idea of survival of the species. Fear and anxiety serve a protective function for all members of the animal kingdom who are capable of experiencing this biological warning. Some theorists believe that the ability to plan for the future is also dependent on anxiety and fear.

Seligman, Öhman, and others posit that humans, and some lower animals, are *prepared* or predisposed to fear certain animals and other stimuli. Human beings more frequently fear stimuli that can potentially cause harm (e.g., rodents). This theory of evolutionary *preparedness* implies that some aspects of what humans learn to fear, along with the fear response, may be innate. For example, investigators have suggested that humans may have an innate fear of small stimuli that move rapidly or abruptly (e.g., snakes, spiders). It is somewhat less frequent for people to fear things that have little or no apparent danger, although quite unusual fears are observed clinically (e.g., distress about opening large dictionaries).

This fear of evolutionarily relevant creatures (e.g., poisonous snakes and spiders) is observed even in individuals living in geographic regions in which no such threat exists. Therefore, even without the risk of encountering a dangerous animal, the fear persists. In contrast, the likely harmful aspects of modern life (e.g., overconsumption of alcohol, tobacco use, excess dietary fat, obesity, casual unprotected sex), are typically not feared, even though they are encountered more often and are more of an actual threat to individual well being.

Genetic and Familial Transmission

A variety of studies have asked, 'Are fear and anxiety inherited?' and 'Are fear and anxiety acquired through learning?' These questions are an example of the 'nature versus nurture' debate that permeates much of psychology. Researchers have looked at family histories, parenting characteristics, and prevalence rates of anxiety disorders within families to answer these questions. Comparative psychologists have demonstrated that it is possible to breed anxiety/fear in rats and dogs and have observed severe social anxiety to be naturally occurring in a subset of certain nonhuman primates. When exploring the heritability of the global category of *anxiety neurosis*, one study noted that as many as 50% of the children with parents with an anxiety neurosis also carried that diagnosis. Studies with twins suggest a genetic component in transmission of anxiety disorders. Studying the connection between phobias and the stress-diathesis model, Kendler, Myers, and Prescott suggested the importance of nonassociative models of fear acquisition, proposing vulnerability that primarily is biologically determined and innate. Most studies with humans support the idea that in some individuals, tendencies to develop fear and anxiety are inherited, but learning through familial

transmission has been demonstrated to be extremely influential as well. These interacting influences are represented in the diathesis-stress model, which integrates genetic or other biological vulnerability (diathesis) with environmental influences, particularly early learning. Further development of this model in the stress-vulnerability-protective factors approach also introduces the idea that there can be genetic and other biological hardiness as well, and certain earlier learning can 'inoculate' an individual from otherwise negative environmental events.

The contribution of heritability has ignited another question: *What is it that is inherited?* The most widely accepted answer is that one inherits a vulnerability to fear and anxiety generally, which may or may not develop in pathological proportions based on an individual's environment. Chronic stress is an example of an environmental influence that may induce problem fear and/or anxiety in a vulnerable person. Without that stress, the individual might never have developed an anxiety disorder.

Conclusions

The knowledge base about anxiety and fear continues to evolve. There are scientific journals devoted to anxiety and anxiety disorders as their exclusive subject matter. In the last several decades, national organizations (e.g., Anxiety Disorders Association of America) have come into being, with memberships including lay people afflicted with problem fear and/or anxiety, and professionals who provide treatment and/or research in the area.

In the anxiety and fear literature, theories of emotion and emotion regulation have gained prominence in recent decades. Learning, cognitive, and particularly cognitive-behavioral models continue to be important, but, theorists increasingly try to understand fear and anxiety in the context of the theoretical work and basic research emerging from the field of emotion.

Anxiety and fear are important emotional states, but are in truth like the proverbial double-edged sword. On the one hand, they are motivating emotions, prompting people to behave in healthy and safe ways. Conversely, in extreme forms, they are associated with misery and distress, causing chronic and lifelong problems that can disrupt an individual's life entirely and indefinitely if left untreated. While anxiety and fear are scientifically fascinating, and reveal much about the human condition, the associated distress can be

overwhelming. Anxiety disorders are also often associated with other emotional problems, particularly depression, as well as problems with alcohol and other drug abuse. While there is an extensive knowledge base on anxiety and fear, further conceptual work and more research is needed to better understand and more fully understand these emotions and the treatment of their pathological manifestations in anxiety disorders.

Glossary

Agoraphobia Fear and avoidance of situations associated with panic, or from which escape might be difficult, due to the fear of having a panic attack or not being able to obtain help.

Diagnostic and statistical manual of mental disorders The reference manual used by mental health professionals to diagnose psychological disorders. The DSM is published by the American Psychiatric Association and contains information on the diagnostic

criteria, associated features, prevalence, and course for each disorder.

Exposure A treatment technique that involves facing a feared stimulus (including images, thoughts, objects, events, or situations), and remaining with that stimulus until anxiety has decreased.

Panic attack A rush of intense fear or discomfort accompanied by physical sensations.

Phobia Excessive and/or unreasonable fear of an object or situation.

What Is Anxiety?

In general, anxiety is good and is an adaptive survival mechanism. It helps in keeping us from danger and in remaining motivated. Without anxiety, we would not jump out of the way from a car about to hit us, or study for a test, or be alert to signs of potential danger. Anxiety can be described in terms of behavior, thoughts, and physiological sensations. For example, behavior related to anxiety involves moving out of the way of the car that is about to hit us or paying attention to our surroundings in potentially dangerous situations. An anxiety-related thought might be, 'If I don't study, I may fail my test.' Physiological sensations of anxiety might include palpitations, sweating, or trembling. Thus, anxiety can be very adaptive, such as when it leads us to take precautions to protect ourselves from real dangers or to take action to run from or fight off real dangers (e.g., the fight-or-flight response). Even in safe situations, mild anxiety typically leads to better performance than does none at all.

When anxiety is excessive for a situation, however, it may become harmful rather than helpful. Maladaptive anxiety may include the same behaviors as adaptive anxiety, but in different circumstances. For example, the level of hypervigilance for potential danger that makes sense while one is walking alone in the street at night would likely be excessive while one is walking in a hallway in an office building during the workday. Another example of maladaptive anxiety is avoidance, such as refusing to participate in class due to fear of evaluation. The Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition, Text Revision (DSM-IV-TR) describes 11 disorders related to anxiety, and as a whole, anxiety disorders are among the most prevalent of all psychological problems.

It is important to recognize that anxiety falls along a continuum. So while everyone experiences anxiety and many people experience common symptoms of an anxiety disorder, this does not in itself mean they have an anxiety disorder; diagnosable anxiety disorders require that the anxiety leads to distress and/or functional impairment. For example, it is very common for individuals to fear public speaking due to fear of evaluation by others, a symptom of social phobia. Yet, many

people with this common fear will not meet the criteria for social phobia because it does not bother them to have this fear, nor does the fear or fear-related avoidance affect their lives. On the other hand, if the same individuals, with the same fear level, were to receive a job promotion that required them to give presentations, the same fear of public speaking might now be problematic for them, and might then be considered a diagnosable social phobia. Alternatively, the same individuals might find themselves developing stronger fears of the same situation, and becoming more distressed by their fear, which would also lead to their reaching the threshold of a diagnosable social phobia. Thus, distress or interference with functioning may be prompted by symptoms becoming more intense or more frequent, or by the same symptoms becoming problematic in a way that they had not been before (e.g., having a new job requirement to give presentations). Without distress or interference, however, even excessive or irrational anxiety would constitute nonclinical features of a disorder rather than a clinical disorder itself.

The Anxiety Disorders

Panic Disorder and Agoraphobia

Panic disorder is a common mental health condition that affects between 1% and 3.5% of the population in their lifetime. This disorder requires unexpected panic attacks, at least initially (often people with panic disorder then begin expecting to panic in specific situations, and thus may experience cued attacks as well as uncued ones). Panic attacks are periods of intense fear or discomfort that peak within 10 min and are accompanied by at least four of the following symptoms: palpitations; pounding or racing heart; trembling or shaking; feelings of choking; chest pain or discomfort; dizziness, unsteadiness, lightheadedness, or faintness; fear of losing control or going crazy; fear of dying; chills or hot flushes; numbness or tingling sensations; sweating; nausea or abdominal distress; sensations of shortness of breath or smothering; and derealization. Panic attacks can occur in all anxiety disorders, but in panic disorder, the attack is unexpected, rather than caused by a specific stimulus. Further, panic disorder requires at least 1 month of one or

more of the following symptoms: persistent concern about additional attacks, worry about the implications of an attack, or a significant change in behavior linked to the attacks. Finally, the attacks must not be due to a medical condition or substance use.

The change in behavior noted above can take many forms. It might include always having one's cell phone charged to be able to call for help if necessary. Using distraction, such as playing the radio loudly while driving, is another form of behavior change. One of the most common forms of behavior change is agoraphobia, or fear/avoidance of being in places where escape might be difficult or where help might not be available if the individual were to have a panic attack. One-third to one-half of all individuals with panic disorder also have agoraphobia, and are thus diagnosed with panic disorder with agoraphobia. (Those who do not develop agoraphobia are diagnosed with panic disorder without agoraphobia.) Common situations avoided in agoraphobia include bridges and tunnels, highways, and crowds. Such individuals avoid these types of situations entirely or in part (e.g., they will enter such situations with another person, but not alone) or endure them with marked distress.

More infrequently, agoraphobia may exist in the absence of panic disorder. This is most common in individuals who experience limited symptom attacks, which include panic symptoms fewer in number than are required for a panic attack. It may also occur in the presence of other nonpanic symptoms, such as someone with irritable bowel syndrome avoiding situations for fear of not having immediate access to a bathroom, in those who have never experienced the symptoms they fear but who avoid situations because 'it could still happen,' or for a small number of people, without the individuals being able to specify exactly what the fear is.

Specific Phobia

Specific phobia is characterized by excessive or unreasonable fear that is induced by the anticipation or presence of a specific object or situation, such as flying, animals, the sight of blood, or heights. The five specific phobia subtypes classified within the DSM-IV-TR are animal, natural environment (e.g., storms), blood-injection-injury (BII), situational (e.g., flying), and other (e.g., vomiting); however, there has been some discussion about these subtypes in the preparation of DSM-V. The person must recognize that the fear is unreasonable and the phobic stimulus must be avoided or endured with significant distress.

As noted earlier, it is important to keep in mind that many people have very strong fears that would not be considered phobias, due to a lack of distress or functional impairment. For example, a person may be very fearful of air travel; however, if the person does not need or want to fly anywhere, and does not mind having that fear, it would not rise to the level of a diagnosable phobia. If that person is offered a job that regularly requires air travel, however, the same fear may now become a phobia (e.g., if having to fly now leads to significant distress, refusing to fly would lead to poor job performance reviews, or the person must turn down the job despite otherwise wanting to accept it). Approximately 7–11% of people meet criteria for a specific phobia within their lifetimes.

Social Phobia (Social Anxiety Disorder)

Social phobia, also referred to as social anxiety disorder (with this term being considered as the official diagnostic term for DSM-V) is characterized by fear of negative evaluation or of embarrassing or humiliating oneself. Social phobia can be very specific, limited to just one or two situations such as public speaking, or it can extend to almost all social interactive situations. As with specific phobias, some social evaluative fears (such as public speaking) are quite common, and do not necessarily rise to the level of a diagnosable social phobia due to a lack of distress regarding the fear or impairment (such as avoidance of social evaluative situations) caused by the fear. In addition to the distress/impairment requirement, a diagnosis of social phobia requires that the individual should recognize that the fear is unreasonable, that anticipation of and/or exposure to such social situations induces anxiety, and that these situations are either avoided or endured with significant distress.

Social phobia is one of the most commonly diagnosed anxiety disorders, affecting between 3% and 13% of the population in their lifetime. Most commonly, people fear public speaking and performance. Typically, people fear more than one social situation; for those who fear most social situations due to fear of evaluation, the specifier 'generalized' is given. In some severe forms of social phobia, even situations not usually thought of as socially evaluative might be avoided, such as driving during the daytime when other drivers might be encountered at stop lights, for example.

Obsessive–Compulsive Disorder

Obsessive–compulsive disorder (OCD) is characterized by obsessions and compulsions. Obsessions are defined by the DSM-IV-TR as "persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate and that cause marked anxiety or distress." Typically, individuals with OCD feel that the obsessions are not under their control and often feel alien to them, in that they are not the kind of thoughts the individuals wish to have, or that make sense to them. Similarly, compulsions are defined as "repetitive behaviors or mental acts the goal of which is to prevent or reduce anxiety or distress, not to provide pleasure or gratification," and thus are engaged in to neutralize the obsessions or otherwise prevent feared thoughts or impulses from happening. Thus, many behaviors often referred to as 'compulsive,' such as gambling or shopping, would not be considered symptoms of OCD, as these behaviors are both enjoyed and engaged in for pleasure, albeit sometimes regretted later.

Common obsessions include contamination (e.g., being contaminated by touching a door handle), a need to have things in a certain order (e.g., feelings of distress when objects are asymmetrical), aggressive or horrific impulses (e.g., to yell out profanity in public or assault someone), repeated doubts (e.g., wondering whether one has turned off the stove), and sexual imagery (e.g., obscene thoughts or images); common compulsions include washing and cleaning, checking, repeating actions, ordering, requesting or demanding assurances, and counting. Often the compulsions are readily linked to the obsession, although far in excess of what would realistically make sense, as in the case of washing compulsions to neutralize

contamination fears. In other cases, the compulsions are not realistically connected to the obsession the individual is attempting to neutralize or prevent; for example, someone with an obsession of hurting another person intentionally may attempt to neutralize the thought by counting to ten backwards and forwards 10 times. Compulsions may include both overt (e.g., hand washing) or covert (e.g., bringing up positive images mentally to counteract horrifying images) behaviors.

For a diagnosis of OCD, individuals may experience obsessions only, compulsions only, or both, and these symptoms must cause significant distress or functional impairment, and/or take up at least one hour per day. Thus, as with the other disorders reviewed, it is important to note that many individuals engage in some forms of compulsive behaviors at levels that would not be considered clinically significant, such as occasionally feeling as if one needs to check the locks again, or even doing so again despite having done so already; without causing distress or interference or being time consuming, such symptoms would not be considered OCD.

There is also increasing attention being paid to problems sometimes referred to as 'obsessive-compulsive spectrum disorders,' such as skin picking, trichotillomania, and body dysmorphic disorder, and there is some discussion about consolidating these disorders, currently classified elsewhere in the DSM, into an obsessive-compulsive spectrum disorders group in the DSM-V or a later edition. Further, compulsive hoarding, currently classified as a form of OCD, has been the subject of increased attention in both the popular and research literature, and there is some discussion of classifying hoarding as a separate disorder rather than as one form of OCD. At the time of this writing, however, no such decisions have yet been made for the DSM-V.

OCD is somewhat less common than other anxiety disorders, affecting between 0.5% and 2.1% of the population in their lifetime. It typically begins in adolescence and is as common among women as it is in men (as opposed to other anxiety disorders, which are more common in women); however, childhood-onset OCD is more common in boys than in girls.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is one of only two anxiety disorders that specify a cause for the onset of the disorder: extreme trauma. The traumatic event must involve serious injury or actual or threatened death, a threat to one's physical integrity, or the witnessing or learning of such events. The individual's response at the time of the trauma must be one of fear, helplessness, or horror. Additional required symptoms include reexperiencing of the trauma, avoidance of stimuli associated with the event and general numbing of responsiveness, and increased arousal. Reexperience can range from flashbacks to intense distress when exposed to reminders of the trauma. In children, reexperiencing symptoms may take the form of distressing dreams or repetitive play related to the trauma. Avoidance can be effortful (avoiding thoughts, feelings, or situations related to the trauma) and could also include symptoms of emotional numbing, such as diminished interest in significant activities, and feelings of detachment. Increased arousal can take the form of difficulty in sleeping, outbursts of anger, trouble in concentrating, and hypervigilance. These

symptoms must be present for over a month, must represent a change since the trauma, and must cause distress or impairment in the individual's functioning.

While PTSD does have a specific cause identified, it should be noted that not all people with exposure to an extreme trauma go on to develop PTSD. The severity of, proximity to, and duration of the trauma affect the likelihood of an individual's developing PTSD. Estimates of lifetime prevalence of exposure to trauma range from 40 to 60% in the general population, yet only about 8% of the population actually develops PTSD. Clearly, exposure to an extreme trauma is necessary but not sufficient for the development of PTSD.

Acute Stress Disorder

Acute stress disorder (ASD) is similar to PTSD in the requirement of a precipitating traumatic event; however, the time frame needed for a diagnosis differs as do some of the prominent symptoms. For ASD, the individual must exhibit symptoms within 4 weeks of exposure to the traumatic event and these symptoms must last a minimum of 2 days and a maximum of 4 weeks. If symptoms last longer than 1 month, a diagnosis of ASD is no longer applicable, and a diagnosis of PTSD or another disorder should be considered.

Like PTSD, ASD requires exposure to an extreme trauma; response of fear, helplessness, or horror; symptoms of reexperiencing of the trauma, avoidance, and increased arousal and significant distress or interference from these symptoms. In addition, the individual must experience at least three dissociative symptoms such as a subjective sense of numbing, reduction in awareness of surroundings, derealization, depersonalization, or an inability to recall important events of the trauma; and at least one symptom of reexperiencing the trauma; these symptoms must also interfere in the individual's daily functioning.

Less information is available on the prevalence of ASD than other anxiety disorders, but the lifetime prevalence rate is estimated to be between 14% and 33% for individuals exposed to severe trauma. Individuals with ASD also have an increased risk of developing PTSD.

Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is characterized by excessive and persistent worries that the individual feels are uncontrollable. The worry must be experienced more days than not for at least 6 months, and focus on multiple topics. The diagnosis of GAD also requires at least three of the following: restlessness, fatigue, difficulty in concentrating, irritability, muscle tension, or sleep disturbance. Finally, the individual must experience marked distress or impairment in functioning due to these symptoms.

Those with GAD worry about common concerns, such as work, health, and finances, but the degree of worry is excessive, given the actual likelihood or impact of the event. Further, those with GAD feel as if they cannot stop worrying even if they want to. Often, the worries interfere with other tasks because the person is unable to focus on other tasks due to worrying, or engages in reassurance-seeking behaviors such as calling home to make sure everyone is okay.

The lifetime prevalence rate for GAD is ~5%, and the disorder is more common in women than in men. Often, people with GAD report worries as far back as they can remember, and describe their worry as a personality trait.

Anxiety Disorder due to a General Medical Condition

Anxiety disorder due to a general medical condition is characterized by symptoms of anxiety that are deemed the direct consequence of the medical condition, with the anxiety symptoms causing distress or functional impairment. The relationship of anxiety to the general medical condition is usually determined by examining the history, laboratory findings, or physical examination of the individual. Some medical conditions that have been known to cause anxiety symptoms include hyperthyroidism, cardiac arrhythmia, pneumonia, vitamin B12 deficiency, and encephalitis.

Substance-Induced Anxiety Disorder

Anxiety symptoms that cause marked distress or an impairment in functioning and are the direct effect of substance use are categorized as substance-induced anxiety disorder. Here again, the relationship of the anxiety to the substance must be determined by examining the history, laboratory findings, or physical examination of the individual. The anxiety symptoms must occur during intoxication or within 1 month of use and should be in excess of typical anxiety symptoms incurred during use or withdrawal from the substance.

Anxiety Disorder Not Otherwise Specified

Anxiety disorder not otherwise specified (NOS) is diagnosed when someone experiences a clinically significant level of anxiety but does not meet criteria for a specific anxiety or adjustment disorder. For example, a person who reports excessive worry that interferes with functioning but without enough accompanying physical symptoms (e.g., fatigue, muscle tension) to warrant a diagnosis of GAD could be diagnosed with anxiety disorder NOS.

Etiology

As with the majority of mental disorders, it is difficult to identify a single cause for the development of anxiety disorders. Anxiety disorders are thought to develop due to a combination of factors. While no single gene has been found that passes on an anxiety disorder to an individual, we know that children who have parents with anxiety disorders are more likely to have anxiety disorders. Some researchers believe that rather than a deficient gene that is passed from one generation to another, it is a general vulnerability or sensitivity to anxiety that is transmitted. This hypothesis may be supported by the fact that it is not uncommon for children to have a different anxiety disorder than that of their parents.

Environmental factors also play a role in the development of anxiety disorders. Parents may model anxious behavior for their children, or may transmit messages suggesting that various objects, situations, or feelings are dangerous and should be

avoided. Excessive levels of stress may trigger biological and psychological vulnerabilities that can manifest in an anxiety disorder.

Many clinicians focus less on causal than on maintaining factors in anxiety disorders, with the idea that one cannot change the past, but can change the present. Specifically, behavioral, cognitive, and physiological factors are thought to maintain anxiety. Generally speaking, individuals with anxiety disorders tend to avoid anxiety-provoking stimuli or to distract themselves so that they do not feel as anxious. While these behaviors can be helpful in temporarily reducing anxiety, they are harmful in the long term because the individual does not learn that the anxiety will decrease eventually on its own, even without such avoidance. Cognitive factors also play a role in the maintenance of anxiety disorders, with negative and unrealistic thoughts often perpetuating anxiety. For example, someone with social phobia may believe that everyone around her thinks she is stupid for dropping her books when in reality most people did not notice, and those who did notice did not think about the event or pay any further attention to it. Finally, physiological factors, such as higher autonomic lability, leading to frequent fluctuations in bodily sensations such as heart rate, can also maintain anxiety. Often, these maintaining factors interact to perpetuate a cycle of anxiety.

Treatment

Cognitive Behavioral Treatments

Currently, the psychosocial treatment with the most empirical evidence to support its use in the treatment of anxiety disorders is cognitive-behavioral therapy (CBT). CBT may include a variety of treatment components, such as psychoeducation, relaxation, exposure, and cognitive challenging; exposure is by far the method most implicated in the successful treatment of anxiety disorders. Psychoeducation refers to providing information about the nature of anxiety, such as the interaction of different components described in the previous section. Relaxation training, often in the form of breathing retraining, is taught as a coping strategy. Breathing retraining involves breathing more slowly, and diaphragmatically rather than from the chest, to dampen physiological sensations. When using such physical relaxation methods, however, especially in conjunction with exposure treatment, therapists generally emphasize that the idea is not that one *must* use these methods to decrease anxiety, or that experiencing anxiety is a dangerous thing that must be avoided by using such methods. Rather, such methods are presented as ways for individuals to decrease anxious responding at times when it is inconvenient (e.g., during an exam), and the anxiety should then be revisited at a later time.

The cognitive component of CBT typically involves recognizing and challenging maladaptive and/or unrealistic thoughts. Once the thoughts have been recognized, clients engage in an examination of the evidence for and against such thoughts and of the consequences of these thoughts, leading to the development of a rational response that best fits the evidence and the individual's desired outcome. Common unrealistic thoughts include overestimating the likelihood of a particular outcome (such as thinking that a panic attack will lead to a heart attack)

and catastrophizing, or thinking things are much worse than they are, or that they cannot be coped with (such as fearing embarrassment as something one cannot live with). Generally, consequences that are likely are also the least serious, while those that are the most serious also tend to be the least likely, and so countering the two thinking errors described above is generally sufficient for most anxiety-related thoughts. Another component in cognitive challenging is to continue drawing out one's fears to the fullest; this generally allows the individual to recognize that most of these fears are in fact quite irrational, something that had not been noticed due to the refusal to consider the next steps in a chain of anxious thoughts. For example, those with social phobia often fear being laughed at or being embarrassed in front of others, but may not continue drawing out those scenarios. When the scenarios are drawn out further, they may realize that their fears include having to run out of the room, that everyone will continue talking about their performance, that it will be printed in the paper for others to laugh at, etc. Using this method, it becomes much clear that these further consequences are truly unlikely, and that without those additional consequences, temporary embarrassment is not that big a deal.

Exposure, a key component in most CBT programs and the component with by far the most research to support its use, requires individuals to confront anxiety-provoking stimuli and to remain with those stimuli until their anxiety decreases. Exposure can be conducted in a gradual manner, beginning with easier situations and moving on to harder ones, or all at once, referred to as flooding. With flooding, the individual confronts the most anxiety-provoking stimuli from the start. While flooding has been found to be as effective as exposure conducted in a gradual manner, most clinicians use gradual exposure over flooding due to the decreased perceived distress related to working up to the most feared anxiety-provoking stimulus. Flooding may be preferred by some individuals, however, such as those who wish to overcome their problems in the quickest manner possible.

There are many different forms of exposure used to target different kinds of stimuli. In *in vivo* exposure, or real-life exposure, the individual physically confronts the feared stimuli. For example, a person with a specific phobia of snakes would remain in a room with a snake, touch a snake, or hold a snake. A person with a fear of public speaking would give a speech in front of others. Imaginal exposure is often used when *in vivo* exposure is not feasible or the individual is reluctant to begin with *in vivo* exposure, or when the anxiety-provoking stimulus is an image or memory. In the previous example, if the snake-phobic individual refused to get anywhere near a real snake, imaginal exposure might be used first, having the person imagine touching a snake, with the goal of then moving on to the *in vivo* exposure. Imaginal exposure is often used in the treatment of PTSD, wherein the memory of the trauma itself is anxiety-provoking. Interoceptive exposure, generally used for panic disorder, involves exposure to bodily sensations such as fast breathing or increased heart rate. Exercises such as running in place or spinning in a chair are used to induce feared sensations and continued until anxiety diminishes. Phobias are particularly helped by exposure treatment, as the focus of fear in these disorders is so specific. As noted above, these phobias are typically treated with *in vivo* exposure, with imaginal

exposure sometimes being used to start off, and sometimes with the use of modeling as well, wherein clients first observe the therapist confront the feared object before confronting it themselves. In general, exposure treatments are conducted similarly across the anxiety disorders, as only the focus of the exposure needs to vary. One exception to this is in the treatment of BII phobia, in which the phobic response is often a bit different from that in other phobias. Specifically, while most anxiety responses include increased physiological arousal, BII phobics often respond with decreased blood pressure, lightheadedness, and even fainting, an opposite physiological response. Thus, for BII phobia, applied muscle tension is generally added (generally by clenching one's fists), to prevent the fainting response by boosting blood pressure during the exposure.

Another addition to exposure treatment is response prevention, which is used for individuals with OCD. Individuals are first exposed to the thought, image, or impulse that triggers the obsession, but then they must also refrain from engaging in any behaviors or mental rituals aimed at neutralizing that obsession. For example, an individual with contamination obsessions would touch objects felt to be contaminated, and then refrain from washing. In complete response prevention, sometimes used in the treatment of more severe cases of OCD, the neutralizing behaviors are completely avoided; for example, contamination-fearful individuals would not touch any water at all for a period of several days, and would immediately 'recontaminate' upon the completion of the allowed shower at that time. Of course, in any exposure treatment it is important that clients do not engage in safety behaviors, whether they are ritualizing, distraction, or other behaviors, that detract from the idea of fully confronting one's fears.

Finally, exposure treatment may be augmented by the addition of D-cycloserine, an antibiotic that has been shown in some recent studies to enhance the learning process that occurs during exposure. This medication is not used as a treatment in itself for anxiety, but rather, is taken prior to the exposure session, to facilitate the exposure treatment.

Medication

Two different classes of drugs have been extensively studied for the treatment of anxiety disorders: anxiolytics and antidepressants. The anxiolytic drugs, benzodiazepines, are often used to treat anxiety disorders, but it is typically recommended that they be used as a short-term rather than long-term treatment due to the increased likelihood of dependency with long-term use. Further, both low-potency benzodiazepines (such as diazepam) and high-potency benzodiazepines (such as alprazolam) tend to decrease anxiety only temporarily. In addition to the dependency issue and the related withdrawal symptoms, benzodiazepines tend to have fairly high relapse rates once the medication is discontinued, and alprazolam for panic disorder may also lead to rebound panic attacks, where the panic attacks are more frequent and/or severe, following discontinuation, than they had been before treatment.

Antidepressants, such as selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs), have been shown to be helpful in treating a number of anxiety disorders. SSRIs (e.g., fluvoxamine, fluoxetine, sertraline) are often the first-line pharmacological

treatment for anxiety disorders due to their tolerability and their effectiveness in many anxiety disorders. The TCA most commonly used in the treatment of anxiety is imipramine, which is most indicated in the anxiety realm as a treatment for panic disorder; another TCA, clomipramine, is indicated for the treatment of OCD. MAOIs have also been shown to be effective in some anxiety disorders, especially social phobia and panic disorder; however, they carry a greater risk. Specifically, those on MAOIs must adhere to a strict diet, avoiding foods (such as red wine and aged cheese) with tyramines and related substances in order to avoid a steep rise in blood pressure, which can be fatal.

It should be noted that while pharmacological treatments have been shown to have a positive effect in terms of symptom remission for many with anxiety, they are often found to be no more effective, and sometimes less effective, than cognitive-behavioral treatments. Further, cognitive-behavioral treatments tend to be more effective in the long term, have a lower likelihood of relapse, involve lower overall cost, and have fewer adverse effects.

Other Psychosocial Treatments

While cognitive-behavior therapies and medication treatments enjoy considerable empirical support for their use, they are not the only treatments used for anxiety disorders. Another common intervention for anxiety disorders is psychodynamic therapy. In this form of therapy, the anxiety is not seen as the problem in itself, but rather as the symptom of an underlying problem that needs to be recognized and resolved. Thus, the focus of psychodynamic treatment is not on reducing anxiety symptoms directly. While this treatment does not have the extensive research to support its use in decreasing anxiety that CBT or medication treatments do, some individuals prefer to focus on the possible causes of their problems rather than on the alleviation of their anxiety symptoms, and thus may prefer this more insight-oriented approach to treatment. Similarly, there are numerous self-help approaches for the treatment of anxiety, as well as other therapist-led treatments such as group therapy, that individuals sometimes find more helpful and/or prefer, compared to the CBT or medication approaches.

Issues in Diagnosis

Among the anxiety disorders, there is significant overlap in symptoms, which is reasonable given that this group of disorders requires the presence of anxiety that causes the person marked distress or impairment in functioning. While the reason for symptom overlap is expected, sometimes differentiating between different anxiety disorders can be difficult. For example, people with social phobia as well as those with agoraphobia may fear going to a store. They may both experience significant physiological sensations while in this situation, such as increased heart rate, sweating, and trembling. They may both attempt to leave the situation or distract themselves to feel less anxious, and both may exhibit impairment in their social functioning due to their anxiety. They may even fear evaluation by others in this situation. However, what

differentiates these two disorders is the specific focus of their fear. For individuals with social anxiety, their fear centers on others negatively evaluating them, such as the belief that others will think they are stupid. Individuals with agoraphobia fear having symptoms of a panic attack or not being able to escape a situation if they experience these panic symptoms. While they may also fear the evaluation by others, this fear would be focused on others noticing their panic symptoms, not the social phobia focus of tripping, saying something stupid, or other such foci separate from the anxiety symptoms themselves; further, the person with social phobia is likely to feel anxious only in the presence of others, whereas the person with panic disorder will likely be anxious even when others are not around.

As treatment often stems from the specific diagnosis (e.g., applied tension for blood phobia) and certainly on the specific focus of the anxiety, it is important to make an accurate diagnosis. For example, treating all panic attacks with interoceptive exposure ignores the reality that only in panic disorder is the panic attack itself the focus of anxiety, and thus an appropriate target for interoceptive exposure; an individual who experiences panic attacks when near a dog would not be expected to benefit from interoceptive exposure, and should instead receive in vivo exposure to dogs, if properly diagnosed with a specific phobia of dogs.

Special Populations

Children

It is not uncommon for children to experience excessive anxiety or worry that warrants an anxiety disorder diagnosis; in fact, some anxiety disorders, such as GAD, often have an onset in childhood. Separation anxiety disorder, excessive anxiety related to separation from parents or other caregivers, is relatively common in childhood, yet rarely diagnosed in adulthood. Children with separation anxiety disorder often experience significant distress at the idea of separation from caregivers, and may be reluctant, or outright refuse, to attend school, go on sleepovers or to camp, or even be in a different room from their parents while at home. This fear is generally focused on the possibility of caregivers being harmed while away from the child, their not coming back for the child, or harm befalling the child while away from the caregivers; the fear is often expressed in nightmares and/or physical symptoms, such as stomach aches instead of, or in addition to, words. Symptoms must persist for at least 4 weeks for such a diagnosis to be warranted; ~4% of children meet criteria for separation anxiety disorder in their lifetime.

In general, children are more likely to express their anxiety through somatic symptoms such as headaches, vomiting, and stomachaches, than are adults. This may be due to their developmental stage and their lack of insight into their symptoms. For example, children with a phobia may demonstrate freezing, tantrums, or crying when presented with their particular feared stimulus. Often, children with an anxiety disorder do not report distress related to the fear, especially if a parent accommodates the child and his or her fears, such as by allowing a child with separation anxiety to stay with the parent throughout the day.

Elderly Adults

As is true of children, elderly adults may also experience the same anxiety disorders as other adults. Differential diagnosis may become even more important in this population, however, when one recognizes that medical conditions and neurological difficulties, more common among geriatric patients, can cloud the diagnostic picture. For example, it is not uncommon for those with dementia to exhibit symptoms of anxiety, especially in the early stages of the disorder when the dementia has not been clearly recognized. While both dementia and anxiety disorders can coexist, for a specific anxiety disorder diagnosis to be warranted, the anxiety symptoms must be in excess of those typically found in dementia.

It is also fairly common for older adults to experience worries and anxieties related, in full or in part, to aging. For example, while some worries tend to decrease as people age, other specific worries, such as those about one's health, personal safety, finances, and independence may increase with age, due to changing life and personal circumstances, which make these issues more salient.

Dually Diagnosed/Severely Mentally Ill Patients

It is not uncommon for individuals with an anxiety disorder to also have another diagnosis. Anxiety disorders tend to co-occur with one another. For example, as many as half of the individuals with GAD may also have another anxiety disorder, especially social phobia. Anxiety disorders also commonly co-occur with depressive disorders and substance use disorders. Some individuals with anxiety disorders self-medicate with alcohol or recreational drugs, using these substances to cope with anxiety-provoking situations or to mask their symptoms of anxiety.

Due to this high comorbidity, careful assessment is needed not only of anxiety, but also of related problems. Additional treatment may be needed to target these other problems, although treating the primary anxiety problem may also generalize to other anxiety disorders, or alleviate the co-occurring depression or substance use.

Individuals who suffer from severe mental illness, such as psychotic disorders, along with an anxiety disorder may also benefit from anxiety treatment. For example, a person with schizophrenia who also suffers from panic disorder with agoraphobia may avoid leaving home for fear of having a panic attack. This could interfere with the person's obtaining treatment for schizophrenia. With treatment for agoraphobia, the individual may be more likely to properly manage the schizophrenia. Further, even anxiety that is not separate, but instead is better considered part of the psychotic (or other) disorder, may be alleviated by targeted intervention; this symptom reduction, while not 'fixing' the primary problem, may certainly improve the individual's life by removing at least some source of distress.

Non-Western Cultures

Anxiety disorders can be seen across the world; they are not simply a Western phenomenon. A number of culture-bound syndromes, or disorders specific to a particular region, resemble

DSM-IV-TR diagnoses, but often with a focus that more reflects culturally specific fears. *Ataque de nervios*, seen in Latin American and Latin Mediterranean cultures, is associated with a sense of being out of control, uncontrollable shouting, trembling, crying, heat in the chest rising to the head, and fainting or seizure-like episodes, and somewhat resembles panic disorder. *Koro*, found in south and east Asia, refers to extreme anxiety and panic regarding the penis (in men) or vulva and nipples (in women) retracting into the body and causing death. In Korea, *shin-byung* is characterized by excessive anxiety, dissociation, and somatic complaints (e.g., weakness, dizziness, insomnia, gastrointestinal problems) that are attributed to possession by ancestral spirits. Numerous other culture-bound syndromes exist as well.

Medically Ill Patients

Anxiety disorder symptoms may also overlap with a range of medical conditions; for this reason, physical exams are generally recommended before anxiety treatment begins, to rule out a medical explanation for the anxiety and/or to ensure that anxiety treatment is safe medically. For example, hyperthyroidism can result in palpitations, nervousness, insomnia, fatigue, trembling, and sweating, and can resemble a panic attack. While the symptoms may be similar for both issues, the treatments differ greatly.

Medical conditions can also lead to diagnosable anxiety disorders, when the initial symptoms caused by the medical problem become exacerbated by the attention to those symptoms or what they may lead to. For example, a person with hyperthyroidism may become quite frightened of the increased heart rate, and fear that it is leading to a heart attack and death. This fear may prompt increased monitoring of heart rate and heart rate changes, leading to more frequent fears of heart attack, well beyond what the hyperthyroidism itself would involve. In such cases, where the anxiety is beyond that expected from the medical condition alone, an anxiety disorder may also be diagnosed.

Treatment for anxiety may also need to take medical conditions into account. For example, while interoceptive exposure may be among the best treatments for panic disorder, it may be contraindicated for an individual who also has a heart condition and must avoid the increased heart rate that such exposure often entails. In such cases, exposure may still be used, perhaps with modifications such as monitoring heart rate to ensure it does not exceed the medically advised level, or an alternative treatment may be used instead.

Conclusion

Anxiety disorders are common across gender, age, and culture. Accurate diagnosis of an anxiety disorder rests on determining the specific feared stimuli and the presence of functional impairment or distress related to this fear. Generally speaking, CBT is the psychosocial treatment of choice for all anxiety disorders, and it has also been shown to be effective when treating clients with severe mental illness, dual diagnoses, and medical illnesses. Medication is frequently used to treat anxiety disorders and is often preferred by many for its initial lower cost in terms of money, time, and effort; however,

medication tends to be less cost effective in the long term and involves higher relapse rates when discontinued than does CBT.

Aphasia

H S Kirshner, Vanderbilt University School of Medicine, Nashville, TN, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Agraphia An acquired inability to write.

Alexia An acquired disorder of reading.

Aphasia An acquired disorder of language caused by brain disease.

Frontotemporal dementia or frontotemporal lobar degeneration A neurodegenerative condition in which frontal lobe behavioral syndromes or aphasia are the presenting features.

Language A system of symbols used to convey thoughts, or internal, nonverbal images and representations, from one individual to another.

Lexical Of or pertaining to a word.

Literal (phonemic) paraphasic error An incorrect utterance based on substitution of an erroneous sound.

Morpheme A word ending which may vary depending on the use of a word, for example, in singular or plural, masculine or feminine, present or past tense.

Phoneme The smallest unit of speech which can alter the meaning of a word.

Semantics The meaning of words.

Syntax A system of grammatical rules used in language.

Verbal (semantic) paraphasic error An incorrect utterance based on substitution of an erroneous word.

Aphasias are disorders of language, or symbolic communication, acquired as a result of brain disease. Aphasia strikes at that most human of capabilities, symbolic language, and deprives the subject of communication with others.

By this definition, aphasia can be distinguished from several related conditions. First, aphasia is a disorder of language, and not a motor speech disorder. Motor speech disorders are abnormalities of speech articulation brought about by weakness or incoordination of the muscles of the speech apparatus. Neurological motor speech disorders include dysarthrias, abnormalities of speech articulation; dysphonias, disorders of voice; and speech apraxias, impairments of the ability to sequence a series of phonemes. In motor speech disorders, language comprehension and production are normal; in a patient with abnormal sounding speech output, language production can be ascertained by examining the patient's writing or by transcribing speech output into type. Second, aphasia is an acquired language disorder, not a congenital or developmental disorder. In North America, developmental language disorders are often called 'dysphasias,' just as developmental reading disorders are 'dyslexias,' and developmental writing disorders are 'dysgraphias.' It should be noted that in the UK, and in Europe, these terms are sometimes used in the sense of partial and not total language disorders. Third, the language disorder of aphasia must relate to brain disease, and not to psychiatric disorders. Psychotic disorders such as schizophrenia and bipolar affective disorder typically derange thought, or the content of language, rather than language itself. This last distinction is the most problematic, for two reasons. First, language is difficult to separate from thought. Even severely aphasic patients, however, seem capable of nonverbal thought, and their behavior, outside of language function, usually seems normal. On the other hand, patients with psychoses such as schizophrenia usually express their disturbed thoughts in normal articulation and syntax. Second, these psychotic disorders, though they remain in the domain of psychiatry rather than neurology, are likely brain diseases as well.

Introduction

History of Aphasia

Historically, language was the first of the higher cortical functions to be correlated with focal lesions of the brain. The French physician Paul Broca, in 1861, provided a clear description of nonfluent speech associated with lesions of the dominant hemisphere, especially the left frontal lobe. The principal syndrome of nonfluent aphasia is still called 'Broca's aphasia.' Similarly other nineteenth century physicians correlated areas of brain damage, usually resulting from stroke, with specific syndromes of abnormal language. Carl Wernicke, in Germany, described the fluent aphasia syndrome which now bears his name, as well as conduction aphasia; Lichtheim outlined the 'transcortical aphasias'; and Dejerine designated the syndromes of pure alexia with and without agraphia. The late nineteenth and early twentieth centuries saw slow progress in the understanding of aphasia, largely because physicians had to outlive their patients to correlate an aphasic syndrome with a brain lesion at autopsy. In addition, the early twentieth century witnessed a decline in interest in behavioral syndromes, in favor of the 'hard' neurological deficits of paralysis, sensory loss, and incoordination. The higher cognitive functions were either accorded little interest or assumed to have a diffuse distribution throughout the brain.

Modern Techniques in Aphasia Research

In the late twentieth and early twenty-first centuries, aphasia has undergone a revolutionary expansion of knowledge. First, brain imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) have permitted the study of brain lesions in living patients, simultaneously with behavioral studies. Functional brain imaging modalities such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional MRI (fMRI) allow the mapping of brain regions which are

metabolically active or show increased blood flow during specific behavioral tasks in normal subjects or in patients with aphasia. In addition, the language tasks themselves have been refined. Speech/language pathologists administer standardized test batteries to compare performance between subjects, or in the same subject over time. Neuropsychologists, cognitive neurobiologists, and linguists have constructed language tasks to test specific steps in language processing at which deficits occur, thereby creating models of the language process. Finally, knowledge about language and the brain has been acquired not only from the study of patients with strokes, head injury, and brain tumors, but also in normal subjects, with the use of functional brain imaging. In addition, in the evaluation of patients with epilepsy, to prepare for surgical resection of epileptogenic foci, techniques of electrical stimulation of brain loci have permitted mapping of areas of the language cortex. These areas can then be correlated with the results of surgery to ablate epileptogenic foci. These additional sources of information about language and the brain have modified our maps of language function in the brain. Stimulation of the cortex in epileptic patients, for example, has confirmed the general concepts of the localization of language functions derived from stroke patients, but electrical stimulation has identified new language areas and has suggested that the traditional areas may be smaller and more variable than previously thought.

Handedness and Cerebral Dominance

As Broca observed, the vast majority of right-handed patients with aphasia have left hemisphere lesions, suggesting that the left hemisphere is dominant for language function. In general, at least 95% of right-handed patients and a majority of left-handed patients have relative left hemisphere dominance for language. Cerebral dominance can be determined definitively by Wada testing, in which sodium pentobarbital is injected into the internal carotid artery, thus temporarily 'putting to sleep' the frontal, temporal, and parietal cortical areas of one hemisphere. Wada testing is carried out to determine whether an area of the brain can be surgically removed without producing aphasia. Newer methods of determining language dominance include mapping of language activity during language tasks by PET or fMRI, magnetoencephalography, and other techniques. The Wada test, however, remains the gold standard for determination of language dominance. The dominance of language in the left hemisphere appears genetically programmed, since it is present even in illiterate people. Geschwind and Levitsky pointed out that, in most human brains, the superior temporal plane ('planum temporale') is larger in the left hemisphere than in the right. Subsequent measurements using CT and MRI scans have shown similar asymmetries in living patients. The most reliable measurement is the occipital length, which is longer in the left than the right hemisphere in most right-handed people. This asymmetry is present at birth, again indicating that the enlargement of the left language cortex is genetically programmed, rather than acquired through use in language function. Studies have suggested that patients with atypical cortical asymmetries on brain imaging may have abnormal language dominance and atypical recovery patterns after injury to the language cortex.

Occasionally, a right-handed patient with an acquired right hemisphere lesion develops aphasia, a phenomenon termed

'crossed aphasia,' or 'crossed aphasia in dextrals.' These patients presumably have atypical cerebral dominance, and some have atypical hemispherical asymmetries on CT scan. The specific 'crossed aphasia' syndromes are frequently atypical, milder than would be expected with a lesion of similar size in the left hemisphere. Patients may also have expressive language in the left hemisphere, and receptive language in the right, or vice versa, leading to partial syndromes in which deficits are more specific to expressive or receptive functions than in the typical, expected aphasia syndrome.

Aphasia in left-handed patients also differs from the typical syndromes of right-handed patients with aphasia secondary to left hemisphere lesions. More left-handed patients than right-handed patients develop aphasia after a stroke, regardless of the side of the stroke, suggesting that left-handed patients have some language representation in both cerebral hemispheres. Though aphasia is more common in left-handers, recovery may be better. Taken together, these findings imply that the language dominance of left-handed patients is less rigid than that of right-handers, and either hemisphere can subserve recovery of language function. Most left-handed aphasic patients in a large series had typical aphasia syndromes, but two patients had large right hemisphere infarctions, with nonfluent aphasia but preserved comprehension. These patients appeared to have language expression arising from the right hemisphere, but language comprehension from the left. Most left-handers, like right-handers, have left hemisphere dominance for speech and language, but there may be separate loci of dominance for handedness, motor speech, and auditory comprehension. There is some evidence that women have less rigorously defined language dominance than men, and recovery may be better in women.

Epidemiology and Etiologies of Aphasia

Aphasia has classically been described in association with focal brain lesions. The most common such lesion is stroke, long the leading etiology of aphasia in research studies. Stroke can be thought of as an 'experiment of nature,' in which one area of the brain is damaged, while the rest remains intact. Both major types of stroke, cerebral infarctions, in which the brain is damaged by reduced blood flow, and hemorrhages, or bleeds into the brain, cause aphasia. Approximately 750 000 strokes occur annually in the United States. About 20% of stroke patients, or over 100 000 persons each year, develop aphasia following a stroke. The total prevalence of aphasic stroke victims in the United States approaches 1 million.

Traumatic brain injury frequently disrupts discourse and produces other language impairments, which are often part of a syndrome of general cognitive dysfunction. Penetrating brain injuries cause focal areas of damage which resemble strokes, except that the lesion locations are different, and the 'remote effects' of swelling, increased intracranial pressure, and contrecoup injuries are greater with traumatic brain injuries than with stroke.

Brain tumors, abscesses, and other mass lesions may also disrupt language. These syndromes typically develop gradually, over weeks or months, unlike the abrupt onset of aphasia secondary to stroke or head injury. As in head injuries, there are remote effects related to mass effect and edema, in addition

to the focal damage. For this reason, these disorders have been less useful than stroke in aphasia research. Focal brain damage from encephalitis and other infections also causes aphasia. The Herpes simplex virus causes encephalitis, with a predilection for the orbital frontal lobes and temporal lobes. Patients may present with fluent aphasia, as well as confusion, memory loss, seizures, and fever. Patients undergoing epilepsy surgery have also provided new knowledge of the language areas of the brain, as discussed earlier.

In addition to the language disorders associated with focal brain lesions, generalized brain diseases produce language disorders. Aphasia accompanies such diffuse syndromes as encephalopathies, acute confusional states, dementias, and chronic syndromes of memory and cognitive loss. These syndromes will be discussed after the focal aphasias.

Evaluation of Aphasia

Bedside Evaluation

Language functions are tested informally at the bedside to arrive at a preliminary syndrome diagnosis of aphasia. Deliberate testing is carried out for spontaneous and automatic speech, naming, repetition, comprehension, reading, and writing. Physicians correlate these language tests with other findings of the neurological examination such as motor paralysis, visual field defects, and sensory loss to arrive at a localization of the responsible brain lesion. Brain imaging studies are then performed to confirm the diagnosis.

Standard Aphasia Batteries

In addition to the bedside language evaluations carried out by neurologists and other physicians, a number of standardized aphasia tests are available. Most are used by speech/language pathologists or neuropsychologists for documentation of the type and severity of aphasic deficits and of progress during recovery. Among the widely used batteries are the Boston Diagnostic Aphasia Examination (BDAE), its Canadian adaptation the Western Aphasia Battery (WAB), and the Porch Index of Communicative Ability (PICA). More specific language tests have also been developed by cognitive psychologists, linguists, and speech pathologists for research studies.

Classification of Aphasias

Aphasia experts have used a variety of terminologies and classification systems. This article utilizes the 'Boston' aphasia

classification, developed from classical neurology, as reflected both in the bedside examination and in the BDAE and WAB. **Table 1** summarizes the language characteristics of the major aphasia syndromes.

Broca's Aphasia

Broca's aphasia was the first aphasia syndrome described, and the first correlated with a specific brain region. The syndrome involves reduced speech output, sometimes with complete mutism or hesitant, struggling efforts to produce single words or short phrases. Subjects utter the most important, meaningful words of a sentence, leaving out the small grammatical words. This speech pattern is called 'telegraphic speech' or 'agrammatism.' Patients struggle to recall names, often stuttering on the initial phoneme ('tip-of-the-tongue' phenomenon). Repetition is hesitant, like spontaneous speech. Auditory comprehension is intact for simple conversations, but detailed testing reveals deficits, especially for complex grammatical relationships, which also cause difficulty in expressive speech. Reading is often less preserved than auditory comprehension. Writing is influenced by the usual association with right-sided paralysis, or hemiparesis, but patients with Broca's aphasia usually cannot write well even with the nonparalyzed left hand, indicating the presence of an expressive language disorder. Interestingly, studies have found that patients write better with the paralyzed right arm, aided by a mechanical device resembling a skate. This technique removes the necessity of transmission of language information to right hemisphere motor centers.

The lesions of Broca's aphasia traditionally involve the inferior frontal gyrus, just anterior to the face area of the motor cortex (**Figure 1**). Small lesions in this area are associated with excellent recovery of language function. Larger lesions, involving the frontoparietal cortices, produce an early global aphasia, or loss of all language function, followed by gradual evolution toward Broca's aphasia, or 'mixed nonfluent aphasia.' Studies by the Boston VA group of CT scans in patients with nonfluent aphasia have established three lesion patterns: (1) lesions restricted to the lower motor cortex of the precentral gyrus produce only dysarthria and mild expressive disturbance; (2) those involving the more anterior frontal operculum (Brodmann areas 44 and 45) result in difficulty initiating speech without true language difficulty (see discussion of 'aphemia,' below); and (3) lesions combining these two lesion sites, plus the subcortical white matter and periventricular white matter cause deficits of Broca's aphasia. These additional aphasic disturbances may result from interruption

Table 1 Characteristics of aphasic syndromes

Syndrome	Fluency	Naming	Repetition	Comprehension	Reading	Writing
Broca	—	—	—	+	!:	—
Wernicke	+	—	—	—	—	+
Global	—	—	—	—	—	—
Conduction	+	±	—	+	!:	+
Anomic	+	—	+	+	+	+
TCM	—	+	+	.+.,	+	±
TCS	+	—	+	—	—	—
Isolation	—	—	+	—	—	—

of pathways from the posterior language areas. Damage to two subcortical areas, the rostral subcallosal fasciculus deep to Broca's area and the periventricular white matter adjacent to the body of the lateral ventricle, appears necessary for the permanent loss of functional expressive speech (Figure 2).

Aphemia

The term 'aphemia' was Broca's original choice for the name of his nonfluent aphasia syndrome, but the term 'aphasia,' promoted by Trousseau, was adopted instead. Aphemia was then

Figure 1 A drawing of the lateral surface of the left hemisphere of the brain. The approximate locations are given for Broca's area in the left inferior frontal convolution, Wernicke's area in the left superior temporal convolution, and the angular and supramarginal gyri of the inferior parietal lobule.

Figure 2 MRI scan from a patient with Broca's aphasia immediately after stroke. MRI images are displayed in the standard orientation used in radiology, with the left side of the brain on the right side of the image. This is a diffusion-weighted image, showing an acute, left frontal infarction.

applied to a more restricted, often transitory syndrome of muteness or nonfluent speech with difficulty of initiation of speech, dysarthria, and phoneme substitutions. Repetition is impaired in a similar manner, and to a similar degree, as spontaneous speech. Both auditory and reading comprehension are preserved, and writing is usually much superior to speech. Most patients have right facial weakness, and some have an associated right hemiparesis. Aphemia is more closely related to the motor speech disorders, apraxia of speech and dysarthria, than to aphasia. Some authorities have even equated it to apraxia of speech, a disorder in which hesitancy of initiation and inconsistent substitutions of phonemes, are also characteristic. Aphemia is associated with lesions of the lower motor cortex for the face in the precentral gyrus, with extension in some cases into the inferior frontal gyrus and underlying white matter.

Wernicke's Aphasia

In contrast to the nonfluent speech of the patient with Broca's aphasia, the Wernicke's aphasic speaks fluently, with abnormal language content. Spontaneous speech contains empty phrases, circumlocutions, neologisms (new or nonexistent words), and errors reflecting sound substitutions (literal or phonemic paraphasic errors, e.g., 'poon' for 'spoon') and word substitutions (verbal or semantic paraphasic errors, e.g., 'fork' for 'spoon'). Sometimes no meaning at all is conveyed, amounting to 'jargon speech.' To a nonnative speaker of English, however, the fluent speech productions sound normal. Naming often produces paraphasic utterances that have no obvious relationship to the target word, and repetition is also disturbed. Comprehension of spoken language is severely impaired. Reading is typically affected in the same way as auditory comprehension, but occasional cases show interesting dissociations between comprehension of auditory versus printed language. Spared reading comprehension may be important in providing a means of communication with the patient. Writing is often well-formed, since patients with Wernicke's aphasia usually have no hemiparesis, but the written productions share the same lack of meaningful words as the speech output. Written language productions also contain misspellings; patients with mild Wernicke's aphasia may be detected most easily by analysis of writing.

Patients with Wernicke's aphasia typically have no motor or sensory deficits; some have a partial or complete loss of vision in the right visual field. As Wernicke originally demonstrated in 1874, the lesions of patients with Wernicke's aphasia typically involve the posterior portion of the left superior temporal gyrus, the traditional 'Wernicke's area.' Studies by Naeser and colleagues have suggested that damage to a major part of Wernicke's area is necessary for lasting loss of comprehension, while more temporary loss of comprehension can be seen with lesions elsewhere in the temporal lobe or in the inferior parietal lobule. Some patients with lesions restricted to the temporal lobe may have spared reading ability in the presence of severe auditory comprehension deficits, whereas those with lesions primarily affecting the inferior parietal lobule may have disproportionate reading difficulty (Figure 3).

Pure word deafness

Pure word deafness is a rare syndrome involving the inability to understand or repeat spoken language, in the absence of

Figure 3 MRI scan, diffusion weighted image, showing an acute stroke in the left temporal lobe, resulting in Wernicke's aphasia.

other language difficulty. The patient is not deaf to pure tones or to meaningful nonverbal noises such as animal cries or the ringing of a bell. Classically, the deficit occurs with bilateral temporal lesions. By the 'disconnection' theory, these lesions disconnect the left hemisphere Wernicke's area from both primary auditory cortices (Heschl's gyrus in the superior temporal gyrus of each hemisphere), such that sounds can be heard but not analyzed by the receptive language cortex in Wernicke's area. Destruction of the auditory cortices themselves causes cortical deafness, or complex auditory disorders referred to as 'auditory agnosia.' Patients with cortical lesions are usually not completely deaf; some cannot recognize either words or nonverbal sounds. Cases of unilateral, left temporal stroke have also been reported to develop pure word deafness. As mentioned earlier, some patients with Wernicke's aphasia and damage predominantly affecting the temporal lobe may have disproportionate involvement of auditory comprehension, as compared to reading comprehension, thus resembling the deficit of pure word deafness. In fact, pure word deafness is often not entirely 'pure,' in that mild paraphasic speech dysfunction is usually associated.

Global Aphasia

Global aphasia may be thought of as the sum of Broca's and Wernicke's aphasia. It is a loss of all six of the commonly tested language functions: spontaneous speech is mute or severely nonfluent, naming is reduced, repetition and comprehension are severely impaired, and the patient cannot read or write. Most such patients have large areas of damage in the left hemisphere and profound associated neurological deficits such as right hemiplegia, right-sided sensory loss, and right hemianopsia. Occasionally, strokes can damage both Broca's and Wernicke's areas, without massive involvement of the motor system, and global aphasia without hemiparesis can result. When lesser degrees of deficit are seen across all language functions, the syndrome is called 'mixed aphasia.'

Conduction Aphasia

Conduction aphasia is an unusual but interesting language syndrome, in which repetition is affected, out of proportion to all other aphasic deficits. Patients speak relatively fluently, though some make frequent literal paraphasic errors and pause frequently for self-correction, giving the speech output a hesitant, choppy pattern. Naming is often impaired, but auditory comprehension is intact. Reading aloud and copying may be affected in a way similar to repetition.

Wernicke originally postulated that conduction aphasia might be caused by a lesion that did not damage either Wernicke's or Broca's area, but disrupted the connections between the two areas, namely the arcuate fasciculus. Geschwind rediscovered this explanation of conduction aphasia as a 'disconnection syndrome,' in which the language impairment is caused by disconnection between cortical language centers, in the absence of damage to the centers themselves. In fact, most cases of conduction aphasia are related to stroke and do have evidence of cortical damage, either in the left temporal lobe, without complete destruction of Wernicke's area, or in the left inferior parietal lobule. Recent research has indicated that the arcuate fasciculus, originating in Wernicke's area, terminates not in Broca's area, but in the precentral gyrus, or motor cortex, shedding doubt on the importance of arcuate fasciculus damage to the syndrome of conduction aphasia. While the disconnection theory of conduction aphasia has remained popular, some investigators have favored a disorder of auditory processing, with some evidence favoring the supramarginal gyrus as a site where auditory inputs are processed for transmission to Broca's area, thus enabling repetition. Others have analyzed the deficit as a disorder of immediate memory for word sequences, such that phrases cannot be maintained in the immediate memory store long enough to allow repetition. These theories sound very different, but they are difficult to separate, in terms of practical details of language deficits.

Anomic Aphasia

As its name implies, anomic aphasia involves the selective loss of naming ability, out of proportion to other language deficits. Patients speak fluently, though with word-finding pauses and circumlocutions. Repetition, auditory comprehension, reading, and writing are intact. This syndrome is less well correlated with focal pathology than the other classical aphasia syndromes, though anomic aphasia can occur with focal lesions of the left temporal or inferior parietal region. Anomic aphasia may also be the last stage in the recovery process from other aphasia types, including both Broca's and Wernicke's aphasia. Anomic aphasia is also common in the early stages of dementing conditions such as Alzheimer's disease.

Transcortical Aphasias

The transcortical aphasias were named to describe the sparing of the perisylvian language circuit, and thereby of repetition. The word 'transcortical,' as used by Lichtheim, implies that the damage is not to the language cortex itself, but to other areas of the brain which project onto the language cortex. Lichtheim referred to these other cortical areas as the 'area of concepts.'

Current neuroanatomy texts do not list an area of concepts, but this would be part of the association cortex of the frontal, temporal, and parietal lobes. The three transcortical aphasia syndromes share the sparing of repetition, despite marked aphasic deficits.

Transcortical motor aphasia is similar to Broca's aphasia, in that the patients speak nonfluently, often with long pauses before utterances and single word or whispered replies to questions. Patients may remain mute when asked questions requiring sentence length responses, but if a single word will suffice, the patient may answer accurately. Auditory comprehension is usually quite good. These patients, unlike Broca's aphasics, can repeat long sentences, even with complex grammatical constructions. The lesions of transcortical motor aphasia spare Broca's area itself but involve adjacent portions of the left frontal cortex, including medial frontal areas such as the supplemental motor cortex, or the frontal subcortical white matter. These lesions all fall within the distribution of the anterior cerebral artery, a relatively uncommon locus of stroke, as compared to the middle cerebral artery, parts of whose territory are affected in Broca's, Wernicke's, global, and conduction aphasias.

Transcortical sensory aphasia resembles Wernicke's aphasia, in terms of fluent, paraphasic speech and poor auditory comprehension, but these patients can repeat normally. The lesions are located posteriorly, in the left temporo-occipital confluence. This syndrome is seen uncommonly in stroke patients, but it occurs in patients with Alzheimer's disease, in later stages of the disease. In one electrical stimulation study in normal subjects, stimulation of adjacent groups of neurons in the temporal lobe could produce either Wernicke's or transcortical sensory aphasia.

Mixed transcortical aphasia, also called the 'syndrome of the isolation of the speech area,' is a syndrome resembling global aphasia, except for the sparing of repetition, which may even be excessive or palilalic. These patients cannot speak spontaneously or comprehend spoken or written language, but they can repeat fluently. Some patients have a tendency to complete partial utterances, as in poetry lines or common idioms (if the examiner says 'roses are red,' the patient may repeat 'roses are red, violets are blue'). Geschwind and colleagues reported the case of a young woman who had extensive, bihemispherical damage from carbon monoxide poisoning, sparing the perisylvian language circuit. This patient could not speak in any meaningful way, could not comprehend conversation, but she could repeat long sentences and could even memorize lyrics to songs which became popular after her illness implying that the medial temporal lobe memory circuit was also spared. Mixed transcortical aphasia has also been reported in patients with severe dementia.

Subcortical Aphasias

Unlike all of the aphasia syndromes described up to this point, subcortical aphasias are defined more by the location of the responsible brain lesion than by the language characteristics of the aphasia. While aphasia is usually thought of as a cortical phenomenon, several patterns of aphasia with subcortical lesions have been described, all within recent decades since brain imaging became widely available. First, lesions of the left

thalamus have been associated with fluent aphasia, usually with better comprehension and repetition as compared to Wernicke's aphasia. A 'dichotomous state' has been described, in which the patient may speak clearly while awake, but drift into incomprehensible, paraphasic speech when sleepy. The thalamus has a role in activating the language cortex; Luria referred to thalamic aphasia as a 'quasiaphasic disturbance of vigilance.' 'Thalamic aphasia,' as it is called, was first described in patients with thalamic hemorrhage, but many cases have also been reported with ischemic strokes involving the thalamus.

Ischemic lesions of the basal ganglia and subcortical white matter also cause aphasia. Lesions of the head of the caudate, anterior limb of the internal capsule, and anterior putamen produce a nonfluent aphasia with dysarthria, termed the 'anterior subcortical aphasia syndrome.' The syndrome bears some resemblance to Broca's aphasia, but these patients usually have longer phrase length and better comprehension and repetition than patients with Broca's aphasia from cortical lesions. More extensive damage in the subcortical structures can produce other aphasic syndromes; lesions which extend posteriorly in the basal ganglia and laterally into the deep temporal lobe white matter can cause syndromes resembling global and Wernicke's aphasia. Similar aphasias are seen with hemorrhages into the basal ganglia, but deficits tend to be more severe because of pressure effects on surrounding structures and on the overlying language cortex.

Alexias

Alexia is an acquired disorder of reading secondary to brain disease. Since reading is a language function, alexia falls under the definition of aphasia as an acquired disorder of language. The alexias can be either largely restricted to reading, or they may be part of an aphasic syndrome.

Pure alexia with agraphia is an acquired illiteracy, a syndrome in which patients cannot read or write, but they can speak, repeat, name, and comprehend spoken language. In fact, most patients with alexia with agraphia do not have such a 'pure' syndrome; they often have a mild fluent aphasia, and the syndrome overlaps with Wernicke's aphasia. The lesion involves the inferior parietal region, particularly the angular gyrus. This type of alexia is also referred to as 'central alexia.'

Pure alexia without agraphia is, in effect, a linguistic blindfolding. Patients cannot read, but they speak normally and can understand spoken language, even when words are dictated in spelled form. These patients can write, but they cannot read their own written productions, a striking feature of the disorder. Naming for objects is usually preserved, but patients may be unable to name colors. They have not lost the concept of color names, as shown by their ability to name the usual colors of common objects such as bananas or apples, but they cannot name a perceived color. In addition, they usually have short-term memory loss and a right visual field defect. Pure alexia is associated with a lesion of the left occipital cortex, within the territory of the left posterior cerebral artery, usually also involving the splenium of the corpus callosum, and sometimes the medial temporal cortex as well. Pure alexia without agraphia is a classical disconnection syndrome, as originally postulated by

the French physician Dejerine in 1891, and later rediscovered by Norman Geschwind. By the disconnection theory, the non-damaged right occipital cortex can subserve vision in the left visual field, but visual language and color information cannot be transmitted properly to the left hemisphere language cortex. Like the disconnection theory of conduction aphasia, this model does not account for all of the complexity of the pure alexia syndrome. Some investigators have pointed to a disturbance of visual immediate memory as a factor in pure alexia; if the patient cannot keep a string of letters in mind, then the letters cannot be processed into a word. In fact, patients with pure alexia often can read letters one by one, but they cannot read a word at a glance. The ability to recognize words (or 'word forms') at a glance is likely a left occipital lobe function. Alternate names for the syndrome are 'letter-by-letter' alexia and posterior or occipital alexia.

Many patients with aphasia have associated reading disturbance, termed 'aphasic alexia.' Benson called the alexia of Broca's aphasia the 'third alexia' following the syndromes of alexia with and without agraphia. It is also called 'frontal alexia.' This type of alexia can vary from a mild alexia related to difficult syntactic material to a severe alexia, in which patients can read only by recognition of a few familiar words. Wernicke's aphasics often have deficits in reading and writing similar to the syndrome of alexia with agraphia, though patients have been described with more partial, selective deficits.

In recent years, neurolinguists and cognitive psychologists such as Marshall, Newcombe, and Coltheart have divided alexias according to the specific stages in the reading process which go awry (Figure 4). Four patterns of alexia (or 'dyslexia,' as these investigators often call it) have been recognized: letter-by-letter, deep, phonological, and surface dyslexia (Table 2).

Figure 4 Three separate routes to reading. (1) The grapheme–phoneme conversion system used in learning reading. This is the only route available in surface dyslexia. (2) Reading only from recognizing the meaning of familiar words, the only route available in deep dyslexia. (3) A direct conversion of words to sounds, available along with route 2 in phonological dyslexia.

Letter-by-letter dyslexia is equivalent to pure alexia without agraphia, while the other three patterns are usually seen with aphasia.

Deep dyslexia involves several distinctive features: intact reading of familiar words, inability to read nonsense syllables or nonwords, semantic and visual errors in reading aloud, and pronounced effects of word frequency, word imageability, and word class. Imageable words, those which denote an object or animal that can be seen by the mind's eye, are read more accurately than abstract words, while nouns and verbs are read better than adjectives, adverbs, and prepositions. Word reading is not much affected by word length or by regularity of spelling; for example, patients have been described who can read 'be' but not 'B,' or 'ambulance' but not 'am.' Examples of semantic errors are 'jail' for 'prison' and 'soccer' for 'football'; examples of visual errors are 'perform' for 'perfume' and 'banish' for 'blush.' Deep dyslexia involves the loss of reading by the 'phonological,' or grapheme-to-phoneme conversion route, with residual reading involving only recognition of familiar words (route 2 in Figure 4). Most cases have severe aphasia, with extensive left frontal and parietal damage. The residual reading of patients with deep dyslexia may involve the right hemisphere.

Phonological dyslexia is similar to deep dyslexia, except that single content words are read in a nearly normal fashion, and semantic errors are rare. As in deep dyslexia, reading of nonwords is poor. Patients sometimes read words without access to meaning. The syndrome of phonological dyslexia, like deep dyslexia, involves the loss of grapheme-to-phoneme conversion. In deep dyslexia, only words whose meaning is recognized can be read aloud; only a semantics-to-phonology reading route can operate. In phonological dyslexia, words can also be read via a lexical-phonological route (route 3 in Figure 4), in which printed words can be recognized and transferred into their sounds, without access to semantics, or meaning. Only the nonlexical-phonological route, by which nonwords must be read, is inoperative. Most patients with phonological alexia have severe, nonfluent aphasia.

In surface dyslexia, subjects can read laboriously by grapheme–phoneme conversion, but they cannot recognize words at a glance. They can read nonsense syllables, but not words of irregular spelling, such as 'yacht' or 'colonel.' Their errors tend to be phonological rather than semantic or visual; an example would be to pronounce 'pint' as if it rhymed with 'lint.' Reading in these patients is accomplished without access to semantics until the word is pronounced. Individual graphemes are sounded out by the most common way they are

Table 2 Characteristics of alexic syndromes

Characteristic	Deep dyslexia	Phonological dyslexia	Letter-by-letter dyslexia	Surface dyslexia
Nonwords	–	–	–	+
Word class effect	+	+	–	–
Imageability	+	–	–	–
Word length	–	–	+	+
Regular spelling	–	–	–	+

Source: Patterson KE (1981) Neuropsychological approaches to the study of reading. *The British Journal of Psychiatry* 72: 151–174.

pronounced in the language, producing errors for both irregularly spelled words and regular words which have atypical pronunciations. For example, a surface dyslexic might pronounce 'rough' and 'though' alike. Surface dyslexia represents a syndrome in which only one route of reading, the grapheme-phoneme route, is operative (route 1 in [Figure 4](#)). Patients cannot read words without pronouncing their component graphemes. This syndrome is also seen in patients with aphasia, and also in patients with primary progressive aphasia (PPA), or the frontotemporal dementia (FTD) syndrome (see below).

Graphias

Like reading, writing may be affected either in isolation ('pure agraphia') or in association with aphasia ('aphasic agraphia'). In addition, writing can be deranged by motor disorders, by visuospatial or constructional impairments, and by apraxia, a disorder of learned motor activities. Isolated agraphia has been described with left frontal and occasionally left parietal lesions. In the past, a cortical writing center called 'Exner's area' was postulated, just above Broca's area. The existence of a specific writing area has not been supported, however, either by stroke cases or by electrical stimulation studies; stimulation of Broca's area interferes with writing, while excitation of other frontal regions does not produce agraphia without disturbing speech.

Agraphias have also been analyzed in ways similar to the alexias. A syndrome of 'phonological agraphia' has been described, in which patients cannot convert speech sounds (phonemes) into letters (graphemes). These patients cannot write pronounceable nonsense words but can write familiar words, even when irregular in spelling. Reported cases have been relatively few, with limited neuroanatomic data, but some cases have had lesions of the supramarginal gyrus. Most patients have had associated aphasia, but of varied types. 'Deep' dysgraphia is similar to phonological agraphia, but as in deep alexia, mainly familiar nouns and verbs can be produced, with a marked word class effect.

A 'lexical agraphia' syndrome, also called 'surface agraphia,' has also been described. Patients can write regularly spelled words and pronounceable nonsense words, but not irregularly spelled words. These patients have intact phoneme-grapheme conversion but cannot write using a whole word, or 'lexical' strategy. Lesions have been reported in the posterior angular gyrus and occipitotemporal gyrus, but other cases have had more anterior localizations.

Recovery of Aphasia

Patients with aphasia from acute disorders such as stroke generally show spontaneous improvement over the first several months. The traditional opinion in rehabilitation is that this improvement is maximal during the first 3 months, but, as Sarno has pointed out, patients with severe, global aphasia may actually improve more in the second 6 months than the first. The aphasia type often changes during this improvement; global aphasia often evolves into Broca's aphasia, and Wernicke's aphasia may evolve into conduction or anomia aphasia. The neuroanatomical correlates of language recovery appear to involve the taking over of language functions by

adjacent cortical areas of the left hemisphere, and the right hemisphere may also participate. Studies of activation of language areas by PET, SPECT, and fMRI techniques promise to advance our understanding of the neuroanatomy of language recovery. To summarize a growing and not always congruent literature, if left hemisphere language cortex can resume language functioning, recovery is excellent, but if centers in the right hemisphere take over, the recovery is incomplete. Recovery using the contralateral hemisphere to assume lost functions may be a 'second best' strategy.

Speech therapy, carried out by trained speech/language pathologists, seeks to facilitate improvement in language function by a variety of techniques. Repetitive exercises are carried out to promote better articulation, and matching vocabulary tasks are designed to improve receptive language. Other techniques in speech therapy include melodic intonation therapy, which attempts to involve the right hemisphere in speech production through the use of melody, and computer techniques originally developed for primate communication. Patients who cannot speak can learn to produce major nouns and verbs and associate them into simple phrases or sentences. A variety of augmentative devices are also available to help make language outputs available to others via printers or voice simulators. Therapy techniques are now chosen based on the patient's aphasia test results, and some investigators are using brain imaging studies to predict which techniques are likely to succeed. While many speech therapy techniques have been developed empirically, large, randomized trials have clearly indicated that patients who undergo formal speech therapy recover more communicative function than untreated patients.

New techniques in aphasia therapy include drugs, such as amphetamines or beta blockers, both of which have been shown to improve fluency and naming, and dopaminergic agents such as bromocriptine, which may improve speech output in nonfluent aphasias. All the evidence of the benefit from these drugs has come from small studies and series, and there is a lack of strong evidence of clinical effectiveness. Another avenue for aphasia therapy involves brain stimulation techniques. Transcranial magnetic stimulation is a noninvasive way of stimulating the language cortex, and some preliminary studies have indicated benefit. Again, large clinical trials are lacking. Direct, transcranial electrical stimulation, or surgical placement of electrodes in the brain or subdural space has also been attempted, but these procedures are more invasive and will require much better evidence of benefit to justify the risks. Transplantation of stem cells has also been attempted in patients with poststroke aphasia, though this research, too, is at an early stage of development. These new techniques carry new promise for patients with aphasia secondary to strokes and other causes of brain damage.

Miscellaneous Topics in Aphasia

Aphasia in Polyglots

Aphasia in patients who speak more than one language ('polyglots') has been the subject of considerable interest. In 1895, Pitres postulated that the language used most before the onset of aphasia would be the first to be recovered. In contemporary

terms, the language in which the patient works every day, and in which hospital personnel and therapists speak, is likely to be recovered faster and better than another language the patient has learned, or even grew up speaking. Ribot, in 1906, predicted that the first-learned or native language would be the most resistant to later brain injury. These two rules are now known as Pitres' and Ribot's laws. Other investigators have considered both the time of acquisition and the relative skill level in each language. Thus, Canadians who acquired French and English simultaneously in growing up ('compound bilinguals') have more congruent language involvement than those who learned one language later than the other ('coordinate bilinguals'). In recent studies, coordinate bilinguals have even developed different aphasia syndromes in two languages; for example an Israeli patient was globally aphasic in Hebrew but had only a mild anomic aphasia in Russian. In general, the language used more extensively before the brain injury, as Pitres originally postulated, appears to be less disturbed than the less used language, regardless of which was learned first.

Aphasia in Acute Confusional States and Dementias

Patients who develop acute delirium or confusion frequently utter meaningless or nonsensical phrases. In most cases this involves abnormal thought, or language content, rather than abnormal language, resembling a psychosis. In some cases, however, delirious patients produce fluent, paraphasic speech and even neologisms. Naming is frequently disturbed in acute confusional states. Comprehension is at least partially preserved, if the patient's attention and memory can be entrained to the task. Many delirious patients have abnormal writing. The diagnosis of delirium rests on a general confusional state, with impaired attention, reasoning, and often hallucinations and delusional thinking as well as agitation or drowsiness and autonomic signs such as tremor, sweating, tachycardia, hypertension, and fever. All of these 'positive' cognitive symptoms such as agitation, delusional thinking, and hallucinations, and also the autonomic signs, are much less prominent in dementing illnesses, except in advanced cases.

Patients with dementing diseases such as Alzheimer's disease frequently demonstrate abnormal language functions. The dementia of Alzheimer's disease usually begins with memory loss, and among the earliest symptoms is a loss of memory for names. Recollection of proper names and rapid generation of a series of names are very sensitive to aging and dementia. For example, patients with early dementia have marked difficulty with the 'animal naming' subtest of the BDAE, which requires the subject to name as many animals as possible in one minute. Articulation, repetition, and auditory comprehension tend to remain intact into later stages of dementia. At an early stage, an Alzheimer's disease patient often shows the profile of anomic aphasia. As the disease advances, reading and writing deteriorate, and auditory comprehension begins to decline. Repetition and articulatory fluency remain preserved, and the patient may then show the language profile of transcortical sensory aphasia. The content of expressive speech is also severely impoverished, devoid of abstract content. Ultimately, language expression becomes limited almost to statements of biological need. Some patients

become mute in late stages, resembling global aphasia, while others repeat fluently.

Alzheimer's disease is a 'diffuse' degeneration of the cerebral cortex, but pathological studies indicate early involvement of the association cortex, particularly of the parietal and later the frontal lobes. Medial temporal structures such as the hippocampus, which are important to memory function, and medial forebrain structures such as the nucleus basalis, also show neuronal loss and senile plaques.

Other dementing diseases also produce language disorders. After Alzheimer's disease, the most common cause of dementia is multiinfarct or vascular dementia. The specific features depend on the size and location of the cerebral infarcts, but many patients manifest aphasia.

Pick's disease was described in the nineteenth century as a lobar atrophy involving predominantly the frontal and temporal cortices, with microscopic stains showing intraneuronal, silver-staining inclusions called 'Pick bodies.' Many cases with similar clinical and neuroradiological features lack Pick bodies, and the newer term for this family of focal neurodegenerative disorders is 'FTD' or 'frontotemporal lobar degeneration.' Some cases begin with 'frontal' syndromes of behavioral abnormality, others have isolated aphasia at onset. What was described in North America as 'PPA' is now thought to be a variant of the syndrome of FTD, described in Europe. Some cases of PPA have been followed for several years, with steadily worsening language function, usually with nonfluent, or Broca-like aphasia, but no significant memory loss or generalized dementia. Brain imaging studies show only a lobar atrophy. PET studies have consistently shown left frontal and/or temporal hypometabolism, with more advanced cases showing more widespread metabolic changes. The pathology is usually of lobar atrophy, without the typical changes of Alzheimer's disease, but with neuronal loss and glial scarring. A variant of the syndrome is 'semantic dementia,' in which patients speak fluently but lose their ability to name or even to comprehend the meaning of names given to them. This syndrome can be seen in either FTD or Alzheimer's disease. A great deal of research has been published recently on this family of conditions. Two different gene mutations have been found in familial cases of FTD and PPA, both entirely separate from the genes associated with Alzheimer's disease. Another disease that can present with progressive aphasia is corticobasal degeneration, a variant of Parkinson's disease also associated with mutations in the tau protein, one of the two gene mutations associated with FTD.

Creutzfeldt-Jakob disease is a more rapidly progressive dementia, often with myoclonus and seizures, and often a fatal course within several months. Numerous variants of the syndrome have been described. Aphasia has been documented as a presenting symptom of Creutzfeldt-Jakob disease, but the development of a rapidly progressive dementia with myoclonus and seizures usually makes the diagnosis clear.

Language and the Right Hemisphere

While the right hemisphere has traditionally been called the 'minor' hemisphere because of its lack of language dominance, research has shown that patients with right hemisphere disease have significant problems with verbal communication. While

they can produce and understand appropriate words and sentences, patients with right hemisphere lesions speak monotonously, lacking the emotional tone or 'prosody' which makes normal language colorful. These patients lose the ability to understand emotional tone, connotation, irony, sarcasm, satire, and humor, responding only to the literal meaning of the words; they understand what is said, but not how it is said. The right hemisphere may have a similar organization to the left in terms of speech prosody, the emotional intonation, and emphasis present in spoken language; frontal lesions disturb production of prosodic speech, while temporal lesions disturb comprehension of emotional tone. Right hemisphere stroke patients have difficulty even with nonemotional aspects of prosody, such as placement of emphasis within sentences or inflections, as in the difference between a statement and a question. Despite their intact language skills, these patients are at a great disadvantage in normal human communication.

Aside from these effects of right hemisphere disease, the right hemisphere appears to have considerable linguistic ability. Patients with surgical commissurotomy, or section of the corpus callosum, are able to recognize words flashed in the left visual field, or presented in tactile fashion to the left hand. They can perform simple matching tests between words or short phrases which are semantically related. The mystery about these abilities is the failure of patients with left hemisphere lesions and global aphasia to perform similar tasks, despite the presence of an intact right hemisphere. It is possible that the corpus callosum contains fiber tracts which inhibit the right hemisphere from expressing its full language capability. If such systems could be therapeutically disrupted, the recovery of aphasia might be significantly enhanced.

Conclusion

The subject of aphasia is a rich field. Language was the first of the higher brain functions to be analyzed in terms of specific localization of brain lesions, and it remains the best studied and understood of all of the cognitive functions. Increased understanding of both normal language and aphasia is likely to emerge from new studies combining specific language testing measures with precise neuroanatomic techniques such as MRI and functional activation methodologies such as PET and fMRI. The result should be not only a better knowledge of language and the brain, but also improved therapies for patients afflicted with aphasia.

Glossary

Anorexia Decreased appetite and eating caused by illness, aversion, or abnormal interference with the normal physiological controls of eating.

Appetite The subjective experiences and behaviors associated with the urge to eat including food seeking and meal initiation and with eating, including flavor hedonics and satiation.

Body mass index A measure of normal or abnormal adiposity equal to weight divided by height squared (BMI, kg m^{-2}); normal BMI is 18.5–25, overweight is 25–30, and obese is >30 .

Flavor hedonics The component of food reward referring to the pleasure or displeasure accompanying eating a particular food and the associated increase or decrease in selection and ingestion of that food; hedonic reactions are responses of the brain, not intrinsic properties of foods.

Homeostasis The maintenance of crucial physiological variables within relatively narrow ranges by active physiological mechanisms.

Hunger A synonym for appetite; formerly often limited to urges to eat elicited by physiological consequences of nutrient depletion.

Meal An organized bout of eating which is the functional unit of eating upon which physiological controls act.

Obesity A degree of excess adiposity associated with markedly increased health risks, often defined as BMI > 30 .

Palatability A synonym for flavor hedonics.

Postprandial satiety The subjective experiences and behaviors associated with the lack of eating during intermeal intervals.

Satiation The subjective experiences and behaviors produced during a meal by the ingestion of food that cause the termination of the meal; the physiological mechanisms of satiation and postprandial satiety are thought to be partially independent.

Introduction

Scope

The physiology of eating is a crucially important problem because of the epidemic proportions of obesity and the immense societal costs of obesity-related health disorders. Thus, why so many of us eat more than we need to and how this might be controlled are pressing scientific questions. Psychiatric eating disorders, although far less prevalent than obesity, are significant causes of morbidity and mortality, and therefore are also important basic research medical challenges. Unfortunately, the physiology of eating is very poorly understood. A reflection of this situation is that at present no truly effective physiologically based medications for disordered eating are available. Such medications are urgently needed to aid obese persons to diet or to aid persons with eating disorders to overcome their afflictions.

My aim in this article is to introduce the physiology of eating to students of physiology, neuroscience, and behavioral science. Fundamental physiological knowledge is emphasized, with some current areas of intense research interest highlighted. Social and cognitive aspects are not included. Disordered eating, as occurs in obesity and psychiatric eating disorders (anorexia nervosa, bulimia nervosa, etc.) are very briefly introduced.

Some background in neuroscience and physiology, such as could be easily obtained in basic texts, is assumed. **Table 1** lists hormones involved in the control of eating (except those discussed in connection with sodium appetite) together with their abbreviations; **Table 2** lists neurochemicals involved in the control of eating, only some of which are discussed, with their abbreviations. Because space requires that the review be incomplete, many mechanisms and mediators are not covered; this includes several of the molecules listed in **Tables 1** and **2**.

The role of *learning* in the physiological control of eating can hardly be overestimated. Although I cover this topic in a separate section, several examples of how learning shapes physiological controls are included. Finally, my discussion is organized around a few concepts that, although in wide use, are not universal or have varying definitions in the physiological literature. Therefore, I begin by describing my use of these concepts.

Concepts and Categories

The basic behavioral and subjective concepts used in various scientific approaches to eating – for example, appetite, hunger, palatability, satiety, and satiation – have no standard definitions. These days, as physiological and psychological methodologies are growing ever closer, as exemplified by functional brain imaging work, the semantic opportunities for miscommunication and confusion abound. The student of eating must keep in mind what actually is measured, rather than the names used to describe the measures.

The physiology of eating comprises: (1) the behaviors and subjective phenomena of eating; (2) the types of exteroceptive and interoceptive information that affect eating; (3) the peripheral neural and endocrine sensory mechanisms relaying this information to the brain; and (4) the brain neural networks that process and integrate this, and other, information to control acts and subjective phenomena associated with it. An important aspect of this processing is the plasticity of the brain's eating-control systems – that is, experience shapes every aspect of the physiology of eating.

Eating in humans and other mammals is organized into discrete meals, which, in turn, are thought to result from four functional processes: (1) *hunger* processes related to the

Table 1 Peripheral within- and across-meal feedback signals in the control of eating

<i>Control</i>	<i>Species</i>	<i>Within-meal</i>	<i>Across-meal</i>	<i>Physiological role</i>
Flavor hedonics	R-M, H	✓		◆◆
Gastric mechanoreception	R-M, H	✓		◆
Cholecystokinin (CCK)	R-M, H	✓		◆◆
Glucagon-like peptide-1 (GLP-1)	R-M	✓	✓	◆
GLP-1	H	✓		◆
Peptide YY (PYY)	R-M, H		✓	◆
Amylin	R-M	✓		◆◆
Amylin	H	✓		◆
Amylin	R-M	✓		◆
Ghrelin	R-M, H		✓	◆
Metabolic signals	R-M	✓	✓	◆
Insulin in overweight	R-M		✓	–
Insulin in underweight	R-M		✓	–
Leptin in overweight	R-M		✓	–
Leptin in underweight	R-M, H		✓	◆

Summary of within- and across-meal controls discussed in the text. Several other candidate mechanisms are not included. Species refers to laboratory rats or mice (R-M; for simplicity, the sometimes-important species differences between rats and mice are ignored) or to humans (H). Physiological role means the likelihood that the control produces a graded, dose-related effect on normal eating, rated as unlikely (–), somewhat likely with very incomplete evidence (◆), probable due to promising but incomplete evidence (◆), or well established (◆◆).

Table 2 Brain neurotransmitters and neuromodulators involved in the control of eating

<i>Neurotransmitter</i>	<i>Typical abbreviation</i>
Agouti-related peptide	AgRP
Cholecystokinin	CCK
Cocaine- and amphetamine-related transcript	CART
Corticotropin-releasing hormone	CRH
Dopamine	DA
Dynorphin	Dyn
Enkephalin	Enk
Galanin	GAL
γ-aminobutyric acid	GABA
Gastrin-releasing peptide	GRP
Glutamate	Glut
α-Melanocyte-stimulating hormone	α-MSH
Neuropeptide Y	NPY
Norepinephrine	NE
Orexin-A and orexin-B	Or-A, Or-B
Oxytocin	OT
Melanin-concentrating hormone	MCH
Serotonin (5-hydroxytryptamine)	5-HT
Thyrotropin-releasing hormone	TRH

This list is not exhaustive. Many neurotransmitters are named for their initially discovered endocrine roles. This is an example of how signaling molecules often have different roles in different parts of the body. There are variants for several of the abbreviations listed.

initiation of meals; (2) *flavor hedonics* processes related to the evaluation of the food that stimulate or inhibit eating during the meal; this is one aspect of food reward; (3) *satiety* processes related to inhibitory feedbacks from postingestive food stimuli that act to terminate eating at the end of the meal; and (4) *postprandial satiety* processes inhibiting eating during the intermeal interval. These four processes appear to have at least partially independent underlying neural mechanisms. Although each process includes both behavioral and subjective phenomena, for simplicity, I use single names for both aspects.

We make the decision to select this food or that food, or to have a little more of a particular food during a meal, many times a day, usually with little conscious effort or thought. Nevertheless, these are important decisions that can be subject to many influences, some physiological, some not. Furthermore, these various influences may push us in opposite directions at the same time – for example, feedbacks from the stomach and intestines may signal us to stop eating at the same time that sensory feedbacks related to food flavor tell us to keep on. For example, the influence of flavor hedonics is often in opposition to the influence of another category of controls, *homeostatic* or *regulatory* controls of eating. Both hedonic (section ‘Flavor Hedonics’) and homeostatic (section ‘Eating and Homeostasis’) controls of eating are discussed in more detail below.

Finally, my review of the physiology of eating is organized around *within-* and *across-meal* controls of eating. Within-meal controls refer to mechanisms in which a signal (e.g., changed peripheral sensory neural signals or changed plasma hormone concentrations) and a change in eating occur during the same meal; across-meal controls are those in which the signal and the eating response are not linked to the same meal. The major peripheral within- and between-meal signals are presented in the sections ‘Within-Meal Controls of Eating’ and ‘Across-Meal Controls of Eating,’ respectively. As it becomes clear, however, within- and between-meal controls function along a continuum, so that the distinction is mainly heuristic.

Eating and Homeostasis

Because eating is our only source of metabolic fuel and of essential nutrients, it is an integral part of homeostatic regulation, that is, the maintenance of crucial physiological variables within relatively narrow ranges. The concentrations of glucose, O₂ and CO₂ in the blood, blood pressure, body temperature, and a number of other variables are maintained within ranges that are much smaller than would occur if there were no

Figure 1 Schematic diagram of the organization of a negative-feedback control system, such as is thought to regulate micronutrient homeostasis and energy homeostasis. An afferent feedback signal related to the regulated variable is compared by the brain to the desired level of the signal and to other inputs. This integrated signal then causes the brain to initiate or adjust effector signals that affect control of the selection of food, amount eaten, energy expenditure, etc., in ways that bring the regulated variable back to the appropriate level, that is, reestablishes homeostasis.

regulation. Similarly, physiological regulations providing for appropriate supplies of metabolic energy, of protein, and of micronutrients can powerfully influence how much is eaten and what is eaten. As a consequence, homeostasis is a major conceptual scheme used to understand eating. **Figure 1** shows the basic organization of a negative-feedback regulatory system. Interestingly, many regulatory controls of eating seem to be organized asymmetrically, in that they protect from deficits but not from surfeits.

Specific Appetites for Micronutrients

Sodium appetite is an excellent example of the contribution of eating to micronutrient homeostasis. The concentration of sodium ions, Na^+ , in the extracellular fluid and blood plasma, is maintained near 150 mOsm. Loss of Na^+ , for example, when little or none is ingested for several days, leads to a number of homeostatic responses. These include secretion of the mineralocorticoid hormone aldosterone from the adrenal cortex, activation of the peptide hormone angiotensin II from its circulating precursor, and stimulation of neural baroreceptors in the vasculature. The synergistic action of these three sensory feedback signals in the brain produces a specific appetite for sodium, that is, a marked increase in the palatability of any sodium-containing food or fluid and an increase in its intake. This appetite is innate: it occurs during the first occurrence of sodium depletion, and the taste of salt is recognized without prior experience. Only a few other similar molecules, such as potassium, are partially confused with sodium. The occurrence of sodium appetite sensitizes the system in a way that increases 'need-free' salt ingestion. Although sodium appetite is generally considered in the context of body fluid homeostasis, salt preference increases food palatability, which may lead to chronic increases in the intake of salty foods.

In contrast to the sodium appetite, most specific appetites are learned. Vitamin B appetite is a good example. When rats

are fed a diet containing no vitamin B, deficiency signs begin to appear in about a week. If the rats are then offered a choice of a few new and differently flavored diets, they consume significant amounts of all of them. If just one of the new diets contains vitamin B, they learn in the course of a few days to eat mostly that diet. They do not recognize the flavor of vitamin B; rather, the enriched diet must have a salient flavor. If the experimenter switches the vitamin B to a different diet after the rats have learned to choose the first vitamin B-containing diet, the rats continue to eat the originally enriched diet until deficiency signs reappear. Learning capacity is also limited. If deficient rats are offered about ten diets, with only one enriched with vitamin B, they cannot learn to select it. Most micronutrient appetites appear to function like vitamin B appetite. Such specific appetites, however, do not exist for all micronutrients. Finally, in the cases of sodium appetite, vitamin B appetite, and most other micronutrient regulations, only deficits and not surfeits lead to regulatory behavior.

Energy Homeostasis

Food is the only source of metabolizable energy. Both the supply of readily available energy metabolites and the amount of stored energy are physiologically regulated. These regulations together are referred to as 'energy homeostasis.'

Energy balance refers to the relation between the metabolizable energy content of the food eaten and the energy expended (as physical work, heat, or in excretions) over a specific time. During positive energy balance, excess energy is stored as chemical energy in the body, and during negative energy balance, stored energy is utilized. Body weight is a relatively accurate indicator of an individual's history of energy balance. Young, growing individuals are normally chronically in positive energy balance, as energy is transformed into increased lean body mass. In adulthood, however, increases in body weight usually reflect increases in adiposity, that is, energy stored as fat, that is, triacylglycerols. These relationships are described by the energy balance equation:

$$\text{Energy stored} = \text{Energy ingested} - \text{Energy expended.}$$

Fat is stored in the adipose tissue. There is also ectopic storage of triacylglycerol in liver, muscle, and other tissues in overweight people. Although ectopic fat has important health consequences, the amount is much less than the amount of fat in the adipose tissue. Similarly, the few thousand calories of energy stored in the form of carbohydrate, that is, glycogen, is quantitatively negligible in comparison to fat stores.

The gold standard for measuring adipose tissue mass is computed tomography. In humans, much handier methods are waist circumference and body mass index (BMI):

$$\text{BMI} = \text{weight (kg)} / \text{height}^2 (\text{m}^2).$$

BMI correlates well with body adiposity for most people, although the relation breaks down in more muscular and taller people, especially women, and in children. BMI scores predict different percent body adiposity in males and females, in accordance with the higher normal fat content of females after puberty. The standard threshold BMI for overweight and obesity are 25 and 30. These days, about two-thirds of adult

US American adults are overweight or obese. Waist circumference is increasingly used because it correlates better than BMI with abdominal adiposity (i.e., the sum of abdominal subcutaneous and intra-abdominal adipose tissues) and has a better predictive value for risk factors of metabolic disease. The threshold waist circumferences for increased risk are 102 cm in men and 88 cm in women.

Despite the high prevalence of overweight and obesity, three lines of evidence indicate that the brain senses energy stored and, depending on its level, appropriately adjusts eating and energy expended. (1) The relative stability of body weight over longer periods. Although people gain several kilograms from young adulthood to middle age, the cumulative error in energy balance is small – if there were only a 1% constant error in energy balance over 25 years, weight gain would be over 1000 kg. (2) Dynamic compensatory responses that experimentally induced overweight (or underweight) elicit. For example, after experimentally induced obesity, animals usually decrease eating and increase energy expenditure and return to near the initial levels of body weight and adiposity. Why the compensation is often incomplete is not understood. (3) Our increasing understanding of the extensive neuronal networks in the brain that contribute to the regulation of adiposity, is introduced below. Why does this system not function better? It seems that the increased availability of highly palatable foods and the decreased amount of physical activity in our society overwhelm the regulatory system and cause many people to take in more energy than they need and become overweight or obese.

Finally, it is generally agreed that starvation, rather than obesity, was the more important challenge during the mammalian evolution. Accordingly, it should not come as a surprise that the physiological adaptations and compensatory responses elicited by starvation, including the drive to eat more, are more powerful than the responses elicited by overweight.

Within-Meal Controls of Eating

Flavor Hedonics

The effects of food hedonics on eating are often considered the antithesis of homeostatic influences. In fact, this is not entirely true, as shown by the example of increased sodium palatability in sodium-deficient animals or people. Indeed, in many ways we seem to be physiologically programmed to like what we need. Unfortunately, in the environments in which most of us live, energy-dense foods are available in abundance, so that flavor hedonics opposes the regulation of adiposity.

The flavor of preferred foods is a biological pleasure, as basic as the pleasure of sexual behavior. In fact, eating and sex activate extensively overlapping neural networks in the brain, as, unfortunately, do drugs of abuse. The neural evaluation of the pleasantness of flavor stimuli can either stimulate (for preferred flavors) or inhibit (for nonpreferred flavors) eating during a meal. Thus, flavor hedonics is an important within-meal control of eating.

The perception of flavor arises from olfactory, gustatory, tactile, and thermal food stimuli affecting receptors in the nasal and oropharyngeal cavities. Flavor has two roles in eating. (1) Flavor stimuli provide information guiding food selection, that is, identification of the type (e.g., *it's sweet*) and

intensity (*it's as sweet as candy*) of food stimuli, independent of the stimulus' hedonic qualities. (2) Flavor stimuli produce hedonic (used especially when conscious experience is measured) or palatability (used for behavioral as well as subjective measures) judgments, that is, the pleasant (or unpleasant) subjective experiences of food stimuli (e.g., *I like sweet*) that stimulate or inhibit eating. Although some preferences (e.g., sweet in any intensity, salt in moderate intensities) and aversions (e.g., bitter, sour) seem to be innate, the vast majority of preferences and aversions are learned. Some such learning is linked to the physiological consequences of eating – for example, hungry rats learn to prefer food with higher energy contents. But much learning occurs independent of nutritional or physiological consequences. Emotional, cognitive, and cultural associations, and even just repeated exposure, produce learned flavor preferences. Repeated exposure is a recommended method to induce children to eat usually nonpreferred vegetables or other foods the parents may be interested in, such as hot chili (capsaicin). Most people learn to like certain specific foods, for example, chocolate or pizza, very much, and their eating is markedly influenced by stable, strong 'cravings' for such foods. Because flavor preferences dramatically affect patients' success in adhering to therapeutic dietary regimens, the origins and plasticity of flavor preferences are important areas for behavioral and physiological research.

One mechanism for learned preferences seems to be associations between flavors and the postingestive consequences of the food. A dramatic example of the ability of such learning to overshadow the strong innate hedonic response to sweet was described by Anthony Sclafani of the City University of New York, Brooklyn, NY, USA. Hungry rats were offered either a noncaloric bitter solution or a noncaloric sweet solution (0.2% saccharin) to drink on alternate training days. Food, but not water, was available. On training days with the bitter solution, glucose was intragastrically infused in proportion to the amount drunk, and on training days with the sweet solution, water was intragastrically infused. After 4 days training with each solution, the rats were offered the bitter and the sweet fluid simultaneously, and no intragastric infusions were done. Rats selected 80% bitter solution and only 20% sweet solution, the opposite of the normal preferences.

It is important to note that, as the data just described indicate, hedonic judgments are responses of the brain, not properties of food. A flavor that is judged pleasant in one situation (e.g., garlic added to salad dressing) might be judged unpleasant in another (e.g., garlic added to chocolate cake). The neural processes producing flavor hedonics are thought to be mainly in the telencephalon (cerebral hemispheres). They include both subcortical areas (e.g., parts of the striatum, including the anterior caudate, ventral pallidum, and nucleus accumbens (NAc), and parts of the *amygdala* (central nucleus and basolateral)) and, at least in primates, several cortical areas (e.g., cingulate cortex, insular cortex, and orbitofrontal cortex (OFC)). The OFC is especially interesting. It receives relatively direct inputs from both olfactory and gustatory receptors, and, as increasing numbers of functional imaging studies indicate, it is involved in the evaluation of the pleasantness of flavor and other stimuli. For example, as shown in [Figure 2](#), it has been reported that the sight or flavor of chocolate produce greater activation of the OFC in people who describe themselves as

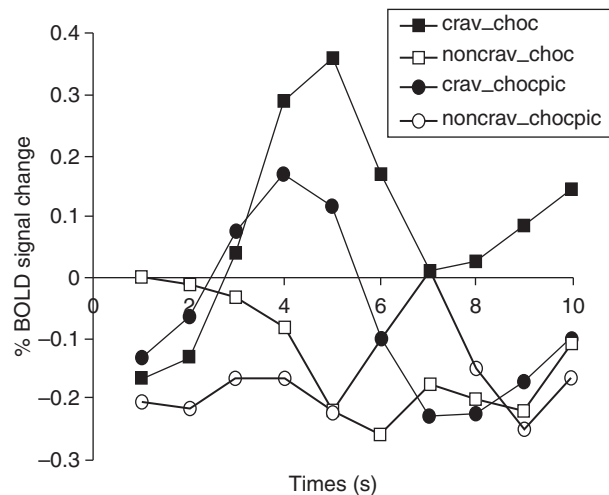

Figure 2 Demonstration that persons who are chocolate cravers (crav) increase activation of the OFC to the sight (chocpic) or flavor of chocolate (choc) more than persons who are not chocolate cravers (noncrav). Data are percent changes in blood oxygenation level (BOLD) measured for 10 s after presentation of the chocolate or picture of chocolate. Reprinted with permission from Rolls ET and McCabe C (2007) Enhanced affective brain representations of chocolate in cravers vs. non-cravers. *European Journal of Neuroscience* 26: 1067–1076.

chocolate cravers than in people who do not. Finally, the neurochemicals most strongly implicated in hedonics include dopamine (especially dopamine acting on D2 dopamine receptors in the NAc), endogenous opiates, and serotonin.

Finally, hedonic judgments are conscious perceptual states, and eating is a behavior. What, then, is the relationship between subjective states and behavior? Since acceptance of the principle of evolution by natural selection, the most parsimonious view is that subjective states evolved as causal agents, that is, conscious experience can cause behavior. This has been especially forcefully argued by the philosopher John Searle. Part of his view is that the belief that the (subjective) mind and the (physical) brain are fundamentally different kinds of things is illusory. How neural activity produces consciousness, and how consciousness affects neural activity, however, remain beyond the scope of today's technologies. Nevertheless, functional brain imaging methods are yielding more and more information about the relationships among neural processes in the brain, conscious states, and eating.

Gastric Mechanoreceptors

The stomach is richly innervated with mechanoreceptors, that is, sensory nerve endings that respond to stretching the smooth muscle of the stomach wall. These sensory nerves project to the brain via both vagal and spinal visceral (splanchnic) afferents. Studies in animals and humans indicate that the increase in gastric volume that occurs during large meals is an adequate stimulus for these mechanoreceptors and that the resulting neural signals contribute to satiation. The chemical nature of the gastric contents, in contrast, is not sensed. (More nutrient-dense gastric loads empty into the intestines more slowly than less nutrient-dense loads, however, to produce longer-lasting volume signals.)

Figure 3 Demonstration that learned associations between flavor stimuli and gastric and postgastric signals control meal size. Rats consumed daily test meals of a sucrose solution during which pyloric cuffs were closed, so that ingested food could not pass from the stomach to the duodenum, in two conditions: first, with the gastric drainage cannulas closed (closed symbols), and second, with the gastric drainage cannulas open, so that the stomach remained empty (open symbols). Three phenomena are visible. First, meal size increased about twofold on the first test with the gastric cannulas open (day 3). This reflects the absence of normally operating *unlearned* controls of eating. Second, meal sizes in both conditions increased progressively during days 4–20, when two tests with the gastric cannulas closed were done between each test with the cannulas open. These progressive increases reflect the gradual weakening of learned associations between the flavor of sucrose and the absent gastric or postgastric food stimuli. Third, meal size increased even more rapidly in tests after day 20, when the gastric cannulas were open in every test. Because the only difference between the two conditions was that gastric filling occurred when the gastric cannulas were closed (recall that the pyloric cuffs were closed in all tests), this indicates that learned flavor-gastric volume signals are potent controls of meal size. Reprinted with permission from Davis JC, Smith GP, and Meissner J (1993) Postpyloric stimuli are necessary for the normal control of meal size in real feeding and sham feeding rats. *American Journal of Physiology* 265: R888–R895.

Neural recording studies in animals indicate that some of the vagal afferents respond synergistically to gastric volume and other meal-control signals, such as cholecystokinin (CCK). In humans, the volume of the antrum, that part of the stomach nearest the pyloric sphincter, which separates the stomach from the small intestine, seems most important for the feeling of fullness. Functional brain imaging studies suggest that fullness perceptions arising from increased gastric volume involve neural networks in the amygdala and the insular cortex, two areas also implicated in flavor hedonics.

The normal influence of gastric volume on eating is in large part learned. This has been elegantly demonstrated in rats that were surgically prepared so as to break the normal association between the flavor of the food eaten and gastric volume during test meals. As shown in **Figure 3**, this disconnection caused a progressive increase in meal size over test days, indicating the gradual deterioration of learned satiation signals.

Cholecystokinin

The gut peptide hormone CCK is an important mediator of the satiating effects of nutrients in the small intestine. CCK is

secreted from glandular cells dispersed in the epithelial cell layer of the small intestine, especially its initial part, the duodenum. As is the case for many other endocrine cells of the gastrointestinal tract, one side of the cell is exposed to the gastrointestinal tract lumen and expresses receptors that stimulate secretion from the opposite side of cells. CCK is secreted from the other side of the cell into the extracellular space of the lamina propria, from which it diffuses into the blood. The digestion of fats and proteins stimulate CCK secretion within minutes of meal onset. CCK satiating was first described in a series of classic studies starting in the 1970s by Gerard P. Smith, James Gibbs, and their colleagues at Cornell University Medical College. By now, tests of a number of stringent endocrine criteria indicate that one of the normal effects of CCK is to elicit satiation both in rats and humans. Some of the most important results are (1) infusion of CCK in amounts that reproduce levels reached during meals are sufficient to inhibit eating in humans; (2) infusion of selective CCK-1 receptor antagonists just before meals blocks the satiating effect of intraduodenal infusions of fat; and (3) CCK-1 receptor antagonist infusion during meals increases meal size (and the perception of hunger in humans). **Figure 4** shows some of these data. The amount of evidence implicating CCK in normal satiation is greater than for any other meal-control signal. Whether long-term treatment with CCK or CCK agonists can be used effectively to control eating therapeutically, however, remains unclear.

Figure 4 Demonstration of the satiating action of CCK in human subjects. Left: Intravenous (IV) infusions of the CCK-1 receptor antagonist loxiglumide (LOX) or a control saline solution (SAL) and intraduodenal (ID) infusions of a fat emulsion (FAT) or SAL were done while normal-weight male volunteers ate a lunch of orange juice, ham sandwiches, chocolate mousse, and coffee. ID fat infusions reduced meal size, and this satiating effect of fat was blocked by CCK-1 receptor antagonism, indicating that endogenous CCK was necessary of it. Right: Under similar conditions, except without ID infusions and a banana shake preload before the IV infusion, IV infusion of a larger loxiglumide dose increased meal size, indicating that endogenous CCK was involved in normal satiation under these conditions. Meal sizes are expressed in calorie equivalents because of the different foods eaten. *Statistically significant effect. Reprinted with permission from (left) Matzinger D, Gutzwiller J-P, Drewe J, et al. (1999) Inhibition of food intake in response to intestinal lipid is mediated by cholecystokinin in humans. *American Journal of Physiology* 277: R1718–R1724; (right) Beglinger C, Degen L, Matzinger D, D'Amato M, and Drewe J (2001) Loxiglumide, a CCK-A receptor antagonist, stimulates calorie intake and hunger feelings in humans. *American Journal of Physiology* 280: R1149–R1154.

CCK's satiating action may be in part endocrine (i.e., reach receptors via the circulation) and, at least in rats, in part paracrine mode (i.e., locally, in the lamina propria of the small intestine, before entering the blood). In rats, the CCK-1 receptors that mediate the paracrine action appear to be located on gastrointestinal smooth muscle in the pyloric area and on sensory fibers of the vagus nerve that innervate the same region, and those that mediate the endocrine action appear to be in the hepatic–portal vein or liver. The signals generated by all these CCK-1 receptors elicit afferent signals in the vagus nerve, which projects from the gut directly to the brain, to a region known as the nucleus of the solitary tract (NTS) in the hindbrain. A wealth of data, some reviewed below, indicate that the NTS is an important processing station in the control of eating.

Glucagon-Like Peptide 1 and Peptide YY

Glucagon-like peptide 1 (GLP-1) and peptide YY (PYY) are also gut peptide hormones. They are cosecreted by a single endocrine cell type, located mainly in the ileum, during and after meals. Glucose produced during the digestion of carbohydrates is the most potent stimulus for GLP-1 and PYY secretion. These peptides may contribute to both satiation and postprandial satiety. In rats, GLP-1 may act locally, on receptors on vagal neurons in the lamina propria of the small intestine, to produce a vagal signal to the brain. Whether its across-meal action is also vagally mediated or is the result of stimulation of GLP-1 receptors in the brain is unknown. The brain also contains neurons that use GLP-1 as a neurotransmitter. These neurons have been implicated in inhibition of appetite during visceral illness. The site of action of PYY is not yet clear; the NPY-Y2 receptors that mediate its actions of are expressed in the hypothalamus, the hindbrain, and abdominal vagal afferents.

As for CCK, infusion of GLP-1 in amounts that produce levels reached during meals are sufficient to inhibit eating in humans. In contrast, pharmacological amounts of PYY, which often elicit illness, seem to be required to inhibit eating. Note, however, that intravenous administration may not mimic the potentially paracrine effect of PYY on vagal afferents. The effects of GLP-1 or PYY antagonism have not been tested in humans as yet. GLP-1 agonists are in use to facilitate insulin secretion in patients with type-2 diabetes mellitus (T2DM), who are generally obese, and may also be useful for appetite control.

Amylin

The peptide hormone amylin (or islet amyloid polypeptide, IAPP) is synthesized mainly by pancreatic β -cells and cosecreted with insulin beginning in the first minutes of meals. Meal-related amylin secretion may function as a within-meal satiation signal, and basal amylin levels may function as an across-meal control of meal size (basal levels). Thus, in rats, acute injection of an amylin receptor antagonist, just prior to a meal, increased the size of that meal, and continuous infusion of the antagonist over 2 weeks chronically increased meal size and body weight. Amylin acts on receptors in the area postrema, a part of the brain with little or no blood–brain barrier that is adjacent to and heavily interconnected with the NTS. Amylin's satiating effect has not yet been investigated in detail

in humans, although pharmacological use of amylin agonists is attracting interest both as an aid to weight loss and for the control of diabetes.

Ghrelin

Ghrelin is a peptide hormone synthesized and secreted mainly by endocrine cells in the gastric wall. Ghrelin has attracted great interest as a potential hunger signal because it is the only gut peptide whose secretion is stimulated during fasting and inhibited by eating and because it is the only gut peptide whose administration stimulates eating, which has been shown in animals and humans. This appears to be an endocrine effect of ghrelin acting on receptors in the arcuate nucleus (Arc) of the hypothalamus. The physiological status of ghrelin is not yet well established.

Across-Meal Controls of Eating

Metabolic Signals

Neural sensitivity to metabolic processes in three organs, the intestines, the liver, and the brain, appears to contribute to the control of eating. Systemic administration of metabolic fuels often reduces eating, and pharmacological inhibition of glucose or fatty-acid utilization often increases it. These appear to be across-meal signals, that is, the changes seem to develop over durations that are longer than individual meals. Changes in glucose, however, may lead to within-meal as well as across-meal effects. Finally, whether metabolic processes are normally involved in the control of eating or contribute only in metabolic emergencies, such as severe hypoglycemia or starvation, remains unknown.

Glucose

Glucose is the most important metabolic fuel and has been much studied. Several demonstrations that intravenous glucose infusions inhibit eating and that coinfusion of insulin increases the effect suggest that the metabolic utilization of glucose contributes to the control of eating. Mice with a transgenic, relatively brain-specific deficiency in the glucose transporter-2 (GLUT-2) eat more than wild-type mice and show abnormal patterns of hypothalamic neuropeptide expression during the fasted-to-fed transition, suggesting the absence of GLUT-2 compromised the function of glucose sensors that contribute to the hypothalamic control of eating (see next section).

The liver also expresses GLUT-2, and meal-related increases in hepatic-portal vein glucose concentration may contribute to satiation. For example, intrameal hepatic-portal vein infusions of small amounts of glucose or of glucose plus insulin selectively reduced the sizes of spontaneous meals in rats. Electrophysiological and anatomical data indicate that the glucose receptors stimulated are likely to be on vagal afferents terminating in the wall of the hepatic-portal vein.

Glucose-sensing neurons, that is, neurons that change electrophysiological activity depending on changes in glucose level or utilization within the normal range, are present in several brain areas, from the hindbrain to the hypothalamus. Many of these neurons express GLUT-2, sulfonylurea receptor-1 (whose activation stimulates insulin secretion), and glucokinase

(the rate limiting enzyme in glycolysis), thus making them excellent candidates as glucose-utilization sensors. There is evidence that brain glucose-sensing neurons contribute both to the homeostatic regulation of blood glucose level and to the control of eating.

Finally, a small, transient decrease in blood glucose level occurs prior to spontaneous meals in rats and humans under some conditions. This decrease may be a pattern whose recognition contributes to meal initiation. The decrease seems not to reflect a decrease in glucose utilization because it is very small and because glucose level usually returns to normal before the meal is initiated. One possibility is that the brain periodically initiates a pulse of insulin secretion via vagal afferents in order to test the body's ability to compensate and initiates eating if the compensation is not rapid enough.

Fatty acids

Fatty-acid utilization has also been implicated in eating. Acute pharmacologic inhibition of fatty-acid oxidation (FAO) has been shown to stimulate eating in animals and humans. Although the liver is a primary site of FAO, several results suggest that it is not the site where FAO sensing contributes to the control of eating. Rather, recent evidence suggests that the intestinal wall may be the site. That is, depending on nutritional status, intestinal epithelial cells may absorb fatty acids either from the blood or (when medium or short chain fatty acids are ingested) from the intestinal lumen and oxidize them to cover their own energy needs, and the level of oxidation may be sensed by vagal afferents. Fatty-acid levels or metabolism can also be sensed centrally, in the hypothalamus, and this also appears to affect eating, at least during pharmacological manipulations.

Intracellular energy flow sensors

The intracellular signaling mechanisms linking metabolism and eating have also been investigated. Reduction of cellular-energy availability, whether due to decreases in fatty-acid or glucose utilization, increases the AMP/ATP ratio and activates (via phosphorylation) the intracellular-energy sensor AMP kinase (AMPK), which exists in the periphery and the brain. Local pharmacological activation of AMPK in the hypothalamus increases eating, suggesting that changes in cellular-energy status are sensed. Similarly, pharmacological manipulation of another cellular-energy status sensor, the molecule mammalian target of rapamycin (mTOR), also affects eating. mTOR appears to be expressed by neuropeptide Y (NPY)/agouti-related peptide (AgRP) neurons in the Arc of the hypothalamus, which, as explained in the next section, are supposed to play a crucial role in homeostatic eating. mTOR activity is decreased by metabolic-fuel deficiency and is increased by fuel repletion, that is, the opposite pattern as AMPK activity. In addition, activation of AMPK inhibits mTOR activity in the some brain areas. These data suggest that activation of the two fuel-sensing molecules should have opposite effects on neural activity, but this has not yet been shown.

Insulin

Insulin, besides its many metabolic actions in the periphery, seems to have a direct inhibitory action on eating. This action is

the result of active transport of insulin from the blood into the brain, where it acts on receptors in the Arc of the hypothalamus. It has been suggested that insulin may function as an 'adiposity signal,' that is, a signal providing the brain with information about body fat that enables it to mount compensatory responses when body fat is increased or decreased. A variety of indirect evidence supports this view. Insulin administration into the brain reduces eating and increases energy expenditure, and insulin antagonist infusion has opposite effects. In addition, cross-sectional studies indicate that in humans or animals who are maintaining a steady weight, whether normal or elevated, basal (i.e., fasting) plasma insulin levels are correlated with weight or adiposity. Finally, specific transgenic knockout of brain insulin receptors rendered mice obese. Although these data indicate that insulin is necessary for normal energy homeostasis, they do not provide direct evidence that insulin signals change in adiposity to the brain. In fact, basal plasma insulin is not correlated with either body fat or the magnitude of compensatory eating or energy expenditure responses in rats that were dynamically regulating their weight following experimentally induced obesity or underweight. Thus, insulin's role in the control of eating remains in doubt.

Leptin

Leptin is a peptide hormone secreted by the adipocytes themselves. Its position in the physiology of eating is similar to insulin's. Cross-sectional studies indicate that basal plasma leptin levels are correlated with weight or adiposity in humans or animals who are maintaining a steady weight. Administration of leptin or leptin antagonism decrease and increase eating, respectively, and genetic defects in the leptin signaling pathway produce dramatic obesity phenotypes. But direct support for a role as an adiposity signal is lacking. For example, basal plasma leptin was not correlated with either body fat or the magnitude of compensatory eating and energy expenditure responses in rats that were dynamically regulating their weight following experimentally induced obesity.

Several data suggest that leptin's physiological role may be in starvation or weight loss rather than in obesity. For example, underweight animals become progressively more sensitive to leptin administration, whereas overweight animals become less sensitive. Rudolph Leibel, Michael Rosenbaum, and their colleagues at Columbia University, New York, NY, USA, have performed several fascinating studies of human subjects recovering from a ~10% loss in body weight, which leads to decreased plasma leptin levels, decreased energy expenditure, and, presumably, increased hunger. In one study, these investigators showed that leptin infusions that reinstated normal-weight leptin levels normalized energy expenditure. In a follow-up study, brain responses to the sight of food items or nonfood items were measured with functional magnetic resonance imaging (fMRI) at normal weight and after weight loss. Weight loss caused selective changes in the neural responses to the sight of food items in several brain areas thought to be involved in the control of eating, and normalization of leptin levels reversed many of these. Such data suggest leptin is a necessary part of the brain's complex response to the homeostatic challenge of weight loss.

Brain Mechanisms

Eating is mediated by a complex, anatomically diffuse neural network that is organized hierarchically, redundantly, and recurrently. Three somewhat autonomous subnetworks have been identified: a telencephalic network for hedonic processing, a hypothalamic network especially involved in homeostatic mechanisms, and a hindbrain network. Some of the principal structures in each of these networks are depicted in [Figure 5](#). The telencephalic network was introduced in the section 'Flavor Hedonics.' The others are briefly sketched here.

Hypothalamus

Several subareas, or nuclei, of the hypothalamus have been implicated in the control of eating, and an intrahypothalamic neural network is thought to orchestrate the eating, neuroendocrine and autonomic responses contributing to energy homeostasis. The Arc appears to be an important sensory node in this network ([Figure 6](#)). As mentioned already, Arc neurons are sensitive to hormones including leptin, insulin, and to metabolites. One population of these neurons synthesizes and uses the neurotransmitter NPY and the neuro-modulator AgRP, and another population synthesizes and uses the neurotransmitters α -melanocyte-stimulating hormone (α -MSH; these neurons are often called POMC neurons after the precursor of α -MSH, proopiomelanocortin) and cocaine- and amphetamine-related transcript (CART). NPY and AgRP stimulate eating when injected into the hypothalami of animals and are therefore called orexigenic peptides, whereas α -MSH and CART injections inhibit eating, so they are called anorexigenic peptides. Three main targets of projections of these two classes of Arc neurons are the nearby paraventricular nucleus (PVN), lateral hypothalamic area (LHA), and perifornical area (PFA). Arc NPY/AgRP neurons inhibit PVN neurons that express neurotransmitters including oxytocin (OT) and corticotropin-releasing hormone (CRH), and other anorexigenic peptides, and stimulate LHA neurons that express melanin-concentrating hormone (MCH) and PFA neurons that express orexin-A and -B (Or-A, Or-B), which are orexigenic. In contrast, Arc α -MSH neurons inhibit PVN OT and CRH neurons and stimulate LHA/PFA MCH, Or-A, and Or-B neurons. Additional neural elements of this network include inputs from serotonin (or 5-hydroxytryptamine, 5-HT) neurons projecting from the raphe nuclei in the midbrain and electrophysiologically inhibitory interconnections mediated by γ -aminobutyric acid (GABA) neurons, both local interneurons and projection neurons from the NAc. The latter represents one likely connection between the hypothalamus and telencephalic networks processing flavor hedonics.

This summary is based on a huge number of experiments. Nevertheless, because available methodologies do not permit truly crucial physiological experiments, the extent to which this neural network, or parts of it, controls normal eating is uncertain. Whether or not particular neurochemical signaling systems operate in most conditions, however, does not preclude the development of pharmacotherapies based on them (or on the gut signaling molecules discussed above). Because of the many health problems related to the obesity epidemic, pharmaceutical companies have mounted huge efforts in this direction.

Figure 5 Schematic diagram of the roughly localizing three partially independent subnetworks controlling eating in the telencephalon (cerebral hemispheres), hypothalamus, and hindbrain. Several important brain areas in each region are listed. The view of the brain is the medial aspect of the right side of the brain after a midsagittal section, as can be done by cutting tissue with a knife or by computed tomographic imaging. The front is to the left. AP, area postrema; Arc, arcuate nucleus; BLA, basolateral amygdala; CeA, central nucleus of the amygdala; Cing, cingulate cortex; DMH, dorsomedial hypothalamus; DMV, dorsal motor nucleus of the vagus; HN, hypoglossal nucleus; LHA, lateral hypothalamic area; MRT, medullary reticular formation; MV, motor nucleus of the trigeminal nerve; NAc, nucleus accumbens; NTS, nucleus of the solitary tract; OFC, orbitofrontal cortex; PBN, parabrachial nucleus; PFA, perifornical area; PVN, paraventricular nucleus; Raphe N, midbrain raphe nuclei (dorsal and magnus); VLM, ventromedial medulla; VMH, ventromedial hypothalamus; VP, ventral pallidum.

Hindbrain

The hindbrain (midbrain, pons, and medulla) is the target of both neural and endocrine signals involved in the control of eating. In addition, it contains the interneuronal networks that function as 'central-pattern generators' coordinating the acts of eating and the cell bodies of the motor neurons that project to the muscles involved. The results of neural processing in the telencephalon and hypothalamus must be conveyed to these hindbrain motor networks to have any influence on eating. These descending projections do not appear to target the motor networks directly, but to project to interneuronal networks that process peripheral inputs to the hindbrain, such as vagally mediated meal-control signals. The final integrated output is then directed to the motor networks. The PVN is the source of a number of projections from the hypothalamus to the hindbrain. For example, PVN OT and CRH neurons project to the NTS and nearby sensory and motor areas.

Hindbrain neurons that express the amine neurotransmitters serotonin, dopamine, and the catecholamines norepinephrine and epinephrine are another source of projections to the forebrain involved in the control of eating. Serotonin and dopamine have been implicated in both flavor hedonics and satiation. The catecholamines, which are also expressed by neurons in the forebrain, have been implicated in normal satiation and in anorexia.

A series of elegant studies by Harvey Grill and his colleagues at the University of Pennsylvania, Philadelphia, PA, USA, revealed several unsuspected aspects of the hindbrain's contribution to eating. Much of this work used chronic decerebrate rats, which are rats with transections of the neuroaxis that

separate the hindbrain and forebrain (i.e., telencephalon, thalamus, and hypothalamus). This work indicates that the hindbrain is sufficient for nearly normal effects of gustatory and gastrointestinal feedback signals on meal size. Although these rats do not initiate meals unless food is placed into the mouth, when this is done by intraoral infusion, they take well-defined meals terminated by passive refusal of more food, ingest more of sweeter solutions, ingest less after CCK injections, etc. These investigators have also shown that leptin and a number of other endocrine signals can act directly in the hindbrain to control eating. How these capacities of the hindbrain are integrated with forebrain neural processing is a focus of current research.

Intercellular Signaling

Multiple neurotransmitters and neurotransmitter receptor subtypes in addition to those already mentioned have been implicated in the control of eating. These are listed in Table 2. The assessment of their physiological roles in eating is much more difficult than the assessment of peripheral endocrine signals discussed previously, so that progress in this area is slow. Again, however, it is important to realize that pharmacological treatments for eating can be based on neurotransmitter systems even if they are normally only rarely involved in the control of eating.

Intracellular Signaling

Some intracellular signaling molecules involved in the brain neural networks controlling eating have been identified. These

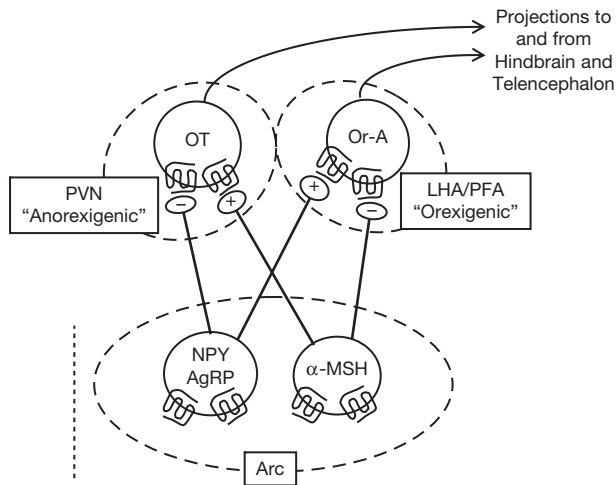

Figure 6 Schematic diagram of the core 'anorexigenic' and 'orexigenic' neural networks in the hypothalamus, as described in the text. Dashed lines indicate the Arc, PVN, and LHA/PFA. Within these areas, neural cell bodies are represented by circles, neurotransmitter or endocrine receptors by squiggles, axons by straight solid lines, and axon terminals by ovals. Excitatory synapses are denoted by a plus sign in the axon terminal, and inhibitory synapses by a negative sign. Arc neurons are receptive to a variety of metabolites, hormones, and neurotransmitters. A medially located population of neurons expresses the signaling molecules NPY and AgRP and has excitatory projections to neurons in the LHA/PFA that express Or-A and other orexigenic molecules; the NPY/AgRP neurons also have inhibitory connections with neurons in the PVN that express OT and other anorexigenic molecules. A more laterally situated population of Arc neurons that express α -MSH has a reciprocal connectivity: it excites PVN neurons and inhibits LHA/PFA neurons. Finally, the PVN and LHA/PFA send and receive projections from a variety of hindbrain and telencephalic areas. The diagram shows only one side of the brain; the dotted line on the left represents the midline.

include adenosine 44/42 mitogen-activated protein kinase (MAPK or ERK1/2), cAMP response element-binding protein (CREB), signal transducer and activator of transcription 3 (STAT3), and suppressor of cytokine signaling 3 (SOCS3). In addition, the immediate early gene products c-Fos and c-Jun, which are activated by neural activity, are useful markers of brain areas activated in particular functional states. The roles of these various molecules are not yet well established. Activation (i.e., phosphorylation) of MAPK is especially interesting because it has been reported that pharmacological inhibition of MAPK affects eating, indicating that it has a necessary role under some circumstances.

Sex Differences

In addition to their functions in reproductive physiology, gonadal steroid hormones, especially the estrogens and androgens, act in the brain to affect eating. The clearest phenomenon, which occurs in women as well as in many animal species, is that eating decreases during the periovulatory phase of the ovarian cycle. In rats and mice, this has been shown to be due to an inhibitory effect of endogenous estrogens on eating leading to reduced meal size. An important

mechanism underlying this is that estrogens increase the satiating potency of CCK. This increase is due to the activation of estrogen receptors on neurons in the NTS about a day before ovulation, as has been shown with local administration of estradiol (the major estrogen) or estrogen antagonists. Three other effects of estrogens have been identified in rats and mice that may also contribute: first, estrogens decrease the eating-stimulatory effect of ghrelin; second, estrogens increase the satiating potency of pancreatic glucagon; and, third, at least under some test conditions, estrogens decrease the eating-stimulatory effect of sweet taste.

In rats and mice, interruption of ovarian cycling increases meal size and leads to increased food intake and adiposity. This phenomenon has also been linked to the effect of estrogens to increase CCK satiation. On average, women increase adiposity during the menopausal transition, but whether this is due to increased eating is unknown (there is also a shift in regional adipose tissue deposition, which may be due to the decrease in circulating leptin levels after menopause).

The estrogenic inhibition of eating is mediated by a particular estrogen receptor, estrogen receptor-alpha (ER- α). Girls with variants of the ER- α gene that lead to partial loss of function have been found to develop an increased risk to become overweight or obese beginning at puberty. This strongly suggests that estrogens control eating similarly in women as in rats and mice. It has been reported that estrogens increase the eating-inhibitory effect of exogenous leptin and decrease the eating-inhibitory effect of exogenous insulin, but whether these are endogenous physiological mechanisms is not yet clear.

There are also sex differences in flavor hedonics. In rats, females prefer sweet solutions less than males, and in humans, women designate less sweet foods maximally pleasant than men. Estrogens appear to reduce the hedonic evaluation of sweets both in female rats and women. Estrogen-independent mechanisms may also contribute. In humans, there is a sex difference in the numbers of sweet- and bitter-sensitive taste receptors which is associated with differences in flavor hedonics. Men and women also tend to have very different sorts of food cravings, although the extent to which this reflects biological sex differences rather than cultural influences is unknown.

Finally, how sex differences in the physiology of eating are related to women's increased vulnerability to psychiatric eating disorders are important, but little understood, issues.

Anorexia

Anorexia is decreased appetite or decreased eating caused by illness, aversion, or abnormal interference with the normal physiological controls of eating.

Illness Anorexia

Anorexia is a common element of systemic infections and other immune challenges. Anorexia during the 'acute-phase response' of the innate immune system, like fever, is unpleasant, but can facilitate recovery. More chronic illness anorexia, such as that which accompanies cancer, however, is a maladaptive response that can increase illness severity.

A number of proinflammatory cytokines (interleukin-1, interleukin-6, tumor necrosis factor- α , etc.), prostaglandin- E_2 , and other immune signaling molecules are involved in acute illness anorexia. These appear to converge on the same neural networks that mediate normal eating. For example, serotonergic neurons in the dorsal raphe nuclei, which project into the hypothalamus and telencephalon, have been implicated in both the normal control of eating and in illness anorexia.

Acute illness leads to a unique form of learning, the conditioned taste aversion. If an unfamiliar food item is eaten in the hours before an acute illness occurs, especially upper intestinal malaise, animals and humans develop a very strong aversion to the flavor. This is an unusual form of Pavlovian conditioning in that it occurs with only one association between the flavor stimulus and illness, it occurs with very long intervals between these stimuli, and it is unusually resistant to forgetting.

Stress Anorexia

The classical hypothalamic–pituitary–adrenal axis stress response involves a three-step endocrine cascade: secretion of CRH from the hypothalamus into the hypophyseal portal circulation, secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary into the systemic circulation, and secretion of glucocorticoid hormones, especially cortisol in humans and corticosterone in rats, from the adrenal cortex. Stress also stimulates secretion of arginine vasopressin and OT from the posterior pituitary and activates the sympathetic nervous system, leading to the secretion of epinephrine and norepinephrine from the adrenal medulla. All of these hormones appear to contribute to stress-induced anorexia, although their specific roles in the many types of stressors that are associated with anorexia are not fully clear.

CRH is secreted into the hypophyseal circulation by neurons in the parvocellular part of the PVN. CRH neurons also project to other brain sites, where CRH is released as a neurotransmitter, as mentioned above. These neurons can be activated in the absence of HPA axis activation, suggesting that CRH has a role in normal eating as well as anorexia. Similarly, as OT also acts as a neurotransmitter, and oxytocinergic projections from the PVN to the NTS also appear to be involved in the control of normal eating.

Glucocorticoid hormones play a crucial role in obesity – most experimental obesity syndromes are reversed by adrenalectomy and reinstated by glucocorticoid treatment. Pathological increases in CRH or ACTH lead to Cushing's syndrome, which includes abdominal obesity. Both overeating and direct metabolic effects of glucocorticoids appear to contribute to the obesity of Cushing's syndrome.

Psychiatric Eating Disorders

Anorexia Nervosa

Anorexia nervosa is a grave disorder characterized by dangerously low body weight (often defined as BMI < 17), an intense fear of weight gain, refusal to eat and, in women, amenorrhea. A substantial number of people who develop anorexia nervosa die from it. The name, however, is a misnomer. That is,

although people with anorexia refuse to eat, it is because of suppression of appetite, not lack of appetite. This is evidenced, for example, by findings that people with anorexia nervosa often consume huge amounts of noncaloric sweetener. The prevalence of anorexia nervosa is approximately threefold higher in women than in men. Furthermore, the incidence of anorexia nervosa is highest around puberty, when the estrogenic inhibition of eating appears. Unfortunately, therapeutic manipulation of the physiological controls of eating to alleviate anorexia nervosa remains a distant goal.

Bulimia Nervosa and Binge-Eating Disorder

Bulimia nervosa and binge-eating disorder are characterized by binge eating (i.e., ingestion of abnormally large amounts of food associated with a perceived loss of control of eating); in bulimia nervosa, binges are followed by inappropriate compensatory behaviors, such as self-induced vomiting or laxative abuse, with maintenance of normal weight. In binge-eating disorder, there is not compensation, so obesity develops. There is considerable evidence that some satiation signals are less potent in patients with bulimia nervosa. For example, food preloads decrease meal size less in patients with bulimia nervosa than in controls, patients with bulimia must eat larger amounts of food to produce equivalent self-reports of fullness, and food-stimulated CCK release is less in patients with bulimia nervosa than controls. There is also evidence that serotonergic processing of satiation signals in the brain is altered in patients with bulimia nervosa. All these abnormalities appear to resolve as bingeing decreases, however, suggesting that they are not the initial cause of bulimia. It is likely that they facilitate the maintenance of bulimia nervosa once it has begun and impede recovery from it. Thus, these are attractive candidates for development of physiologically or pharmacologically based treatments. The risk of both disorders is substantially higher in women (approximately threefold for bulimia nervosa and approximately twofold for binge-eating disorder). Binge-eating disorder, which was recognized more recently, urgently requires investigation as it has a strong statistical association with morbid obesity (i.e., BMI > 40).

Animal Models of Psychiatric Eating Disorders

A number of animal models have been developed in the attempt to understand normal genetic, neurochemical, physiological, and behavioral factors that are involved in the cause or maintenance of psychiatric eating disorders. Activity-based anorexia (ABA) is the most interesting animal model of anorexia nervosa. ABA is produced by limiting food access to 1–2 h day⁻¹ and providing free access to a running wheel. When this is done, rats become progressively anorectic until death. The neurochemical changes produced by ABA have been extensively investigated and have provided several clues as to potential pharmacological treatments for anorexia nervosa. Animal models of binge eating, of which there are several, also seem to hold great promise. These models are based on increased intake of palatable foods stimulated by restricted access, stress, and other factors thought to be involved in the development of the human syndrome.

Genetics of Eating

Heritability of Obesity

Body weight is a highly heritable trait. The heritability (h^2 , the percent of variation in a population phenotype that is due to genetic variation) of body weight or BMI is generally $\sim 75\%$, which is similar to that of height. A recent large ($>90\,000$ subjects) genome-wide association study revealed eight genes that contribute to this high heritability. Some of these are related to eating, such as the gene for the α -MSH receptor, the melanocortin-4 receptor (*MC4R*). About 100 *MC4R* variants have been associated with obesity. People bearing such gene variants report constant hunger and apparently lack a normal sense of satiation. *MC4R* variants are quite common, occurring in about 2–6% of obese people, depending on the population studied, and one variant had a minor allele frequency of about 25% in a cross-sectional study of US American women of all weights.

A common question is, how can the recent increase in the prevalence of obesity, which clearly occurred without any change in the human genome, be reconciled with the high heritability of body weight? The problem evaporates when one recalls that h^2 measures heritability in a single environment. If the environment changes, so will h^2 . Thus, individual estimates of h^2 in the present high obesity-risk environment and in the former low obesity-risk environment might each be $\sim 75\%$, but this would be markedly reduced if h^2 were estimated in both environments simultaneously. Second, although the genome has not changed much in recent times, the particular genes that are expressed and their degree of expression probably have. That is, different genes are likely to contribute effectively to our phenotypes in the present environment more than in former environments. Genes whose expression is related to sugar and fat intake, for example, would certainly be expressed more now than in former days, when sugar and fat intakes were lower.

Genes and Eating

Fascinating links between genetic variation and eating have begun to emerge. These new findings suggest, among other things, that, at least in some individuals, overeating and obesity may be caused by inborn genetic differences, no more under the person's control than common inherited variations in color vision. Here I describe two interesting examples in addition to *MC4R*, described above, that support this conclusion.

First, Mariken de Krom, Roger Adan, and their colleagues at the University Medical Center, Utrecht, NL, identified women who were obese and who overate, as estimated using photos of food portions, and then searched for the presence of known variants in the *ckk*, *lep*, and *lepr* genes. Women with one particular *lep* variant had markedly increased risk for extremely frequent meals, whereas those with a particular *ckk* variant had increased risk for extremely large meals. These data indicate that specific high-risk eating traits can have genetic bases. Furthermore, the variants identified were surprisingly common.

Second, Eric Stice and his colleagues at the Oregon Research Institute, Eugene, OR, USA, combined genetic and functional imaging approaches to link dopamine neurotransmission with

food hedonics, eating, and body weight. Subjects were people with or without a variant of a gene (rs1800497) that reduces dopamine D2 receptor function. Activation of the striatum, a telencephalic area in which dopamine neurotransmission contributes to the processing of food hedonics, was measured with fMRI while subjects ate a chocolate drink or a tasteless solution. They found that eating chocolate activated the striatum less in subjects with the gene variant in comparison to subjects with other forms of the gene and that the degree of activation of the striatum was significantly associated with BMI. Their interpretation was that the gene variant reduced the hedonic impact of foods, leading people to eat more in order to get the desired or normal hedonic experience (a similar phenomenon is well known in drug-reward studies).

Asperger's Syndrome and Nonverbal Learning Disorder

J M Gillis, M Sevelever, and M Roth, Auburn University, Auburn, AL, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Adaptive skills Living skills needed to live, work, and play in the community.

Crossmodal integration Synthesizing information from different sensory modalities (tactile, gustatory, visual, auditory, and olfactory).

Pragmatics The social use of language; both verbal and nonverbal.

Semantics The knowledge and usage of words; one's lexicon of vocabulary.

Social reciprocity The back and forth of interactions such as playing, gesturing, attention, and conversations.

Introduction

Asperger's syndrome (AS; sometimes referred to as Asperger's disorder) and nonverbal learning disorder (NLD; sometimes referred to as nonverbal learning disability or nonverbal learning disability syndrome) are first identified in childhood and are considered neurological disorders, meaning that the way the brain processes information is affected. These conditions share a substantial number of symptoms and characteristics; however, there are certain features that distinguish these conditions from one another. Understanding the overlapping and distinctive genetic, neurological, cognitive, and behavioral characteristics of AS and NLD is the focus of current researchers across multiple scientific disciplines. There is conflict as to whether these are two separate disorders; that is, whether they are similar enough such that they belong to the same diagnostic continuum. There are no clear definitions of NLD, as compared to AS, which results in relatively more familiarity with and information available on AS compared to NLD.

The diagnostic classification systems commonly used by practitioners (such as psychologists, medical doctors, etc.) to diagnose psychological and psychiatric disorders include the Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV TR) and the International Classification of Diseases, 10th edition (ICD-10). AS was first introduced into these classification systems in 1993 (ICD-9) and 1994 (DSM-IV). Despite NLD's absence in these two diagnostic systems, children continue to be diagnosed with NLD, especially within school settings, and there is increasing research on NLD. Practitioners and researchers currently conceptualize these two conditions as belonging to different diagnostic categories; AS is considered a pervasive developmental disorder, whereas NLD is classified as a learning disability. This is due in part to the available research on these disorders. Examination of the diagnostic criteria can be helpful in understanding the overlap and distinguishing characteristics of each condition.

Diagnosis of Asperger's Syndrome

AS was first described by Hans Asperger, an Austrian psychologist, in 1944. Asperger's early descriptions of AS continue to correspond with current definitions of the disorder. According to Asperger, children with AS display a pattern of social,

communicative, and behavioral difficulties, including a lack of empathy, difficulty forming friendships, a tendency to engage in one-sided conversations, intense and limited interests, and poor motor coordination skills. To date, there is substantial overlap between the diagnostic descriptions of AS in both the DSM-IV TR and ICD-10.

Within the DSM-IV TR, AS is subsumed under the category of pervasive developmental disorders (PDD), which also includes autistic disorder (more commonly known as Autism), Rett's syndrome, child disintegrative disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS). Broadly, the criteria for a diagnosis of AS identified by the DSM-IV TR and ICD-10 include impairments in social interaction (often including social communication impairments) as well as the presence of restricted, repetitive, or stereotyped interests, activities, or behaviors. AS is distinguished from Autism in the area of language development. Specifically, individuals with AS do not present with a delay in or absence of language development before the age of 3, which is a requirement for the diagnosis of Autism. There is ongoing research to increase knowledge about important similarities and differences between AS, autistic disorder, and PDD-NOS. For example, it is often difficult to differentiate persons with AS from individuals with Autism who demonstrate average to high average intellectual abilities. As such, there is significant debate among researchers and practitioners as to whether HFA and AS are distinct psychological disorders or manifestations of the same disorder across a spectrum of severity.

As part of the established research literature and the process of updating diagnostic classification systems, proposed revisions for new DSM-V (to be released in 2013) suggest removing the diagnosis of AS and subsuming three of the pervasive developmental disorders (i.e., autistic disorder, Asperger's disorder, and pervasive developmental disorder-not otherwise specified) under the broader category of autism spectrum disorder. Under these revisions, the level of severity of an autism spectrum disorder would be indicated based on the extent of social deficits, the presence of a language delay, and the level of intellectual functioning. Despite issues related to the diagnosis of AS and whether or not it will be recognized as a separate disorder in the future release of DSM-V, inclusion of AS in the DSM-IV TR and ICD-10 has led to exponential growth in research and knowledge related to the disorder and enhanced our understanding of autism spectrum disorders

more generally. Interestingly, this is one reason why awareness and research on NLD may be more limited at the present time.

Diagnosis of NLD

In contrast with AS, NLD are not represented in the DSM-IV or ICD-10, which can lead to confusion regarding how NLD is defined in research and clinical or school settings. Learning disability is a broad diagnostic category in the DSM-IV TR and only encompasses disorders that describe learning difficulties in the areas of reading, math, and writing (not NLD). The term NLD was first used by Helmer Myklebust in 1975 and is often described as a subtype of learning disabilities within the field of neuropsychology. NLD is used to refer to a profile of neuropsychological strengths and weaknesses, and these neuropsychological impairments are similar to AS in that they are associated with poor understanding of social situations. In the mid-1990s, Dr. Byron Rourke developed a model that includes the primary strengths and deficits associated with NLD. The major strengths that many individuals with NLD possess include strong auditory perception skills, verbal skills, and memory skills related to verbal information. The three primary deficits of NLD include tactile perception, motor coordination, and visual perception. According to Rourke's model, these deficits lead to marked impairments in social perception and awareness (similar to those seen in AS, but often to a lesser degree of severity). For example, due to difficulties in organizing and interpreting visual information, individuals with NLD are often unable to interpret nonverbal cues in their environment, and thus may have difficulty interpreting social gestures and facial expressions. Children with NLD are often incorrectly diagnosed with attention deficit hyperactivity disorder due to their difficulty focusing on tasks and hyperactivity; however, as individuals with NLD age, they often become much less physically active (hypoactive).

Common Characteristics of AS and NLD

NLD and AS are described as neurological disorders, meaning that specific brain processes are impaired or dysfunctional and that these processes in turn affect one's behavior and how one interacts with the world. Even though there are characteristics that distinguish AS from NLD, these conditions do share a significant number of common features, which impact academic performance, executive function, tactile and visual perception, motor function, as well as social skills.

Academic Performance

Because individuals with AS and NLD present with relatively strong verbal skills, they may appear to be more competent in academics even though there is not commensurate performance in the classroom. High expectations can be placed on both groups; however, due to some of the characteristics of these disorders, academic problems can arise. For example, due to difficulty with fine motor skills, handwriting is problematic in AS and NLD. Additionally, sometimes math is identified as a weakness since mathematical concepts are more abstract,

nonverbal, and spatial in nature. At a younger age, children with NLD or AS may be able to memorize formulas and complete simple calculations; however, their performance deteriorates when reasoning skills and word problems are introduced.

Individuals with AS and NLD also demonstrate several academic strengths. For one, strengths in recalling factual information are common due to well-developed rote memory skills. Additionally, word recognition and basic reading skills (i.e., decoding words, phonemic awareness) are well developed. Individuals with NLD and some with AS are also known to have strong spelling, short-term memory, and auditory-perceptual skills. However, comprehension of abstract and inferentially based information is usually impaired in both groups (i.e., reading comprehension, word problems, idioms, analogies, and metaphors). As more abstract understanding is required of students, and the value of memorizing factual information decreases, the academic success of individuals often declines.

Executive Functioning

Many skills associated with executive functioning (i.e., the ability to plan, organize, shift attention, and set goals) are found to be impaired in AS and NLD, and may result in academic difficulties. Difficulty in organizing information can make planning, carrying out work, and breaking down tasks into components challenging. Executive functioning deficits also make cause and effect relationships difficult to understand. Furthermore, poor problem solving is common in NLD and AS; tasks are approached with inflexibility, inhibiting the ability to generate alternative options. Additionally, individuals with AS and NLD have problems generalizing newly learned techniques and behaviors to different tasks and settings.

Some have suggested that individuals with AS have difficulty discerning relevant from irrelevant stimuli. This is known as the weak central coherence theory. Central coherence can be thought as the ability to process different levels of information together to generate overall meaning and understanding in an immediate context. Thus, this theory suggests, individuals with AS tend to attend to detail rather than the 'big picture.' Despite the ability of individuals with NLD to also recall specific details of verbal information rather than drawing inferences (e.g., seeing the forest through the trees), more research related to weak central coherence is needed to better understand this phenomenon in NLD.

Tactile and Visual Perception

Individuals with NLD are known to have deficits in tactile and visual perception, discrimination, and attention. Visual-spatial organization impairments are a hallmark of this disorder. Although individuals with NLD may be able to perform simple tasks requiring these skills (i.e., matching items of a similar shape), they may have more difficulty as tasks become more complex (i.e., finding a figure embedded in a picture or putting blocks in a form board while blindfolded). Due to tactile and visual perception deficits, individuals with NLD are less likely to physically explore their environment. Additional neuropsychological characteristics of NLD include problems with time perception; individuals with NLD often have difficulty placing themselves in space and orientation. Tactile

and sensory disturbances are also well noted in AS. Individuals with AS are known to be hypo- or hypersensitive to visual, auditory, gustatory, olfactory, and tactile stimuli. Thus, they often experience sensory information at a higher or lower degree than typically developing individuals. For example, difficulty in modulating sensory information can lead to individuals with AS avoiding situations where the stimuli may be encountered (e.g., avoiding crowded rooms in an attempt to escape loud noises). Although hypersensitive individuals may attempt to avoid certain types of sensory information, hypo-sensitive individuals with AS may engage in repetitive behavior (e.g., humming, hand flapping), in order to experience sensory stimulation.

Motor Functioning

Motor problems are characteristic of both AS and NLD. Deficits in fine motor (small muscle movements) and gross motor (large muscle movements) skills can cause individuals with AS and NLD to appear 'clumsy' and 'awkward.' Additionally, problems with coordination and balance are known to occur. Simple motor tasks can be performed; however, more complex tasks are challenging. As noted earlier, motor problems can make handwriting difficult. Complex motor tasks are also difficult for individuals with AS and NLD, such as playing sports. Visual-motor coordination or synthesizing visual information with motor output is known to be impaired in NLD and some individuals with AS. This deficit in crossmodal integration (synthesizing the information from different senses) can make tasks such as completing a puzzle challenging.

Social Skills

Individuals with AS and NLD often demonstrate poor social competence due to their inability to perceive and interpret the social interactions, social communication, and behavior of others. Individuals with AS and NLD may appear 'socially awkward,' 'socially inappropriate,' or 'odd' to those around them due to the combination of deficient social skills, impaired social perception, and poor social communication skills. As a result, many individuals with NLD and AS experience difficulty in forming close friendships or relationships, even when having these relationships are important to them.

Conversations can be characterized by a lack of social reciprocity, commonly known as the back and forth of social interactions. Attempts by another person to respond or change topics may be unsuccessful due to problems with turn taking (i.e., people are often interrupted). When conversations are one sided, the individual with AS or NLD often dominates the dialog in a pedantic manner (which can appear as if he/she is showing off). Thus, it can appear that they are 'talking at you' rather than 'talking to you.' Likewise, language can be overly formal and full of jargon. In addition, language impairments are observed both in AS and in NLD that interfere with social interactions. Notably, problems with semantics (the knowledge and use of different words) and pragmatics (the social use of language) are present. This can lead to difficulties interpreting the subtleties of communication, such as humor, sarcasm, and metaphors. Additionally, individuals with AS and NLD demonstrate impairments with prosody,

the patterns of stress and intonation, which cause them to sound monotonous or make it difficult for others to understand their emotional state based on the tone of their voice. In AS, speech may be at a rapid rate or higher volume. Since it is difficult for individuals to use language in a social context, often learned and rote, or memorized, responses are provided even when individuals realize that their repertoire of responses are not appropriate in a number of social situations. Children with AS and NLD may be more successful interacting with adults or even younger peers, as these social situations are generally more structured, predictable, and forgiving.

Individuals with AS and NLD also have difficulty with the nonverbal aspects of the social environment (e.g., reading facial expressions, body language, and gestures). In NLD and AS, these problems can be attributed to the visual-perceptual deficits that are characteristic of the disorder. Another explanation of these deficits is an impairment in theory of mind (the ability to recognize and understand the thoughts, desires, beliefs, and intentions of others); however, the research is mixed and this remains to be clarified. An inability to read the intentions of others might lead individuals with AS and NLD to inappropriately plan their own behaviors in social situations. For both populations, problems with social judgment, inferring intentions of others, and reading nonverbal communication lead to an increased vulnerability to peer rejection and bullying. Although social skills may improve over time from childhood, they often continue to remain problematic into adulthood.

Difficulty in navigating the social world and repeated unsuccessful attempts to form peer relationships can cause low feelings of self-worth and self-esteem in individuals with AS and NLD. Among the most common comorbid (i.e., co-occurring) psychiatric conditions for individuals with AS and NLD are internalizing problems (e.g., depression and anxiety). In AS, increased self-awareness of differences between themselves and their peers contributes to the development and maintenance of internalizing problems.

Individuals with AS and NLD have difficulty adjusting to novel situations and environments. In NLD, these issues may arise due to deficits in nonverbal problem solving, flexibility, and the ability to learn from environmental feedback. They may approach novel situations with a reliance on rote behaviors, which in many cases may be inappropriate. Conversely, problems recognizing familiar situations can lead to approaching the same situation with different responses. Some researchers hypothesize that behavior problems emerge as a result of perceiving the world as unpredictable or 'fast-paced.' Thus, due to deficits in social perception, individuals may feel constantly bombarded by unpredictable and confusing information. Additionally, a lack of emotional regulation, the ability to maintain and control emotional states, can contribute to behavior problems. Since individuals commonly have preference for routine, they often exhibit problem behaviors when these routines are altered or broken. Moreover, impairments in identifying and interpreting emotions can lead to frequent distressing events. For example, 'tantrums,' 'meltdowns,' and withdrawal from situations can often occur when children become upset.

Other behavior characteristics of AS and NLD include difficulty with adaptive skills, which are skills required to live, work, and play in the community. Examples of adaptive skills

that may be deficient in AS and NLD include dressing, diet, hygiene, household chores, managing money, and shopping. Deficits in adaptive skills may continue into adulthood if not taught properly in childhood and adolescence. Furthermore, in NLD, individuals may show hyperactivity in childhood; however, this behavior decreases with age.

Distinguishing Characteristics of AS and NLD

The characteristics that distinguish AS from NLD are debated by researchers and practitioners due to different theoretical orientations, limited research, and conceptualizations or definitions of the disorders. Given the relatively recent research on both disorders, there is not yet a definitive answer. However, some differences that have yielded more support include cognitive profile of nonverbal compared to verbal intelligence, severity of social impairment, and circumscribed interests.

One of the most significant features of NLD is the disparity between verbal intelligence (language-based abilities) and nonverbal intelligence (visual-spatial abilities), with verbal intelligence being relatively stronger. This is not surprising given the visual-spatial deficits characteristic of NLD. Even though there is conflicting evidence and opinions, it appears that not all individuals with AS present with a similar cognitive profile (a higher verbal intelligence score relative to nonverbal intelligence); however, when individuals with AS demonstrate a similar cognitive profile as NLD, the individual is sometimes given a diagnosis of NLD in addition to AS.

Social impairment is a defining characteristic of both AS and NLD. In general, individuals with AS and NLD have deficits in social behaviors and interactions, as well as poor social communication skills. What distinguishes the two disorders is level of severity: individuals with NLD show similar social difficulties as AS, but to a much lesser degree. A social communication difficulty often observed in AS occurs when circumscribed interests are discussed to a long and inappropriate extent (and at times in a pedantic manner). A circumscribed interest is a topic that is of intense focus. Often, a large amount of information on this topic has been acquired by the individual with AS, regardless of age, meaning that young children in addition to adults with AS exhibit circumscribed interests that might interfere with social interactions. These interests can range considerably from a well-known topic such as a popular television show to a more obscure topic such as locations corresponding to zip codes around the world. The research is mixed on whether circumscribed interests are characteristic of NLD.

Etiology

At present, the exact cause or etiology of AS and NLD is unknown. There is ongoing research examining the role of genetics in both, but no consistent findings have yet emerged. There has been and continues to be extensive efforts to determine the neurological characteristics of AS and NLD. Disturbances in the development of, or damage to, white matter in the right hemisphere of the brain have been found to be the main neurologic characteristic that may be responsible for the

manifestation of NLD. The right hemisphere of the brain houses the ability to process information simultaneously and the ability to synthesize novel information and has important neural connections to different areas of the brain. It has been suggested that the perceptual and motor deficits characteristic of NLD are more marked on the left side of the body because of this right hemispheric dysfunction (information to and from the brain travel contralaterally to the other side of the body). It has been reported that some conditions that have deleterious effects on the brain's white matter have led to NLD symptoms (e.g., callosal agenesis, hydrocephalus, multiple sclerosis, seizures, head injuries, tumors, etc.). Conversely, there is not yet a clear understanding of the brain structure in AS despite the efforts of researchers. Abnormalities in the prefrontal cortex, temporal, striatal, and cerebellar regions of the brain and gray matter have all been identified by researchers as related to a potential cause of AS; however, there is not yet a consensus due to a lack of consistent findings. Thus, disruption to several areas of the brain, rather than a focal lesion, is thought to contribute to the development of AS. Even with the use of advanced brain imaging technology, many studies have resulted in inconsistent results, and different areas of the brain have been implicated. Nevertheless, strong evidence exists to suggest AS is at least partially genetically determined and caused by disruption to brain regions important for social and emotional functioning.

Prevalence

Prevalence is a term used to refer to the proportion of the population diagnosed with a certain disease at a specific time. Prevalence estimates can vary dramatically across studies due to differences in how the studies were conducted or the year in which they were conducted. This is especially true for AS since the prevalence of AS appears to be rising over the years. The prevalence of AS has ranged from 0.3 per 10 000 children to 8.4 per 10 000 children. AS is now reported as occurring in 20 per 10 000 children. This is equal to 1 in 500 children in the United States. As NLD is not an official diagnostic category within the DSM-IV or ICD-10, the prevalence of NLD has been difficult to estimate. Approximately 3% of the total United States' population is diagnosed with a learning disability, and of those diagnosed with a learning disability, ~5–10% are diagnosed with NLD. Some estimates suggest that about 2.7 million people have NLD in the United States (or 1% of the population). With regard to differences in prevalence between genders, AS is much more common in males than females: For every nine males diagnosed with AS, one female is diagnosed with the disorder. Currently, it is suggested that NLD occurs in males and females at similar rates (i.e., no gender differences are reported).

Treatment Considerations

Although NLD is not currently part of the DSM-IV or ICD-10, practitioners do diagnose NLD and individuals with NLD are often eligible to receive special education services as are individuals with AS. Currently, there is no biological or pharmacological intervention that improves either disorder in its

entirety. Rather, medication is sometimes prescribed to manage specific symptoms (e.g., hyperactivity, concentration difficulties, anxiety, etc.) experienced by individuals with AS or NLD. Although there is no cure available for AS or NLD, there are several interventions that can help individuals with AS or NLD learn new skills, overcome challenges of their disorder, and adapt to different environments in order to successfully engage in these environments using educational, behavioral, or cognitive-behavioral approaches. Given that the consequences of having AS or NLD surround academic and social functioning, the focus of treatment within the school setting might include addressing poor organizational skills, information processing deficits, difficulty in integrating and adjusting to new information or routines, stress/anxiety in social situations, poor social competence, deficits in comprehension and abstract reasoning, attention and/or concentration difficulties, and time management.

Associative Learning

E Fantino and S Stolarz-Fantino, University of California, San Diego, La Jolla, CA, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Autoshaping The tendency for an organism to make contact with a stimulus (CS) that reliably predicts food (US), as when a pigeon begins to peck a lighted key that appears shortly before food is presented.

Classical conditioning The process by which a conditioned response – for example, salivation – comes to be elicited by a previously neutral conditioned stimulus (CS) – for example, a tone – through the association of the CS with an unconditioned stimulus – for example, food.

Conditioned suppression When a previously neutral stimulus (CS) is paired with an aversive stimulus (US), presentation of the CS will disrupt ongoing operant behavior.

Eliciting stimuli Events that invariably produce reflex actions (or respondent behavior). For example, a puff of air in the eye produces an eyeblink.

Extinction In classical conditioning, when the conditioned stimulus (CS) is presented several times without the

unconditioned stimulus, the conditioned response ceases to occur when the CS is presented.

Habituation A decline in the magnitude of an unconditioned response after it has been repeatedly elicited by an unconditioned stimulus.

Observing responses Responses that produce stimuli correlated with schedules of reinforcement, but that have no effect on the occurrence of reinforcement.

Rescorla–Wagner model A theory that clarifies the specific conditions under which a conditioned stimulus (CS) acquires control over a conditioned response through pairing of the CS with an unconditioned stimulus.

Respondent behavior Behavior that is automatically produced by a specific eliciting stimulus.

Spontaneous recovery In classical conditioning, the return of a conditioned response after a delay following an extinction period; in habituation, the resumption of responding to a habituated stimulus following a rest period.

Basic Concepts

Innate, automatic reactions that occur in all organisms are called reflex actions or respondent behavior, and the events that unvaryingly produce them are known as eliciting stimuli. The experimental procedure known as Pavlovian conditioning was developed from a study of reflexes carried out by the Russian physiologist, Ivan Pavlov (1849–1936). Pavlov had developed a technique to study digestion whereby he could measure the fluids secreted in a dog's mouth and stomach. His aim was to study the precise relationship between a stimulus (food) and a response (salivation). But as his research on digestion progressed, Pavlov encountered the unexpected: his dogs were salivating prematurely, before they even saw the food. In fact they would salivate as soon as Pavlov entered the room. Pavlov then began to study this phenomenon which he called 'conditioning.' Since Pavlov's time, the conditioning process has been intensively investigated and applied experimentally to behavior in addition to reflex actions. The subject of Pavlov's initial research, however, is viewed as a distinctive form of conditioning dealing mainly with reflexive behavior. Thus, it is sometimes called classical conditioning. It is a fundamental form of associative learning – that is, the learning of a relationship between stimuli. We turn first to the basic concepts of classical conditioning.

Paradigm

The central principle of conditioning is the modification of an organism's response by environmental events. Pavlov found that after pairing a formerly neutral stimulus with a positive

stimulus such as food, the organism would come to react to the previously neutral stimulus. Pavlov grasped the significance of this observation and redirected his research effort to its study. Perhaps a great deal of learned behavior might be based on modification of innate reflexes, much as the learned behavior of salivating to the sight of the experimenter developed from the initial food-salivation reflex. Thus, Pavlov developed procedures for studying classical conditioning that remain in use today. Pavlov's discovery also opened up a new way of studying behavior. Pavlov described his dogs' reflexes to experimental stimuli without speculating about the dog's thoughts and feelings. Thus he helped usher in the idea that some behavior may be described and understood in terms of observable and measurable reflexes, helping to lay the foundation for modern behaviorism.

Figure 1 depicts the sequence of events in the experiments conducted by Pavlov. A hungry dog was restrained in an apparatus designed to isolate the dog insofar as possible from distracting stimuli. A tube leading from the dog's mouth carried saliva directly from the salivary gland to a receptacle where it could be measured. When food powder, the eliciting stimulus or unconditioned stimulus (US) was placed in the animal's mouth, the dog salivated reflexively. Salivation was the unconditioned response (UR) to food in the mouth. Pavlov then struck a tuning fork one-half second before each presentation of the food. After several pairings of tone and food, he would occasionally sound the tuning fork without presenting food. On these food-omission trials, the tone alone was sufficient to elicit salivation to almost the same degree as when food was actually placed in the dog's mouth. Thus, the originally neutral stimulus, the tone, had become a conditioned stimulus (CS),

Figure 1 Pavlov's classical conditioning paradigm. See text for details. Reproduced from Fantino E and Logan CA (1979) *The Experimental Analysis of Behavior: A Biological Perspective*. San Francisco: W.H. Freeman.

capable of eliciting a conditioned response (CR), salivation, which it had not previously elicited.

It should be noted that research since Pavlov's era has shown that the CR is not identical to the UR: classical conditioning is not a simple process of substitution in which one stimulus (the CS) merely replaces another stimulus (the US). Even when the CR and UR appear to be the same (as in the salivation example), they differ in detectable ways (e.g., in terms of latency, duration, or magnitude of the response). In other situations, there is no obvious relationship between the CR and UR. For example, in one type of experiment, a rat is periodically subjected to the occurrence of a light for 5 s (the CS), followed by a moderately intense electric shock (the US) delivered to the rats' feet for 2 s. The rat's normal response (the UR) to electric shock is to jump and/or run around the cage. But after a few pairings of the light and shock the rat begins to develop a CR to the light that is the antithesis of running or jumping: it demonstrates rigid immobility ('freezing') at the onset of the light. Freezing (the CR) actually precludes simultaneous expression of the jumping or running (the UR).

Parameters of conditioning

A crucial variable in classical conditioning is the time interval between the CS and US. Conditioning works best when the CS precedes the US by a ½ s or more whether or not the CS remains on until US onset (delayed conditioning) or whether it turns off some time before US onset (trace conditioning). Conditioning works less well, or typically not at all, when the CS and US are contemporaneous (simultaneous conditioning) or when the US precedes the CS (backward conditioning). As with operant conditioning if the CS is presented several times without the US, *extinction* (EXT) occurs, that is the CR ceases to occur upon CS presentation. But as with operant conditioning, if sufficient time passes the CS will again elicit the CR (spontaneous recovery).

Relation of classical to operant conditioning

Whereas the principal relation in classical conditioning is that between the CS and US (a stimulus–stimulus association), the central relation in operant conditioning is that between the response and the reinforcer contingent upon the response (a response–stimulus association). The critical difference is in the *contingency*: in classical conditioning, the US occurs whether or not the CS elicits the CR; in operant conditioning, the reinforcing stimulus occurs if and only if the response has been emitted. That is, the reinforcer is contingent upon the response in operant conditioning but the US is not contingent upon the CR in classical conditioning.

Theory of associative learning

Elegant theories of the processes underlying classical conditioning have been proposed. The most influential is that of Robert Rescorla and Alan Wagner, developed while both were at Yale University. Their theory clarifies the specific conditions under which associative strength accrues to a stimulus when CS–US pairings have occurred. Specifically, under what conditions does contiguity of CS and US result in formation of an association? The model rests on the assumption that the effect of a reinforcer (US) depends not only on that reinforcer itself but also upon the relationship between that reinforcement and the reinforcement *anticipated* by the organism. In other words, the organism's existing expectations form a context that modulates the effectiveness of the US. The following are the essential assumptions of the Rescorla–Wagner model:

1. Any given US can support only a given amount of conditioning. After this point further US presentations will produce no additional behavior change. This parameter, the asymptote of learning, differs for each distinct US, effectively placing a ceiling on the magnitude of changes in associative strength.
2. The rate of learning supported by different USs also differs with qualitative changes in the US.
3. When conditional stimuli (CSs) occur in compound, the total associative strength of the compound is equal to the sum of the associative strengths of each element of the compound.
4. Changes in associative strength occurring with additional experience are determined by the difference between the current strength of the compound and the asymptote of learning (first assumption above) defined by a particular US. Only a certain amount of change can occur. Thus, increments in associative strength with each successive CS–US pairing will become progressively smaller, since each additional change insures that less change is potentially possible. This final assumption most succinctly describes how the associative strength of a CS will be altered during the course of conditioning.

While this contemporary account of classical conditioning is in accord with Pavlov's assignment of an informational, or signaling, function to the CS, agreement on the means whereby that function develops has changed dramatically. Mere contiguity of CS and US should no longer be thought of as necessary or sufficient for conditioning. Instead, conditioning must be considered in a larger, correlational context: only when a CS and US are positively correlated will the CS acquire associative strength. Thus, a CS in close temporal contiguity with a US (say 2 s) may not acquire associative strength if the US is as likely or more likely to follow the absence of the CS within an equivalent (2 s) period. At the same time, a CS that is less contiguous with the US (say 5 s) may acquire associative strength if its occurrence increases the likelihood that the US will follow. This correlational view of conditioning, inspired by the research and theory of Rescorla and Wagner, has a parallel development in operant conditioning, particularly in the area of conditioned reinforcement. We will see further evidence for this contextual and correlational view of associative strength throughout this article.

Habituation

Many behaviors are modified simply as a result of repeated exposure to a stimulus. When these repeated stimulations result in a decrease in responsiveness, habituation has occurred. Habituation is an important behavioral adjustment. An interesting example of habituation occurs in relation to an organism's ability to pay attention to new or unexpected stimuli in its environment. Known as the orienting reaction, this behavior is significant in that it helps the organism detect and prepare for new and potentially dangerous events. It would be inefficient, however, if the organism made an orienting reaction to every occurrence of a previously novel stimulus. Instead, habituation tends to occur; repetition of the once-novel stimulus without any consequence results in a decline (even disappearance) of the organism's responsiveness to that stimulus. It is a form of learning in that the organism has, with repeated exposure to the stimulus, learned not to respond to it. The decline in response is temporary, however; after an interval during which the habituating stimulus does not occur (from several minutes to several days, depending on the particular situation), the response to the stimulus returns. Habituation is an adaptive phenomenon that occurs among a wide range of organisms from those as relatively simple as primitive worms to more complex organisms such as primates. Habituation can occur in organisms without central nervous systems, for example sea anemones. Sea anemones close and retract their tentacles when water strikes them from above, a protective response that prevents intense stimuli from harming the anemone. But sea anemones also employ their tentacles to gather food in the form of organisms residing in the ocean. Were anemones living in tide pools to contract each time that they were struck by a wave or each time a strong current of water passed over them, they would lose the food gathering advantage of having their tentacles ready to capture organisms that might be passing overhead. Thus, it is adaptive for the sea anemone to cease responding (habituate) to repeated presentations of water striking them from above. That they in fact do so has been demonstrated in the laboratory; after a number of repeated stimulations from a stream of water presented from above, the sea anemones stop contracting. The recovery from habituation, noted above, has also been demonstrated with these sea anemones: when water is not presented for 24 h, the next water stimulation produces a response almost as intense as that elicited initially.

In addition to reinstating the original strength of a habituated response by allowing time to pass, an alternative technique is that of dishabituation, in which a novel stimulus is presented. For example, if the habituated sea anemone is stimulated with a glass rod instead of a water stream, there is an immediate loss of habituation to the water stream: the next several presentations of the water stream stimulation produce contraction. This renewed responsiveness is short-lived, however; after a few water streams, the anemone again habituates.

Habituation occurs more rapidly on a second series of stimulus presentations than on the first such series and occurs still more rapidly on a third. This progressively more rapid habituation suggests that habituation may not only represent the simplest form of learning but also a primitive form of memory.

Habituation is a form of simple nonassociative learning: the organism learns that the repeatedly presented stimulus has no significant consequence. This is distinct from associative learning phenomena in which the association between stimuli (classical conditioning) or response and reinforcement (operant conditioning) is centrally important. Habituation can be considered as learning when not to respond. This can be vital to the organism. For example, some insectivorous birds spend 90% of each winter day eating insects (catching them at a rate of one every 2.5 s!) in order to sustain themselves. For these birds, too much time responding to unimportant stimuli may result in starvation. Research with human infants and adolescents suggests that the ability to habituate to unimportant, repetitive stimuli early in life may be a predictor of later mental ability and health.

Complex Phenomena

There are a plethora of phenomena based on associative learning that have important implications for understanding the behavior of organisms. In this section, we discuss research involving biological constraints, taste-aversion learning, and conclude with autoshaping. At this point, we will be ready to address the important theoretical question: What are the necessary and sufficient conditions for the occurrence of associative learning? We will do this by drawing on critical research in the areas of autoshaping, conditioned suppression, and on the determinants of observing and information seeking.

Biological Constraints

For decades, an implicit assumption of researchers in conditioning was that a principle of equipotentiality held, at least to an approximation. According to this principle, learning represents a general process in which the elements of the learning situation, for example, the CS, the US, and the CR (or, in operant conditioning, the stimulus, response, and reinforcer or punisher) can be arbitrarily chosen for conditioning. The specific quality of the elements was deemed unimportant. According to this view, these elements are arbitrary and completely interchangeable. They do not bear an innate fixed connection to one another. Thus, two potent aversive stimuli such as nausea-producing irradiation and electric shock should be equally effective in supporting associative strength regardless of the stimulus with which they are associated (e.g., a gustatory or auditory stimulus). We shall see in the next section (on taste-aversion learning) the inadequacy of this prediction. We will illustrate the limitations of the equipotentiality principle here with an example from the extensive literature on avoidance learning. Then we will summarize the contemporary view of the biological constraints position.

Avoidance learning

Avoidance is a type of negative reinforcement in which behavior is strengthened because it avoids an aversive event such as electric shock. In a typical avoidance acquisition procedure, a CS (say a light) is followed a few seconds later by a US (say an electric shock). After a few CS-US pairings, the previously neutral CS acquires associative strength and the onset of the CS becomes

aversive. In avoidance learning, the organism (most commonly a rat) is given the opportunity to make a response that will simultaneously turn off the CS and avoid the US. Hence this response is termed 'the avoidance response.' When the response is not made, the US occurs and the same response can terminate (escape) the US. Now according to the equipotentiality principle, the nature of the response should not matter. But it turns out that the selection of the response has a profound effect on the ability of the organism to acquire the avoidance response and therefore avoid the shocks. If the response involves jumping up to a platform, a rat will acquire the response in a handful of trials (sometimes as few as one or two). If the response involves running to another part of the apparatus, the rat's acquisition is also fairly rapid. But if the response is a simple lever press, the rat may not acquire the response for several hundred trials, enduring painful shocks along the way. Thus, with respect to the acquisition of the avoidance response, the critical relation is between the required response and the reinforcer. How might we best understand why this is so? One answer is that provided by those who stress that there are biological constraints on the acquisition process.

Consider the rat's normal response to an aversive, say painful, stimulus. Likely responses include freezing, running away, and jumping. These are known as species-specific defense reactions (SSDR). Thus running and jumping, being natural responses to electric shock, are readily associated with avoidance and are acquired swiftly. A more measured response such as a chain pull is not a natural response to shock and is therefore acquired more slowly. But by selecting a lever-press response, researchers were unwittingly selecting a response that was almost designed to fail. First of all, lever pressing is not a natural response to shock. Second, the fact that the rat can escape the shock once it begins, lever pressing keeps the rat in the vicinity of the lever (actually crouching over it) when the CS turns on. Freezing, a natural response to shock, predominates and freezing is incompatible with lever pressing. In fact, rats show good acquisition of the lever-press response when they are required to make the ostensibly more complex response of running to another part of the chamber to press the lever. Running, a natural response to shock, disrupts freezing. At the end of the run, the rat presses the lever, avoiding shock.

Interestingly, the same lever-press response that is resistant to acquisition when the reinforcer is avoidance of shock is acquired rapidly when it produces food, another example of how the nature of the response–reinforcer association is critical in determining the extent and speed of acquisition of associative strength.

Challenge and limitations of the biological constraints position

The focus on biological constraints on associative learning has leveled two classes of criticism against traditional theories of reinforcement and of associative learning. The first criticism is that laboratory research on learning is artificial. Thus, the principles of the acquisition and maintenance of behavior that results from such research lacks generality for any natural settings. Technically principles derived from such studies are said to lack external validity. The second challenge is the claim that traditional theories incorrectly assume that any emitted

response and any contingent reinforcer may be associated with equal effectiveness (technically, the principle of equipotentiality, introduced above).

The first challenge does not negate the value of laboratory research on the principles of associative strength and behavior change. The natural environment imposes temporal constraints on accessibility to vital resources. The study of schedules of reinforcement under rigorously defined laboratory conditions may help determine how natural restrictions result in changes in associative strength and in behavior change. The focus on biological constraints is important in that it correctly suggests that different patterns of responding may emerge depending upon the nature of the species being studied and on the particular selection of stimuli, responses, and reinforcers. But if we are to comprehend how the effects of response and temporal partitioning are altered by biological constraints on learning, we must also understand how they operate when constraints are absent. Because the biological factors are demonstrably potent, an arbitrary laboratory situation in which the effects of these factors are minimized becomes a definitive way to analyze the effects of temporal factors in isolation. The emerging principles must, at some point, be integrated with the constraints presumed to operate in the wild. To summarize, laboratory studies have value for both because they reveal fundamental ways by which behavior change is effected by limiting access to vital resources and because these effects can be assessed most clearly under conditions in which the intrusion of biological constraints are minimized.

The second challenge argues against the equipotentiality position. This challenge is well taken in the sense that most experimenters in the area appeared to harbor the belief that the particular selection of stimulus, response, reinforcing event, and species was relatively unimportant. However this assumption was never made explicit by any of the great learning theorists: in fact Edward Thorndike, B. F. Skinner, and others explicitly stated that the principle was invalid. Indeed, well before the issue of biological constraints on learning became popular, Skinner acknowledged that a thorough appreciation of the determinants of behavior change could not be accomplished simply from the study of representative stimuli, responses, and reinforcers. Recognition of this fact led Skinner to select stimuli, responses, and reinforcers that would likely minimize intrusion by complicating biological factors. He hoped that the resultant behavior would be orderly and that its form would also describe the behavior maintained by other stimuli, responses, reinforcing events, and species. As Barry Schwartz has argued, the central problem centers around appreciating which features of a phenomenon are attributable to general associative principles and which are attributable to situation-specific variables.

We conclude by noting that both the complexity and diversity of behavior require that both phylogenetic and ontogenetic principles are part of any complete explanation of behavior. Whereas phylogenetic factors may predominate where insect behavior is concerned, ontogenetic (learned) factors may assume a more central role in the explanation of the more generally flexible behavior of humans. The real challenge is to achieve the correct mix of phylogenetic and ontogenetic factors that best accounts for the behavior of individual members of a particular species in a given circumstance.

Taste-Aversion Learning

When discussing avoidance learning we showed that the ease or difficulty of associative learning in avoidance depends critically on the interaction between the selected response and the reinforcer. Research on taste-aversion learning instead emphasizes stimulus–reinforcer or stimulus–punisher interactions.

The bulk of the pioneering research on this topic, conducted by John Garcia and his colleagues, was concerned with an analysis of the conditions under which rats would learn to avoid ingestible foods. In one classic experiment, Garcia and Sam Revusky studied the differential suppression of drinking as a function of the type of CS and US used. Four groups of rats were served. For two groups, the CS was ‘bright-noisy (bubbly) water’: when the rats drank from the water tube gurgling sounds and flashing lights were presented. For the other two groups, the water was flavored with sweet-tasting but nonnutritive saccharin. For one group of the bright-noisy rats and one group of saccharin rats drinking was followed immediately with electric shock. Rats in the other two groups received the sensation of nausea (produced by X-ray irradiation). The results are shown in [Figure 2](#): suppression of drinking occurred only for rats that had the taste–nausea association or the visual/auditory–shock association. Shocks following the saccharin-flavored water and nausea following the bright-noisy water were ineffective in suppressing drinking. Thus, the same punisher (whether it was toxicosis or electric shock) was either extremely effective or ineffective in suppressing drinking depending on the stimulus modality with which it was associated. This general finding has been replicated dozens of times with various species. Other studies have shown that rats are capable of associating novel exteroceptive stimuli with illness. Thus, it may not be necessary to interpret the taste-aversion findings in terms of natural predispositions to associate certain stimuli with sickness. From the ecological perspective, it also makes sense that the organism has a flexible response to novelty.

Figure 2 Differential suppression of drinking as a function of the type of cue and consequence used. See text for details. Autoshaping

A hungry pigeon is placed in a standard pigeon chamber for the first time. A circular key on the wall of this box is repeatedly illuminated once every minute for a period of 6 s. When the light turns off, the pigeon is presented with food. In this procedure, food is delivered independently of the pigeon’s behavior vis-a-vis the circular key. That is, the food appears even if the pigeon never approaches the key. Nonetheless, after very few light–food pairings, the pigeon is likely to begin pecking the key as soon as it is illuminated. This procedure is called autoshaping, since the pigeon’s key pecking is acquired without the conventional shaping by differential reinforcement and successive approximations commonly used in animal training. All that appears necessary is the simple association between the light and the food.

The mechanism for autoshaping is well understood. Once the pigeon pecks the lit key, it produces immediate reinforcement of the key pecking. As for the first peck, that too is unsurprising: the lit key is a highly salient stimulus and the pecking response is a high probability one for the pigeon. Moreover, after repeated pairings with food, stimuli become likely to promote food-related behaviors such as pecking, a phenomenon that is the basis for instinctive drift, in which natural, prepotent responses appear spontaneously in a food-related behavioral sequence. For example, in 1937, the legendary American behaviorist B. F. Skinner found that a hungry rat that had been trained to pick up a marble and deposit it down a chute in order to obtain food began holding on to the marble instead. More darkly, a porpoise at Marineland in Florida died playing a game of ‘catch,’ when it swallowed a baseball that had been associated with food. In the case of autoshaping, however, the key peck is actually reinforced and is neither puzzling nor maladaptive.

But a more intriguing finding illustrates the robustness of autoshaping, the power of the association between the stimulus and food and a case where the key pecking is highly maladaptive. David Williams, Alan Silberberg, and their colleagues largely reported these findings at the University of Pennsylvania. The phenomenon has been called automaintenance, negative automaintenance, and food avoidance by different investigators. This procedure differs from basic autoshaping in that pecks at the lighted key actually prevent the next scheduled presentation of food. In other words, when the key light is pecked instead of producing immediate food (autoshaping), the light turns off but no food is presented. The only way to obtain food is by not pecking at the lit key. This proves extremely difficult for most pigeons and rats. Some pigeons acquire the pecking response to such a degree that they rarely obtain food (hence food avoidance). What is the mechanism for this highly maladaptive behavior? Automaintenance appears to depend in part on basic associative learning (fueled by light–food pairings) and instinctive drift, both processes promoting pecking to the light, as well as to conditioned reinforcement associated with the offset of the key light. As in autoshaping, pecking the key does have an effect: it turns off the key light (although unlike autoshaping, food is not presented). On trials when the organism does not peck for 6 s, the key light is turned off and food is simultaneously provided. Thus, the food is always preceded by the termination of the light. Steven Hursh and his colleagues at the University of

California, San Diego showed that light termination developed into a conditioned reinforcer after repeated pairings of light termination and food. Together these sources of strength (classical conditioning, instinctive drift, and conditioned reinforcement) appear to account for the puzzle of automaintenance.

Necessary and Sufficient Conditions for Learning

An important study by Elkan Gamzu and Barry Schwartz at the University of Pennsylvania addresses the necessary and sufficient conditions for the generation of autoshaped responses. This study also makes a central point about the necessary and sufficient conditions for the occurrence of conditioning (in this case autoshaping). In one condition of their study, pigeons were exposed to two alternating schedules of reinforcement, each associated with a different stimulus (technically, a multiple schedule). On one schedule, food was never provided. On the other alternating schedule, food occurred on the average every 33 s and occurred whether or not the pigeon had responded. In other words, these food presentations were response-independent. This schedule is technically a variable-time 33-s schedule (VT 33 s). From our discussion of autoshaping, we would expect that the pigeon might begin responding to the stimulus associated with the VT 33-s schedule even though such responding was superfluous and that no responding would occur in the presence of the EXT stimulus. This is indeed what was found. In another condition, however, the EXT component was replaced with another VT 33-s schedule. Thus, in this condition, two VT 33-s schedules alternated, identical except for the different key colors illuminated during their operation. Would autoshaped responding occur to these two stimuli? The answer was 'no,' suggesting that a differential correlation with reinforcement is necessary for the generation of autoshaped responding. Rephrasing in simple terms, when both stimuli were equally good, neither elicited autoshaping. Recall that in the basic autoshaping procedure, the stimulus follows a period of darkness in which no reinforcement is provided; thus the light onset is correlated with reinforcement and elicits autoshaped responding.

Finally, consider a condition in which the VT 33-s schedule alternated with a VT 100-s schedule (in which food is provided, on the average, once every 100 s). We can guess (correctly as it turns out) that the VT 33-s schedule generates autoshaped responding in this condition since it is differentially correlated with (a higher rate of) food presentations. The interesting question is whether or not the VT 100-s schedule generates autoshaped responding. From what we have suggested above, the VT 100-s schedule should behave more like EXT than a positive stimulus since it is *not* differentially correlated with a higher rate of food presentation. The results supported this view.

Based on these results, we may reach the tentative conclusion that in order to promote associative learning a stimulus must be differentially correlated (or be 'predictive of') reinforcement. The next two sets of studies confirm this conclusion in areas other than autoshaping.

Conditioned Suppression

Conditioned suppression is a quantitative measure of anxiety that has been used extensively in nonhuman laboratories, and,

in modified form, with humans as well. In this procedure, a hungry organism that is emitting a standard operant response such as a lever press, reinforced by food presentations on an intermittent basis, is presented at specific intervals with an originally neutral stimulus (such as a light or tone) and immediately afterward is administered electric shock independent of its behavior. The effect of pairing a neutral stimulus with shock and superimposing the two on a schedule of food reinforcement is to lower the rate of responding in the presence of the stimulus (the light or tone is a CS; the electric shock the US) when compared with the rate of responding in the absence of the stimulus (i.e., the rate when the stimulus is not present). This suppression of response is called conditioned suppression, or a conditioned emotional response. This paradigm has proven effective in the study of anxiety and conditioned suppression with many species of animals including rats, pigeons, monkeys, and humans in order to assess the conditions under which a stimulus paired with an aversive event will suppress or disrupt ongoing behavior.

An additional reason for introducing conditioned suppression is that it was utilized in another critical study evaluating the necessary and sufficient conditions for associative learning. Traditional accounts of conditioning had generally assumed that simple contiguity is the central factor in the reinforcement process. Today we are aware of the central role of the signaling or informative (or predictive) value of the CS. We have already encountered this when discussing research from the autoshaping domain. Mere temporal contiguity between the CS and US is not enough for conditioning to occur. An obvious example is the fact that simultaneous conditioning is ineffective, though in that case it might be argued that the salient US overshadows the simultaneously presented CS. As the autoshaping results suggest, contiguity is effective for conditioning only if a correlation exists between the CS and US. A correlation exists if the CS reliably predicts occurrence of the US, for example, when the occurrence of the US is contingent upon (depends on) the prior occurrence of the CS. Robert Rescorla used the conditioned suppression paradigm to demonstrate this. His rats, responding on an intermittent schedule for food, were also exposed to superimposed CS and US pairings. Unlike the usual conditioned suppression procedure, the US also occurred at times in the absence of a prior CS, and the US sometimes failed to occur following a CS. Thus, Rescorla could independently manipulate the probability of the US following a CS as well as the probability of the US in the absence of the CS. Across conditions, he could observe how the degree of conditioning was affected by manipulating the probability of the US in the absence of the CS while holding constant the probability of the US following the CS. No conditioning was found when the probability of the US was equal following the presence or absence of the CS, that is, when the US was equally likely to occur with or without the CS. The CS no longer predicted (was not correlated with) the US and no longer gained associative strength (here, no longer suppressed ongoing response for food). The conclusion: pairing without correlation is insufficient for conditioning.

Observing

Research on observing explores the question of what types of information reinforces (strengthens) behavior. The procedures

and results are presented at length when discussing conditioned reinforcement (operant conditioning). Thus, here we need only to summarize the rationale and the implications of the results for the issue of the necessary and sufficient conditions for associative learning. Observing responses are those which produce stimuli correlated with schedules of reinforcement, but that have no effect on the occurrence of reinforcement. For example, two equally probable schedules of reinforcement differing only in frequency of reinforcement – say, variable time (VT) and EXT – may alternate unpredictably. Effective observing responses would produce stimuli identifying the schedule in effect. Will organisms respond to produce these stimuli even though they have no influence on the course of reinforcement? Many studies with a wide array of species (including humans) have answered this question in the affirmative. What is the mechanism at play here since it is not an enhanced rate of primary reinforcement? Does a stimulus maintain observing responses because it is correlated with the occurrence of primary reinforcement (the conditioned-reinforcement hypothesis)? For example, according to the delay-reduction theory, a stimulus will be a conditioned reinforcer when its onset is correlated with a reduction in time to primary reinforcement. This prediction is also consistent with other major theories of conditioned reinforcement. Alternatively, does a stimulus reinforce observing responses because it predicts or informs about the availability of reinforcement (the information or uncertainty-reduction hypothesis)? The critical test for distinguishing between these views is whether or not an S-, or bad news, is reinforcing, since bad news is not a conditioned reinforcer but is highly informative. The overwhelming preponderance of evidence shows that bad news does not reinforce (maintain) an observing response. Only good news reinforces observing. Additional research has refined this position: a stimulus maintains observing (shows associative strength) only when it is differentially correlated with positive reinforcement (good news). Thus, an FI 5-min schedule will maintain observing when it alternates with EXT but will not maintain observing when it alternates with a richer schedule (say FI 1-min).

Summary

The results from all three of these areas of research (autoshaping, conditioned suppression, and observing) support the

following conclusion: a stimulus typically acquires associative strength if and only if it is differentially correlated with reinforcement. The role of *contextual variables* is central: depending on the context, the same stimulus–reinforcer relation (whether in classical or operant conditioning) may be sufficient to generate powerful conditioning (or associative strength) or none at all.

Attention

C Spence, University of Oxford, Oxford, UK

© 2012 Elsevier Inc. All rights reserved.

Glossary

Alerting A short-lasting increase in neural activation that is often hard to distinguish from attention. However, while alerting, just like attention, is typically characterized by a speeding-up of participants' behavioral responses, it often leads to more error-prone performance (thus contrasting with attention).

Attention Refers to those (neural) mechanisms giving rise to a temporary enhancement (or prioritization) of the processing of certain stimuli relative to others.

Attentional bottleneck The hypothetical point in information processing at which the selection of certain information, over other information, takes place. For many years, researchers have argued over whether the bottleneck (i.e., selection) takes place 'early' or 'late' in human information processing.

Divided attention The ability to process multiple streams of information, or to perform multiple tasks, at the same time. Typically, those conditions that make dividing one's attention easier will make it harder to focus one's attention, and vice versa.

Focused attention The ability to process a particular subset of the available incoming sensory information while simultaneously ignoring other distracting (or currently task-irrelevant) information.

Perceptual/attentional load According to the theory of perceptual load, our attentional resources are always fully engaged with the processing of any incoming sensory

information. Thus, when a person's primary task is not overly demanding, any spare attentional resources will be available for the processing of other stimuli.

Prior entry Refers to Titchener's (1907) claim that attended stimuli are perceived earlier than unattended stimuli.

Spatial cuing The name given to a popular behavioral paradigm introduced by Mike Posner in the 1970s to study spatial attention. In a typical study, a cue stimulus is presented from one or other side of central fixation, followed a short time later by a target stimulus on either the same or opposite side. Participants normally respond more rapidly and/or accurately to targets presented on the cued side. The claim is that this facilitation of performance reflects the beneficial effects of spatial attention on information processing.

Sustained attention Otherwise known as 'vigilance' – the ability to maintain one's attentional focus on a given task or source of information, often over prolonged periods of time. Vigilance tasks are often repetitive and/or boring, and perhaps for this reason are less popular than they once were.

Working memory The cognitive system thought to contain storage buffers and a central executive that actively maintains goal-relevant information in the service of complex cognition. The central executive, the least well-understood part of the working memory system, is typically conceptualized as controlling attention and the flow of information to/from the buffers.

Everyone knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought.

(William James, *The Principles of Psychology*, vol. 1, pp. 403–404)

Introduction

Research on the topic of selective attention really developed in the years after the end of the Second World War, when scientists began to attempt to understand why it was that fighter pilots sometimes missed perfectly audible signals that had been presented over their headsets. Perhaps unsurprisingly, such applied problems led to the development of the selective (or dichotic) listening task, in which psychologists attempted to simulate the kinds of multispeaker environments faced by the pilots. In a typical study, participants would be required to shadow the speech stream presented to one ear, and then they would be tested for their recall of the information presented to the other 'unattended' ear (or channel). The majority of research efforts in the intervening years have, however, tended to focus on

understanding the mechanism underlying selective attention in the visual modality. That said, the role of selective attention in the other senses as well, such as touch, is now being studied.

Everyone agrees that the human brain has only a limited capacity to process incoming sensory information, and hence selection must occur in order to prevent overload. The key question motivating much of the early research on attention was where exactly selection (or the bottleneck) occurred and just how much processing there was of the information that was not currently task relevant. Some researchers, such as Donald Broadbent, argued that the bottleneck in human information processing occurred early in the process, whereas others, such as Deutsch and Deutsch, argued that all incoming stimuli were processed to a fairly high (possibly semantic) level, just short of awareness. If one were to try and summarize this large body of research, one would have to say that different researchers using different experimental paradigms were able to provide evidence consistent with both early and late selection. Part of the problem in this area was that different researchers also used different measures of awareness (everything from verbal report through to galvanic skin responses and implicit behavioral measures). By the early 1990s, the field had stagnated. However,

two changes occurred that revitalized research in this area. First, the development of neuroimaging meant that for the very first time researchers were able to peer inside the heads of their experimental participants in order to see where exactly attentional selection was occurring in the human brain. Second, Lavie and Tsal put forward the perceptual load theory, which provided a means of explaining the apparently inconsistent pattern of selection sometimes occurring early and at other times appearing to occur much later in information processing.

The Theory of Perceptual Load

According to the theory of perceptual load, our attentional resources are always fully engaged with the processing of any incoming sensory information (i.e., we cannot store them up for use at a later point in time). Thus, under those conditions in which a person's primary task is not overly demanding, any spare attentional resources they have will be available for the processing of other stimuli (e.g., the irrelevant stream of speech presented in the 'unattended' ear in a dichotic listening study). Lavie has argued that under such 'low-load' conditions, late selection can be observed. However, under those conditions in which the load of a participant's primary task is increased (such as when the complexity, or rate of presentation, of the to-be-shadowed message increases, or when the number of stimuli presented simultaneously in a visual display goes up), a participant will need to devote more resources to processing it. Hence, there will be fewer resources left for the processing of any other incoming information. Lavie argues that under such 'high-load' conditions, attentional selection will, on the contrary, likely occur relatively early in information processing.

Perceptual load theory has provided a popular explanation for why attentional selection sometimes occurs early in information processing, whereas at other times (and/or in other studies) it occurs much later. As such, this intuitive theory appears to offer a means of resolving the long-standing (and, for many years, seemingly intractable) debate amongst researchers over early and late attentional selection. In the years since Lavie and Tsal first proposed their theory, a large and ever-growing number of studies have been published in support of the theory's main tenets. Empirical support has come from a number of sources, including both behavioral and neuroimaging research. What is more, relatively few results have been reported that cannot be accounted for by the theory. That said, one limitation of the theory is that no objective measure of 'load' has yet been provided.

Thus far, the majority of studies of perceptual load have tended to restrict themselves to investigating those conditions in which participants are presented with (and hence have to select between) the information presented in just one sensory modality. Most researchers have focused on conditions of unimodal visual selection, though studies demonstrating the applicability of the theory to those conditions requiring unimodal auditory selection have now started to appear in the literature. As yet, there has been relatively little research investigating the validity of perceptual load theory in accounting for participants' behavior under conditions requiring unimodal tactile selection. However, that said, there is no obvious reason to believe that selective attention should operate any differently within the

tactile modality than it does within either of the other spatial modalities (i.e., vision or audition).

Having demonstrated attentional selection under a variety of different unimodal conditions, the next question to be addressed by researchers was whether the attentional resources that lie at the heart of perceptual load theory are unitary, or whether there are instead separate resources for the processing of stimuli in each sensory modality (as originally suggested by Christopher Wickens' 'multiple resource theory,' back in the early 1980s). While the results of the early crossmodal perceptual load studies came to the conclusion that resources were indeed modality-specific, the story has, in recent years, become much less clear. While some researchers have demonstrated that varying the perceptual load in one sensory modality (e.g., vision) affects the level of processing of stimuli presented simultaneously in another sensory modality (e.g., audition), other researchers have failed to observe any such crossmodal effect.

Working Memory and Selective Attention

What has emerged very clearly though in recent years is the close link that exists between selective attention and working memory (WM). It appears that whenever a participant's WM is compromised, his or her ability to selectively attend to one source (or stream) of sensory information and to ignore another (task-irrelevant) source (or stream) of information will be impaired. In laboratory studies, WM is typically loaded by giving a participant a list of stimuli to remember (such as a random list of digits) while he or she simultaneously performs a selective attention task. Many studies have now demonstrated that loading WM effectively impairs a participant's ability to selectively attend to a particular source of information. Intriguingly, it would appear that individual differences in WM capacity can also help to explain the existence of striking differences in people's selective attention abilities. So, for example, it has been known for more than 50 years now that only around one-third of participants will report hearing their own name if it happens to be presented in the 'unattended' ear in a dichotic listening experiment. Counterintuitively, it turns out that those individuals who have a lower WM capacity are significantly more likely to hear their name. One suggestion here is that these individuals are simply more likely to forget which ear it is that they are supposed to be shadowing, and hence will be more likely to inappropriately shift their attention to the other ear (the one containing their name).

Neuroimaging studies have now started to highlight the neural underpinnings of this interaction between selective attention and WM. For example, in one recent study, loading participants' WM (by giving them a digit string to remember) resulted in the suppression of neural activity in the right temporoparietal junction, a brain region that constitutes a core structure in the ventrofrontoparietal attention network.

Inattentional Blindness, Change Blindness, and Change Detection

One intriguing visual analog of auditory shadowing experiments has come from a spate of studies over the last decade

or so that have revealed the existence of severe limitations in our awareness of multiple simultaneously presented visual stimuli. In what is perhaps the most famous example (of what has come to be known as *inattention blindness*), researchers found that participants would often fail to notice a person dressed up in a gorilla suit thumping his chest in the middle of a monitor, if their attention happened to be focused on a group of people dressed in white passing a basketball. It turns out that the more demanding the participant's task – such as, for example, having to keep separate running totals of the number of times that the white team throw the ball and the number of occasions on which they bounce the ball – the more likely it is that participants will miss the gorilla, consistent with the predictions of perceptual load theory. Surprisingly, the results of many such studies now demonstrate that we frequently miss (i.e., fail to notice) even highly salient visual stimuli, if our attention happens to be directed elsewhere (i.e., to another object or stimulus). Such findings show that our subjectively strong belief that we see everything before our eyes is nothing more than an illusion.

A related phenomenon, known as *change blindness*, occurs when a scene and the same scene with a major (i.e., otherwise clearly noticeable) change in it are presented for brief periods of time separated by a blank interval. It turns out that until attention alights on the changed element it will not be reportable. The argument here is that the blank display inserted between the two scenes acts as a global visual transient that obscures the localized spatial transients in the scene that would normally capture our visual attention (as when an item suddenly appears, disappears, or moves). Even when these transients are visible (i.e., when one scene directly transitions to the other), people may not perceive the scene change if mudsplashes (i.e., localized changes in a visual display, such as a bunch of gray circles projected at random points on the screen) happen to be presented at the same time.

Following the original research conducted in the visual modality, it was demonstrated by subsequent studies that a similar phenomenon, known as 'change deafness,' also affects auditory perception. For example, in one study, participants were presented with an auditory scene containing between four and eight auditory stimuli (including sounds such as those of a trumpet, a piano, a female voice, and a clucking hen) for 5 s. Each sound occupied a different position in the virtual auditory display presented over headphones. Next, white noise was presented for 500 ms, followed by a second auditory display for a further 5 s. The two auditory displays were identical except that, on half of the trials, one of the auditory stimuli was removed from the second display (sometimes it was replaced by another item). On each trial, the participants simply had to decide whether one of the auditory stimuli had been removed (or replaced) in the second display. Performance dropped from near perfect when the first display contained four auditory objects, down to chance-level performance when it contained eight. By contrast, in the control condition, in which participants were informed which of the stimuli might change, performance was virtually perfect regardless of the set size, thus demonstrating the attentional nature of the effect (and ruling out an account of the poor performance observed in terms of masking).

Studies of change numbness have revealed even more severe limitations in the perception of tactile stimuli presented

over the body surface or fingertips. So, for example, in a typical study of the tactile analog of change blindness, participants are presented with patterns consisting of vibrotactile stimuli being delivered to two or three locations across the body surface. The mask typically consists of the brief stimulation of a number (e.g., seven) of widely distributed vibrators. A second pattern of two or three vibrotactile stimuli is then presented, and participants have to decide whether there had been a change (which occurs on half of the trials), either in the total number of stimuli presented or in the location of the stimuli on the body surface. The results of several such studies have shown surprisingly poor change detection performance when the two vibrotactile patterns are separated by a mask. By contrast, the performance deficit was far less severe when the interval between the two patterns was empty (i.e., when no mask was presented). Interestingly, researchers have even shown that the presentation of visual mudsplashes can crossmodally give rise to tactile change blindness as well.

Taken together, studies of inattention blindness, change blindness, change deafness, and change numbness support the conclusion that people may actually be unaware of much of the sensory information present in complex multisensory scenes. It would seem that we are only aware of the stimuli that we happen to be attending to voluntarily, or which capture our attention automatically. The results of the many studies published in this area therefore highlight the critical role that attention plays in awareness.

Spatial Attention

Researchers studying attention distinguish between two types of selection – exogenous and endogenous: *Exogenous* (or involuntary) attentional orienting occurs whenever attention is reflexively shifted to the location of a sudden and unexpected peripheral event, such as when a person calls your name at a cocktail party, or when a fly suddenly, and unexpectedly, lands on your arm. By contrast, *endogenous* attention is typically involved in the voluntary orienting of a person's attention to a particular event or spatial location, such as when you choose to attend to a particular person at the noisy party, or when you decide to concentrate on the feel of the MP3 player that you are holding in your hand. Orthogonal to this distinction between endogenous and exogenous (or voluntary and automatic) spatial attention, is the distinction between overt and covert attentional orienting: *Overt* orienting refers to any shift of the sensory receptors (as in eye, head, or hand movements) that helps to bring a stimulus onto the most sensitive parts of the receptor sheet (think, the fovea or the fingertips). *Covert* orienting, which is of most interest to cognitive psychologists studying the topic of selective attention, refers to an internal shift of attention, as when what we attend to visually changes in the absence of any overt movement of the eyes. Many researchers believe that there is a close link between these two forms of spatial orienting, as, for example, captured by the premotor theory of attention. According to the premotor theory, the same frontal-parietal brain circuits control both action – that is, motor behavior toward specific spatial locations – and attention, when those circuits happen to be activated less strongly. Although the premotor theory of attention has

perhaps not received the credit it is due, it is certainly true that the superior colliculus, a subcortical structure implicated in the control of overt eye and head movements, plays an important role in the covert shifting of spatial attention.

Exogenous Spatial Attention

While it is certainly true that attention can be directed, either exogenously or endogenously, to a sensory modality, or to any one of a range of other stimulus features (such as color), by far the most popular topic in attention research in recent decades has been the spatial distribution (or orienting) of attention. The majority of studies in this area have adopted the spatial cuing paradigm first popularized by Mike Posner back in the 1970s. In a typical exogenous cuing study, a cue stimulus is presented in one modality shortly before a target stimulus, presented on either the same or opposite side (and in either the same or different sensory modality). Participants normally have to make either a speeded detection or discrimination response to the target (on occasion, they may be asked to try and detect a near-threshold masked target). The key feature of such studies is that the cue is nonpredictive with regards to the likely location of the subsequently presented target. Often, participants are explicitly instructed to try and ignore the cue as much as possible. However, the results of many such studies conducted over the last 30 years or so have demonstrated that often people simply cannot ignore such cues. Instead, they respond more rapidly, and sometimes more accurately, to targets presented at the cued location as compared to the uncued one. These short-lasting exogenous spatial cuing effects typically last for only a few 100 ms after the presentation of the cue. Often, especially in detection tasks, facilitation is replaced by a longer lasting inhibitory effect, known as 'inhibition of return' (IOR). The idea here is that an inhibitory tag is attached to any location where attention has been directed (either overtly or covertly), but where no target has been found. Such inhibitory tagging is thought to help prevent us from perseverating on uninformative, or irrelevant, locations (e.g., as in visual search tasks; see below).

The presentation of spatially nonpredictive auditory, visual, and tactile cues has been shown to elicit exogenous spatial cuing effects that affect the subsequent processing of auditory, visual, and tactile targets presented from more or less the same location. Researchers using signal detection analysis have demonstrated a genuine enhancement of perceptual sensitivity for stimuli presented at the cued (or attended) location. What is more, the same stimuli reach consciousness sooner when attended than when attention happens to be directed elsewhere, a phenomenon known as 'prior entry.'

Whether peripheral cues always capture our attention automatically, or whether we have to be 'set' appropriately in order for them to elicit a shift of attention has been a topic of heated debate in the attention literature in recent years. The evidence generated by this debate has led many researchers to suggest that even the putative involuntary spatial orienting of our attention may, in fact, be subject to at least some degree of top-down (or strategic) control – that is, it depends on our having the right 'attentional set.' In fact, the interplay between the bottom-up and top-down control of our attention is one that has pervaded the literature on attention over the last three decades or so.

Endogenous Spatial Attention

Turning now to the deployment of endogenous spatial attention, it has been demonstrated that if people deliberately direct their attention to a particular spatial location, performance will normally be enhanced for targets subsequently presented at that location, as compared to targets presented elsewhere. Just as for the case of exogenous orienting, endogenous (or voluntary) attention facilitates the processing of auditory, visual, and tactile stimuli presented at the attended location. Several different methods have been used to direct a participant's spatial attention endogenously to one side or the other. In early studies, peripheral spatial cues were often made informative with regard to the likely location of the target, as when the target appears on the cued side on 75% of the trials, and on the uncued side on the remaining 25% of trials. However, under such conditions, both exogenous and endogenous spatial attention are likely directed to the cued side. In many subsequent studies, therefore, a central cue (such as an arrow pointing to the left or right) has been used to direct attention to one or other side on a trial-by-trial basis instead. That said, it has been argued that even central arrow cues may direct attention exogenously (in a manner similar to centrally presented faces where gaze is deviated to one or the other side). Hence, currently, one of the best means of directing a participant's attention in a purely endogenous manner is by means of blocked cuing, where, for example, the majority of targets appear on the left, say, and only a small number of unexpected targets appear on the other side. The latter approach ensures that any performance facilitation that happens to be observed can unequivocally be attributed to the consequences of endogenous attentional orienting.

Endogenous Versus Exogenous Spatial Orienting: One Mechanism or Two?

There has been a great deal of debate over the years as to whether exogenous and endogenous orienting simply reflect different means of engaging the same attentional resources, or whether instead they have fundamentally different properties/consequences for human perception/performance. Recently, Prinzmetal and his colleagues have reported on a very large number of studies demonstrating that while endogenous spatial attentional orienting typically enhances perceptual sensitivity, exogenous orienting primarily influences which spatial location information is sampled from first. As a consequence, exogenous orienting primarily affects the speed (but not necessarily the sensitivity) or a participant's performance.

Spatial attention has been conceptualized as taking a variety of forms: Early on, researchers typically envisioned spatial attention as a spotlight (the assumption being that it had a fixed size). Subsequently, the analogy of a zoom lens was proposed as an alternative – the idea being that the size of the attentional spotlight was variable, and that there was a trade-off between the size of the spotlight and the 'density' of attentional resources directed toward a particular region of space. When researchers discovered that attention could be directed to objects, as well as spatial locations, a debate started concerning the relation (or interplay) between space- and

object-based attention. While the majority of this research has, once again, focused on the visual modality, researchers have, more recently, highlighted the existence of object-based attention in the auditory modality as well.

Crossmodal Spatial Attention

The question of how attention might be configured crossmodally has been a topic of intense scrutiny over the last decade or so. It now appears that there are extensive crossmodal links in spatial attention, such that visually attending to a particular location will lead to a shift of auditory and tactile attention to the same spatial location (or at the very least in the same direction). Similarly, the exogenous capture of spatial attention by a sudden auditory, visual, or tactile event leads to a shift of attention that will facilitate participants' ability to respond to any target subsequently presented at the cued location (regardless of the modality in which the target happens to be presented). What is more, these crossmodal links in spatial attention update following posture change, such as when the eyes move with respect to the head, or when the arms are moved (often crossed) with respect to the body. This means that attention is always directed in such a way that the processing of all sensory stimuli originating from a given environmental location will be facilitated, regardless of how our various sensors (e.g., the eyes, ears, and skin) happen to be configured spatially.

The Attentive Brain

Neuropsychological studies of patients suffering from spatial neglect/extinction following brain damage have been particularly informative in terms of furthering our understanding the neural substrates of attention. Neglect and extinction typically occur following right hemisphere damage to the parietal cortex. Neglect patients tend to be unaware of stimuli presented in the contralesional field (i.e., the left side of space following right parietal damage). Extinction patients can perceive contralesional stimuli when presented in isolation, but the simultaneous occurrence of an ipsilesional stimulus will typically extinguish the contralesional stimulus from the patient's awareness. Research on such patients has, for example, further helped to highlight the importance of the distinction between space- and object-based attention.

The last few years have seen an explosion of cognitive neuroscience research investigating the neural mechanisms underlying attentional selection. Researchers have used a variety of brain imaging techniques, from PET and fMRI through to electrophysiology and single-cell neurophysiological recordings, in order to better understand how, and where, attention is operationalized in the brain. While a detailed discussion of this literature is beyond the scope of this article, it is worth noting that the spatial distribution of attention in neurologically normal individuals appears to be controlled by a large-scale frontoparietal neural network. Perhaps unsurprisingly, the exogenous and endogenous orienting of attention appears to rely on somewhat different neural circuitry. Consistent with the behavioral data, the neuroimaging and transcranial

magnetic stimulation (TMS: a means of temporarily lesioning a normal participant's brain) data support the view that exogenous spatial attention (and IOR) may be controlled by a supramodal orienting system, while endogenous spatial attention is controlled by a system that approximates to the separable-but-linked account originally proposed by Spence and Driver in 1996.

Feature Integration Theory

Around 1980, Anne Treisman published what has subsequently turned out to be a very influential model of selective attention, known as feature integration theory (FIT). The model helps to account for why visual search through cluttered displays is sometimes difficult (as when we search for our misplaced car keys in our untidy office), while at other times it appears easy (as when a single hand is raised in a crowded auditorium). According to Treisman, attention is required to bind the different features of an object (such as its color, shape, orientation, and motion) into a coherent whole. By contrast, unique features (such as a pink circle in a sea of green circles) '*pop-out*,' thus automatically capturing our attention. Across a series of now classic experiments, Treisman demonstrated that the search for a visual target defined by a unique feature was equally fast regardless of the number of stimuli that happened to be presented in the display. By contrast, search for a conjunction of features (such as for a red square presented in amongst green squares and red and green circles) tended to be slow and effortful (or attention-demanding). Hence, search latencies would increase linearly as a function of the set size. One prediction of FIT is that when attention is overloaded, either because attention has been spread over too wide an area, or because the stimuli are presented for too brief a time (and are, anyway, quite possibly masked), then illusory conjunctions may occur (whereby, e.g., the color of one object may be bound together with the shape of another). Whether such errors reflect perceptual mis-combinations rather than just errors in memory recall remains a contentious issue. Researchers have demonstrated that brain-damage, or repetitive TMS (rTMS) applied to right parietal sites, can impair a person's ability to conjoin features correctly.

Over the intervening years, FIT has generated a huge amount of interest from the psychological research community. Perhaps unsurprisingly, then, a number of findings that are apparently inconsistent with the theory, at least as originally stated, have now been published. In particular, the evidence that is currently available shows that attention is sometimes required to detect (or at the very least, to respond to) targets defined by a unique feature. What is more, many targets that are defined by a conjunction of features appear to pop-out, when, according to Treisman, they should not. However, that said, the general approach still lives through various other models – that can be seen as an extension of Treisman's FIT – such as, for example, Wolfe's '*guided search*' model. It is, though, important to bear in mind that the attentional spotlight thought to be directed to the location of an unexpected peripheral stimulus in the Posnerian cuing task appears to have somewhat different properties than the feature-integrating spotlight made famous by Treisman's FIT. While FIT

was originally formulated to account solely for participants' *visual* search performance, the last few years have seen researchers extending the approach to account for the binding of auditory, tactile, and even multisensory object features.

Temporal Attention

While the majority of studies related to attention have tended to focus on the *spatial* aspects of selection, a growing body of research has, in recent years, started to look at the *temporal* limits on information processing instead, as when participants are offered rapidly presented sequences of visual, auditory, or tactile stimuli. So, for example, using such an approach, researchers have highlighted the existence of a temporal attentional deficit known as the 'attentional blink' (AB). This robust performance impairment is typically observed under those conditions in which two targets, each requiring a behavioral response (often unspeeded), are presented in close succession within a rapidly presented sequence of distractor stimuli. The rate of stimulus presentation in such studies is often very high (~8–10 items per second). If the second target is presented a couple of stream positions after the first target, a participant's ability to identify it will often be severely impaired. (Curiously, if the second target is presented directly after the first target then discrimination performance is often preserved – a phenomenon known as Lag-1 sparing.) As the interval between the first and second target increases, performance typically recovers back to baseline level. It is almost as if there is an attentional gate that is closed after the arrival of the first target in order to prevent it from being overwritten by subsequent items in the stream. Interestingly, certain patients suffering from clinical extinction have been shown to exhibit a significantly larger AB than neurologically normal individuals.

Although originally discovered in the visual modality, the AB has now been demonstrated to occur in the auditory and tactile modalities as well. There is even evidence to suggest the existence of a crossmodal visual–tactile AB. That said, the evidence concerning the existence of an audiovisual AB is, despite the continued efforts of researchers, much more mixed. Researchers have also identified a number of other temporal limitations to our ability to process rapidly presented stimuli. For example, Hal Pashler has conducted very many experiments documenting what appears to be a response selection bottleneck that limits our ability to make speeded responses to different stimuli when two targets are presented in rapid succession. Many neuroscientists have spent the last decade looking for the neural correlates of this psychological refractory period (PRP) bottleneck in the human brain.

Over the last decade or so, researchers have also started to study the temporal orienting of attention to a specific 'point in time.' Many of the studies in this area have simply adapted the spatial cuing paradigm (originally developed to study spatial orienting) in order to study the consequences of temporal expectations on the efficiency of human information processing. So, for example, temporal expectations may be generated in the mind of an observer by making it highly likely that the target will appear a short time after a cue stimulus has been presented (and much less likely that it appears at a later point in time). Target performance in such trials (or blocks) is then compared

to that seen when the probabilities are reversed (such that the target is now much more likely to appear in the later interval than in the earlier one). The results of many such studies now show that stimuli presented at an expected point in time are processed preferentially as compared to when the same stimuli are presented unexpectedly at another point in time.

Attention: The Future

As will have become clear from this brief review, the last few years have seen tremendous advances in our understanding of attention at both the behavioral and neural levels. The field has certainly moved a long way forward since the late Stuart Sutherland uttered the following put-down in a commentary in the science magazine *Nature* in 1998: "after many thousands of experiments, we know only marginally more about attention than about the interior of a black hole." The old box-and-arrow diagrams, once popular in cognitive psychology textbooks (approximately the 1960s), are now increasingly being replaced by neurophysiologically plausible models of the manner in which, and the location where, attention operates in the human (and animal) brain. These models are also increasingly able to explain the deficits in attention (such as neglect and extinction) sometimes observed in patients following brain-damage. One of the other trends in attention research that has been noticeable in recent years is the increasing shift from the traditional approach of considering selection among sensory inputs from just a single modality (most often vision) to a rapid growth of interest in the nature of the *crossmodal* constraints on human information processing.

In the years to come, it is hoped that our growing understanding of attention, fine-tuned by sophisticated behavioral experiments paired with the latest cognitive neuroscience research, will allow researchers to better understand the real-world limitations on human information processing: everything from the problems associated with trying to divide one's attention between eye and ear talking on the mobile phone while driving, through to the difficulties associated with trying to detect infrequent targets (be it a weapon in the luggage at the baggage-scanning machine or the precancerous growths on a radiological image) while engaged in a repetitive visual search task.

Glossary

Dopamine and norepinephrine Catecholamine neurotransmitters that regulate brain activity.

Executive functions Executive functions represent an umbrella construct that includes a collection of interrelated functions responsible for problem-solving behavior. Executive functions include the ability to formulate goals, to focus and sustain attention, to inhibit impulsive responses, to generate effective and efficient problem solving, organizational, and learning strategies, and to

monitor and correct one's performance when necessary (e.g., self-regulation).

Off label use Legal use of an available medication in a manner or for a condition not approved by the Food and Drug Administration.

Prefrontal cortex The most highly developed part of the human brain, which is responsible for executive functions and higher levels of thinking.

Psychiatric comorbidity The presence of one or more psychiatric disorders in addition to ADHD.

Historical Overview

One of the earliest descriptions of a clinical phenotype that we now associate with attention deficit/hyperactivity disorder (ADHD) can be found as early as 1902 in the works of Sir George Frederick Still, a British pediatrician. In a series of lectures, he presented a number of cases with 'a quite abnormal incapacity for sustained attention,' deficits in 'volitional inhibition,' and a 'defect in the moral control over their own behavior.' Over the decades, this clinical constellation has been labeled 'minimal brain dysfunction,' 'hyperkinetic impulse disorder,' attention deficit disorder (ADD) with or without hyperactivity, and finally, in 1987, attention deficit/hyperactivity disorder (ADHD).

Introduction

The operational definition of ADHD is straightforward: the presence of significant and developmentally inappropriate symptoms of inattention, impulsivity and/or hyperactivity in more than one setting, for more than 6 months and with an onset before age 7. These symptoms must be worse than expected for the patient's age. Children with these symptoms are at increased risk of academic underachievement and a variety of interpersonal difficulties, most notably disruptive behaviors. In addition to their core symptoms of inattention and hyperactivity/impulsivity, individuals with ADHD tend to (a) have problem-solving and social skill deficits, which can lead to social marginalization, (b) have more accidents and visits to local emergency rooms, (c) be more likely to smoke and use alcohol and illicit drugs, (d) be less likely to finish high school and college, (e) have children earlier, have more partners, and spend less time in relationships, (f) have a harder time maintaining a job, and (g) have a higher rate of motor vehicle accidents. Although not all those with ADHD show all of these features, a defining feature of ADHD is that it causes serious problems in the patient's life. In fact, the presence of serious problems is essential to make an ADHD diagnosis.

Epidemiology

The prevalence of ADHD in children and adolescents is around 5–10% with most results being between 4.2% and 6.3%, although a recent epidemiological study suggests that the prevalence may be as high as 9.5%. Boys are diagnosed more frequently with ADHD than girls although this gender difference is less extreme in community samples. The most significant risk factor for ADHD in a child is presence of parental ADHD (up to eightfold) followed by low birth weight, and in utero exposure to neurotoxic substances such as alcohol, pesticides, and tobacco.

Etiology

ADHD is a complex trait that likely involves an interplay of numerous genetic and environmental effects. ADHD is one of the most heritable psychiatric conditions, as heritable as schizophrenia or bipolar disorder. Certain environments (gestational nicotine exposure, consumption of food additives, etc.) appear to contribute to ADHD risk in the presence of some but not other gene variants. In addition to genetics and environmental risks, the neurotransmitters, dopamine, and norepinephrine have received attention as being relevant to understanding ADHD possibly because medications which alter the transmission of these chemicals in the brain are effective for treating ADHD.

Neurologically, the prefrontal cortex appears relevant to understanding ADHD. The functioning of prefrontal cortex requires dopamine and norepinephrine and plays a role in cognitive functions such as executive functions. Executive functions are an umbrella term which refers to goal-oriented problem-solving. Included in the definition of executive functions are abilities such as self-regulation of attention, behavior, and emotion. Low levels of dopamine in the prefrontal cortex can cause the prefrontal cortex to have difficulties maintaining effective problem-solving behaviors.

The prefrontal cortex has many reciprocal connections with other brain regions including the striatum (caudate nucleus,

putamen), cerebellum, and parietal cortex. Research has indicated that some of these brain regions are slightly smaller or have decreased activation in ADHD.

Assessment Issues

The symptoms of ADHD are currently defined by the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR). To be diagnosed with ADHD, an individual must have persistent and impairing symptoms of inattention, impulsivity, and/or hyperactivity. ADHD is diagnosed when six or more of the nine symptoms of inattention or hyperactivity-impulsivity occur for at least 6 months, occur in two or more settings, and impair the individuals' functioning (see [Table 1](#) for DSM-IV-TR symptoms).

The DSM-IV-TR is currently being revised to update the diagnosis based on recent research findings. For example, the DSM-IV-TR requires that some impairing ADHD symptoms be present before age 7. The age of onset criterion (before age 7) is highly controversial and is likely to be dropped from the next iteration of the DSM. In its place is likely an age of onset before early adolescence (~ age 12). The decision to change the age of onset criterion is based primarily on a lack of evidence differentiating children with onset before and after age 7. This and other changes are anticipated for the fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5).

Diagnosing ADHD in adolescents and adults is often more challenging than diagnosing ADHD in children. For

example, children are often more carefully supervised by parents and teachers (usually only one) who are able to observe much of the child's functioning. However, in adolescence, many more teachers are involved and outside of school, adolescents have less contact with parents. For instance, parents may be able to provide information regarding homework completion and school grades but may not have as much information on peer interactions and social relationships. In adults, most are not involved in school and thus, obtaining information from others who know the adult (e.g., spouse, parent, employer) is important yet can be difficult to obtain. This may be even more important as significant discrepancies may be present between self report of symptoms and the reports from others. Many times, the self-report will underestimate the level of symptoms and the amount of impairment.

Three subtypes of ADHD now exist in the DSM-IV-TR: Predominantly inattentive subtype (only has threshold levels of impairing inattentive symptoms; occurs in 30–40% of all ADHD), predominantly hyperactive/impulsive subtype (only has threshold levels of impairing hyperactive/impulsive symptoms; occurs in <5% of all ADHD, nearly always in preschool children), and the combined subtype (has threshold levels of impairing inattentive and hyperactive/impulsive symptoms; occurs in 50–60% of all ADHD).

For some patients, these ADHD impairing symptoms may occur in most situations, including high-interest activities. However, for most, these attention and inhibition difficulties are manifested primarily in settings requiring self-restraint, persistence, and a high level of concentration to relatively uninteresting activities. In children with ADHD, these difficulties negatively affect classroom or social functioning and may result in limited learning, disruption of class activities, poor work completion, impaired peer interactions, and increased conflict with teachers/parents.

It is also possible that an adolescent or adult may be present for an ADHD evaluation having never been formally diagnosed with ADHD. The age of referral and recognition of the problem is older for those with the inattentive type, compared with the combined type. Intelligence, family support, and academic placement can be protective and in some cases appear to delay the onset of evident symptoms or impairment to much later than specified in the DSM. For example, sometimes highly intelligent individuals show no academic impairments relative to peers until they complete high school, college, or even later.

Careful attention to potential comorbidities is critical in ADHD, particularly learning disabilities as well as mood, anxiety, and substance use disorders. While psychological testing can be helpful in determining strengths/weaknesses and assessing for the presence of learning disabilities, psychological testing is not necessary to either rule in or rule out the presence of ADHD. Rather, an ADHD diagnosis is based on the careful integration of clinical information from as wide a variety of sources that are available. Rating scales and other clinical instruments have been devised to assist with this. An ADHD diagnosis is not based on brain scans or any other biological test. Despite this lack of biologically sensitive and specific tests, ADHD is a well-validated and highly reliable clinical diagnosis.

Table 1 DSM-IV-TR criterion A symptoms

Inattention

1. Often does not pay close attention to details or makes careless mistakes in schoolwork, work, or other activities
2. Often has trouble keeping attention on tasks or play activities
3. Often does not seem to listen when spoken to directly
4. Often does not follow instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
5. Often has trouble organizing activities
6. Often avoids, dislikes, or does not want to perform tasks that take a lot of mental effort for a long period of time (such as schoolwork or homework)
7. Often loses items needed for tasks and activities (e.g., toys, school assignments, pencils, books, or tools)
8. Is often easily distracted
9. Is often forgetful in daily activities

Hyperactivity/impulsivity

1. Often fidgets with hands or feet or squirms in seat
2. Often gets up from seat when remaining in seat is expected
3. Often runs about or climbs when and where it is not appropriate (adolescents or adults may feel very restless)
4. Often has trouble playing or enjoying leisure activities quietly
5. Is often 'on the go' or often acts as if 'driven by a motor'
6. Often talks excessively
7. Often blurts out answers before questions have been finished
8. Often has trouble waiting for one's turn
9. Often interrupts or intrudes on others (e.g., butts into conversations or games)

Developmental Course

Most often, ADHD symptoms and associated problems occur as early as age 3 or 4 and the first manifestations tend to reflect problems of hyperactivity and impulsivity (disinhibition). Issues pertaining to inattention tend to be more easily noticed later around age 5–7 when the child starts attending school.

In children with ADHD, difficulties exerting physical self-control are central. Children with ADHD fidget, leave their seat when seating is expected, have a hard time waiting for their turn, are often on the go, and run, climb, or touch objects inappropriately. Children with ADHD also have difficulties exerting verbal self-control. Children with ADHD talk excessively, even when restraint is expected, blurt out answers even before the question was completed, and tend to interrupt others or intrude in other's conversations. In adolescents and adults with ADHD, these physical and verbal self-control difficulties appear more as restlessness.

During school years, the problems of inattention and school productivity tend to be almost universal. As the child is progressing into adolescence, often the symptoms of hyperactivity are less obvious but impairment related to impulsive behaviors tends to stay significant. Academic problems that might have been less noticeable or were treated effectively during elementary school may become much more of a problem. This is possibly a function of the increased demands for functional independence that are inherent in the middle- and high-school curriculum. In middle and high school, adolescents are expected to become more independent of adult supervision. Adolescents also change classes and are exposed to multiple teachers, teaching styles, and homework demands. Procrastination, forgetfulness, and poor persistence often become the most academically impairing symptoms.

In adolescents, peer relationships rise in importance. Adolescents with ADHD often struggle in peer relationships, typically as a function of their impulsivity. Emotional impulsiveness manifested as low frustration tolerance, quickness to anger, being impatient, and being easily excitable or annoyed is most predictive of social relationship problems for adolescents and adults with ADHD.

In children, adolescents, and adults with ADHD, the core ADHD symptoms can lead to a wide variety of other associated features. Individuals with ADHD tend to have a hard time regulating arousal levels to meet contextual demands, tend to seek more immediate reinforcements, tend to discount more steeply the value of future rewards, and have a poor sense of time. In addition to the core symptoms, these associated features contribute to functional impairments. In fact, the overall relationship between symptoms and impairment in ADHD seems to be such that as an individual ages, the core symptoms of ADHD, especially hyperactive and impulsive symptoms, decline while functional impairment persists or worsens through adolescence and into adulthood. Due to the decline of ADHD symptoms throughout adolescence, by adulthood, many grown-up ADHD children will no longer show a high level of ADHD symptoms. However, despite this decline of symptoms, about two-thirds of children with ADHD continue to have some impairing symptoms of ADHD as they enter adult life. These impairing symptoms can cause serious problems if not treated.

Treatment Issues

The treatment of ADHD typically includes the following types of interventions: (a) medication(s), (b) behavioral interventions (also known as psychosocial treatments), and (c) a combination of medication and behavioral interventions.

Stimulant Medications

In 1937, Dr. Charles Bradley from East Providence, RI, reported in the *American Journal of Psychiatry* his findings about behavioral changes in children when using an amphetamine drug called benzedrine. From his description of these children, it is likely that most would have been diagnosed as ADHD using modern criteria. His initial thought was that Benzedrine would alleviate the headaches these youth experienced after an experimental procedure. The headaches persisted, but the children's teachers reported "a spectacular improvement in school performance in half of the children." Dr. Bradley also found that "a large proportion of the patients became emotionally subdued without, however, losing interest in their surroundings." These results represent historically one of the first examples of using pharmacology to address behavioral disorders.

Over the last 70 years, the use of amphetamine and other stimulant medications for treating ADHD has grown considerably. Stimulants are now used for treating symptoms of ADHD across the life span from preschoolers to school-age children to adolescents and later adults. The two stimulant medications most often used in the treatment of ADHD are methylphenidate and amphetamine.

Methylphenidate, which has been used since the early 1960s, blocks reuptake of the neurotransmitters norepinephrine and dopamine by blocking the activity of their respective transporters in the brain. As a result, the synaptic availability of norepinephrine and dopamine is increased. Methylphenidate is available in multiple formulations including immediate and extended release. Methylphenidate has a short elimination half-life (1.5–5 h) and this creates significant problems in practical treatment. Therefore, extended release formulations are more often prescribed because one daily dose is often sufficient for treating symptoms throughout the day. Amphetamine was discovered at the end of the nineteenth century and is also used in the treatment of ADHD. Amphetamine is also available as immediate or extended release formulations.

Over 70% of individuals respond to initial trials of either methylphenidate or amphetamine; of those who fail the initial trial, an additional 70% generally responds to the other class. Both medications usually require adjustments in doses (including when doses are taken) in order to maximize effectiveness.

Both amphetamine and methylphenidate are associated with small but generally insignificant changes in pulse and blood pressure. The more common side effects of stimulants include delayed sleep, reduced appetite, headaches, and mild abdominal pain growth delay. There is a good deal of individual variability in these side effects. While significant adverse events may occur, when prescribed correctly, stimulants are generally well tolerated.

Both amphetamine and methylphenidate also have potential for misuse, abuse, and dependence. Misuse refers to situations in which the medication is used for reasons other than treating ADHD. For example, some college students obtain stimulant medication illegally and use it to stay up late to study. Abuse and dependence refer to situations in which the medication is used to get high, which could lead to addiction. Although these are concerns, there is no convincing evidence that the therapeutic use of stimulants causes abuse or dependence. In fact, long-term follow-up studies of stimulant-treated children with ADHD suggest the opposite effect. Treatment with stimulant medication generally decreases the risk for later drug abuse and dependence.

The rate of failure to adhere to treatment with stimulants may be as high as 20–65%. There are multiple factors contributing to poor adherence including perceived stigma, denial, externalization of the problem, unwanted side effects (headaches, emotional blunting etc.), the cost of the medication, as well as the fact that ADHD symptoms (e.g., forgetfulness) may directly contribute to poor adherence.

Nonstimulant Medications

Stimulant medications are usually the first line of treatment for ADHD due to their high efficacy and relatively long history of use. However, there are alternatives, including three food and drug administration (FDA)-approved nonstimulants: atomoxetine, extended release guanfacine, and extended release clonidine. Other medications such as bupropion, desipramine, venlafaxine, and modafinil are sometimes used ‘off label’ in the treatment of ADHD, especially in the adult population. ‘Off label’ means that the use of the medication for ADHD has not been approved by the FDA.

Atomoxetine is a selective norepinephrine reuptake inhibitor (SNRI) that increases the availability of synaptic norepinephrine, especially in the prefrontal cortex. One of the advantages of atomoxetine (and other nonstimulants) is the absence of a potential for abuse, which makes it a preferred agent in many situations where this can be a concern, especially in adults. Atomoxetine tends to be well tolerated; headaches, nausea, and loss of appetite are the most common side effects. Some of the rare events in treatment include increased suicidal thinking and behavior, unusual changes in behavior, and liver problems, potentially severe. While numerous studies found superiority of atomoxetine relative to placebo, atomoxetine is less effective than stimulant medications for most patients.

Guanfacine is an α -2 agonist with some selectivity for the 2A postsynaptic receptors. Guanfacine and other α -2 agonists increase noradrenergic brain activity; yet actually serve to regulate glutaminergic transmissions. A similar agent, clonidine, is also frequently used; yet clonidine is less selective at the level of 2A receptors. Both guanfacine and clonidine have similar side effects including somnolence, dry mouth, hypotension, and constipation. Both of these medications will likely increase in use in coming years because long-acting versions of both were recently approved by the FDA.

While the medication treatments for ADHD are effective, ‘normalization’ of functioning with medication treatments only occurs in a minority of those with ADHD. For this

reason, most in the field recommend that after medication treatment has been instituted, if any significant problems remain, these should be addressed with behavioral (psychosocial) interventions.

Psychosocial Interventions for Children

Behavioral parent training (BPT) programs are effective for children with disruptive behaviors whether or not they have co-occurring attentional/hyperactive difficulties. BPT techniques generally consist of training parents in the use of reward and punishment following appropriate and inappropriate behaviors. Reward procedures have typically relied on praise, privileges, or tokens while punishment methods have usually been loss of positive attention, privileges, or tokens or formal time out from reinforcement.

BPT programs generally consist of weekly training sessions, either in groups of parents or with individuals, each focusing on a discrete method. These methods can be grouped into three basic types of procedures: (1) those that manipulate the setting events that may precede or surround a child’s tasks or activities so as to increase positive or negative behavior (i.e., parental commands, task demands, teacher instructions, etc.); (2) those which may restructure the tasks to be done (reduce work quotas, insert more interesting task materials, etc.); (3) and those that manipulate the nature of the consequences for child behavior in that setting (i.e., attention, praise, token reinforcement, punishment, etc.).

Teachers often receive explicit training in classroom behavioral management during their training and education. Proper classroom placement, adequate attention to concomitant learning disabilities, and reasonable accommodations that might include classroom seating, extended time on tests, and modified work assignments are also commonly employed in school settings. Accommodations (including extended time) on standardized tests are also relatively common. Curriculum modifications, strategy training, and other cognitive behavioral approaches are less reliably associated with classroom behavioral improvements in children.

In general, medication management along with individually tailored psychosocial treatments are the most commonly employed interventions for managing children and adolescents with ADHD.

Adult Psychosocial Interventions

As noted above, behavioral treatments for ADHD children involve direct contact with parents and teachers and less direct intervention with the child. Cognitive behavioral therapy (CBT) is a more individual-delivered therapy which involves less direct contact with parents and teachers and more contact with patients. Unlike behavior therapy which focuses exclusively on changing behaviors, CBT also focuses on changing a person’s cognitions or thoughts and how they can use their thoughts to overcome real-world problems associated with their ADHD. CBT for ADHD children historically included many different treatment components such as self-instruction training, problem solving training, and social skills training; as psychosocial interventions. Research studies suggest that CBT is not useful for treating children with ADHD. In fact, due to its

limited efficacy in children, CBT was not included in the MTA treatment protocols. In adults, however, CBT holds some promise as a psychosocial component to an integrated treatment plan.

There are several CBT protocols for managing adult ADHD. Most protocols address the following topics: (1) education about ADHD; (2) organizational/planning training usually including teaching adults with ADHD how to use a calendar/daily planner, how to use 'to-do' lists, and how to break down a large task into more manageable chunks; (3) reducing distractibility through a variety of means, including managing environmental distractions, reducing large tasks into smaller chunks that correspond to the length of the adult's attention span, and the use of alarms/timers to encourage sustained focus; (4) reducing procrastination; (5) improving communication/social skills; (6) reducing anger and frustration through managing maladaptive thoughts and dysfunctional beliefs.

Although there is relatively little research on the use of CBT for treating adult ADHD, initial studies show that ADHD adults treated with CBT and medication have better outcomes than ADHD adults who are treated with medication alone.

Complementary and Alternative Treatments

The pharmacological treatment of ADHD is effective and safe for the large majority of patients. Nevertheless, because many parents object, in principle, to the idea of using psychiatric medication with their children, they seek help from complementary and alternative medical therapies.

Many alternative approaches for treating ADHD have been attempted. These use nutritional interventions; natural health products such as essential fatty acids, vitamins, and minerals; and other health supplements. Currently, there is no evidence to support recommending such interventions systematically, although anecdotal reports of improvement are numerous. When alternative treatments have been studied systematically, results are typically negative. For example, studies of zinc and omega-3 fatty acid supplementation show they are not effective for treating ADHD. Because most alternative treatments for ADHD have not been adequately studied, parents and patients should use them with extreme caution, keeping in mind that any concerns about the side effects of medications should be balanced by the risks associated with not treating ADHD as effectively as possible.

One alternative treatment that has gained some traction is use of electroencephalogram (EEG) neurofeedback. The EEG measures the electrical activity of the brain and is known in the popular language as 'brain waves.' Attempts to describe patterns of EEG activity in children with ADHD go back many decades. These studies suggest that ADHD children show increased theta and decreased beta and alpha activity. Neurofeedback has the child performing an activity that requires sustained attention. The child will receive negative feedback when the EEG reflects an increased theta/beta ratio and positive feedback otherwise. Initial studies suggest that this method is useful for some ADHD children. However, large randomized, well-controlled studies will likely clarify this issue. In scientific circles suspicion persists as we lack currently a convincing model correlating the EEG findings and the putative correction of the theta/beta ratio with executive functions and attentional processes.

Challenges and Perspectives

Over the past several decades, scientists have made important strides in understanding the causes of ADHD, refining its diagnosis, and developing new and more effective treatments. However, much more work remains to be done. One important challenge, which is faced by nearly all psychiatric disorders, is the lack of a biological test for the disorder. Although we know that ADHD and non-ADHD patients differ on measures of brain structure and functioning and that some genetic variants predispose to ADHD, these measures are not sufficiently accurate to use as a diagnostic test.

Scientists also need to provide a richer description of the causes of ADHD and the effects that these causes have on the brains of ADHD patients. Our hope is that future discoveries along these lines will lead to newer and more effective treatments for ADHD. New treatments are needed for several reasons. Current treatments for ADHD reduce symptoms and the risk for impairing behaviors, but in most cases they do not eliminate ADHD or 'cure' the disorder. Further studies of the brains and genes of ADHD patients may lead us to such improved treatments.

Current medication treatments for ADHD do a good job of reducing the symptoms of inattention, hyperactivity, and impulsivity. They are, however, less effective in treating other features of ADHD such as executive dysfunction or problems with the self-regulation of emotions. More work is needed to develop new medicines for such problems or to combine medicine and psychosocial treatments in a manner that addresses the full range of symptoms and impairments caused by ADHD.

Conclusion

In concluding, it is important to recognize the social context for ADHD in the United States and many other countries. It is not unusual to read on the internet or in newspapers, stories that question the validity of ADHD as a true disorder or describe current treatments as remarkably dangerous. Many of these stories are simply wrong or, at best, exaggerations. Parents and patients should rest assured that the disorder we call ADHD has received substantial scientific scrutiny and can be considered as valid as any other medical disorder that might be diagnosed in their child. They should also rest assured that medical treatments approved by the FDA have been sufficiently studied for safety and effectiveness.

People with ADHD should also understand that, although this article has focused on the clinical features and impairments associated with ADHD, having this disorder does not define the patient as hopelessly impaired or 'abnormal.' All people have strengths and weaknesses. ADHD is a weakness that leads to problems, but ADHD people often have many other strengths that help them lead productive and satisfying lives.

Attitude Change

R E Petty, Ohio State University, Columbus, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Attitude A global evaluation of a person, object, or issue indicating the extent to which it is liked or disliked.

Attitude change Modifying one's evaluation to become different from what it was.

Attitude strength The extent to which an attitude is persistent, resistant, and influences thinking and behavior.

Central route Persuasion through effortful thought and extensive elaboration that involves generating issue-relevant thoughts.

Dissonance An attitude change technique that involves having a person engage in inconsistent thought or action.

Inoculation Providing arguments against one's attitude in an attempt to strengthen it from future attacks.

Peripheral route Persuasion through less effortful mechanisms including mental shortcuts, simple associations, and the impact of contextual cues.

Resistance The extent to which attitudes remain firm when confronted with an attempt to persuade.

Attitudes refer to people's global and relatively enduring (i.e., stored in long-term memory) *evaluations* of objects, issues, or persons (e.g., I oppose capital punishment; I like the President). Numerous procedures have been developed to modify these evaluations with some change techniques involving considerable thinking about the attitude object and some requiring little. Attitudes are one of the most studied and important constructs in psychology because of the critical role of attitudes in guiding everyday choices and behavior.

Overview of Attitudes and Attitude Change

Attitudes are based on some combination of cognitive, behavioral, and affective (emotional) influences and are typically measured by self-report scales such as the *semantic differential*, where a person rates the target on bipolar evaluative dimensions such as how good/bad or favorable/unfavorable it is. Increasingly, in addition to assessing people's explicit or deliberative attitudes, assessments are made of the evaluations that come to mind automatically without much reflection (i.e., quick evaluative associations) using *implicit measures*. Measures such as Greenwald's Implicit Association Test (IAT) and Fazio's evaluative priming measure are popular in this regard. Often, implicit and explicit measures yield the same outcome, but sometimes there are discrepancies which might suggest that people are unwilling to report their attitudes due to social desirability concerns or might be unable to report them due to limited access.

Furthermore, in addition to assessing attitudes on a positive to negative continuum, scholars have also found it useful to assess attitudes on dimensions other than their valence such as their accessibility (how quickly the attitude comes to mind), ambivalence (how consistent the basis of the attitude is), and certainty (how confident people are in the validity of their attitudes). These indicators of attitude 'strength' are useful in determining which attitudes are consequential and which are not. Strong attitudes are those that persist over time, are resistant to change, and predict other judgments and actions. At any given moment, one's expressed evaluation can be influenced by a variety of contextual factors, but a common assumption is

that one's core 'attitude' is the underlying evaluation that is capable of guiding behavior (one's actions), cognition (one's thoughts and memories), and affect (emotional reactions).

Attitude change occurs when one's core evaluation shifts from one meaningful value to another, and is typically inferred from a change in either an implicit (automatic) or explicit (deliberative) measure of evaluation. Often, an attitude change induction produces change on both kinds of measures but sometimes change is more likely on one type of measure than another. Most studies of attitude change involve exposing individuals to a persuasive communication of some sort, but as explained shortly, some attitude change techniques do not involve exposure to any message. The earliest work on attitude change attempted to examine which variables and procedures increased and which decreased the likelihood of change.

Two Routes to Attitude Change

After numerous studies, the accumulated evidence suggested that even the simplest variables (e.g., being in a positive vs. negative mood; using a high vs. low credible source) sometimes increased, sometimes decreased, and sometimes had no impact on the likelihood that a person's attitude would change. Numerous theories and psychological processes were proposed to account for these divergent results. Even though the many theories of attitude change that were developed have different names, postulates, and particular effects and variables that they explain, the many different theories of attitude change can be thought of as emphasizing just two relatively distinct *routes to persuasion*: the *central route* and the *peripheral route*.

Central Route Approaches to Attitude Change

The first attitude change technique, persuasion via the central route, focuses on the information that a person has about the central merits of the object under consideration. Some of the theories and techniques that utilize the central route assume that comprehending and learning the information presented is

critical for attitude change, whereas others focus more on the evaluation, elaboration, and integration of this information.

Message Learning Approach

One of the most influential programs of research on attitude change was that undertaken by Carl Hovland and his colleagues at Yale University in the years following World War II. The Yale group studied how source, message, recipient, and channel factors affected the comprehension, acceptance, and retention of the arguments in a persuasive communication. Although no formal theory tied together the many experiments conducted by this group, they often attempted to explain the results obtained in terms of general learning principles, such as the more message content you learned, the more your attitudes should change. Contemporary research shows that people can be persuaded without learning or remembering any of the message content. That is, people are sometimes persuaded solely by the 'cues' associated with the message (e.g., the source is expert). Or, the message might elicit a favorable thought that persists in the absence of memory for the information that provoked it. Message learning appears to be most important when people are not engaged in an online evaluation of the information presented to them such as when they do not think they have to form an opinion at the time of information exposure. In such cases, subsequent attitudes may be dependent on the valence of information they have learned and can recall.

Self-Persuasion Approach

Self-persuasion theories hold that people's attitudes can change in the absence of any new external information. This is because people can self-generate reasons to favor or disfavor any position. The powerful and persisting effects of completely self-generated messages were shown in early research on 'role-playing' where people were asked to generate messages on certain topics (e.g., the dangers of smoking). The subsequent attitudes of these people were compared to those who had either passively listened to the communication or who had received no message. A consistent result was that active generation of a message was a successful strategy for producing attitude change, and these changes persisted longer than changes based on passive exposure to a communication. Finally, merely asking someone to think about an issue, object, or person can lead to attitude change as a result of the evaluative thoughts generated. *Cognitive response* theorists hold that just as one's own thoughts can produce change in the absence of a message, so too are one's own thoughts responsible for attitude change even when a persuasive message is presented. That is, to the extent that a person's thoughts in response to the message are favorable, persuasion should result, but to the extent that they are unfavorable (e.g., counterarguments), resistance or even boomerang is more likely. These theorists hold that persistence of persuasion depends upon the decay function for cognitive responses rather than message arguments per se.

Expectancy-Value Approach

The message learning and self-persuasion approaches focus on the information (either externally or internally generated) that

is responsible for persuasion. Neither approach has much to say about the particular features of the information that are critical for influencing attitudes. In contrast, expectancy-value theorists analyze attitudes by focusing on the extent to which people expect the attitude issue to be related to important values or produce positive and negative consequences. In one influential expectancy-value model, Fishbein and Ajzen's *theory of reasoned action* holds that the attributes (or consequences) associated with an attitude object are evaluated along two dimensions – the *likelihood* that an attribute or consequence is associated with the object and the *desirability* of that attribute or consequence. If a persuasive message says that raising taxes will lead to reduced crime, the effectiveness of this argument should depend on how likely people think it is that crime will be reduced if taxes are increased (likelihood), and how favorably they view the outcome of reducing crime (desirability). Although some questions have been raised about the necessity of one or the other of these components, a large body of research supports the idea that attitudes are more favorable the more that likely-desirable consequences (or attributes) and unlikely-undesirable consequences are associated with them. The major implication of this theory for persuasion is that a message will produce attitude change to the extent that it introduces new attributes of an object, or produces a change in the likelihood and/or the desirability components of an already accepted attribute. Another proposition of this theory is that the items of information constituting an attitude are combined in an additive fashion. Other theorists, however, have contended that an averaging mechanism is more appropriate.

Self-Validation Approach

Not all of the thoughts that people have with respect to an attitude object will necessarily be used to form an overall evaluative judgment. According to the self-validation approach, people are more likely to rely on thoughts in which they have confidence (i.e., see as valid) than thoughts about which they have doubt. For example, if two people have equal numbers of favorable thoughts about a proposal and each assesses the likelihoods and desirabilities of the consequences as equivalent, the person who has high confidence in the thoughts generated will show more attitude change than the person who has doubts about these thoughts. Numerous studies have identified a wide variety of variables that can affect thought confidence. One well-studied factor is the ease with which thoughts come to mind. For example, it is easier to generate two reasons to stop smoking rather than 12. Because things that come to mind easily are seen as more valid, people who generate two reasons could show more attitude change than those who generate 12, reversing the typical effect of number of thoughts on persuasion. This is because when people generate only two reasons, they have confidence in these reasons, but when they generate 12, there is less confidence in their validity. Other variables have been shown to affect thought confidence and thus reliance on one's thoughts. These variables include whether people are nodding (up and down) rather than shaking (side to side) their heads during the persuasion attempt, and whether they are made to feel powerful or happy right after thought generation. If people have generated mostly favorable thoughts during the message,

increasing thought confidence will lead to more persuasion, but if people have generated mostly unfavorable thoughts during the message, increasing thought confidence will result in reduced persuasion. Finally, it is important to note that people assess their thought confidence primarily when they are motivated and able to think carefully about the message, such as when they are high in their need for cognition or the personal relevance of the topic is high. When motivation and ability are low, meta-cognitive activity (i.e., thinking about one's thoughts) is also low.

Functional Approach

In their expectancy-value theory, Fishbein and Ajzen speculate that five to seven attributes or consequences are critical in determining a person's overall attitude. It is not clear, however, which particular attributes will be the most important (i.e., how the attributes are weighted). Functional theories of persuasion focus on the specific needs or functions that attitudes serve for a person and are therefore relevant for understanding the underlying dimensions of the attitude that are most important to influence. For example, some attitudes are postulated to protect people from threatening truths about themselves or to enhance their own self-image ('ego-defensive function'), others give expression to important values ('value-expressive function'), or help people to understand the world around them ('knowledge function') or facilitate achieving rewards and avoiding punishments ('utilitarian function'). According to these theories, change depends on challenging the underlying functional basis of the attitude. Thus, if a person dislikes lowering taxes because of concern about social inequality (value expressive function), an argument about the amount of money the taxpayer will save (utilitarian function) will be ineffective.

Consistency Approach

Just as functional theories hold that attitudes serve important needs for individuals, dissonance and related theories hold that attitudes are often in the service of maintaining a need for consistency among the elements in a cognitive system; in Leon Festinger's original formulation of *dissonance theory*, two elements in a cognitive system (e.g., a belief and an attitude; an attitude and a behavior) were said to be consonant if one followed from the other, and dissonant if one implied the opposite of the other. Two elements could also be irrelevant to each other. One of the more interesting dissonance situations occurs when a person's behavior is in conflict with his or her attitudes or beliefs because behavior is usually difficult to undo. According to the theory, dissonance, experienced as an aversive tension, can be reduced by changing beliefs and attitudes to bring them into line with the behavior. Thus, if you were opposed to the election of Candidate Smith, it would be inconsistent to sign a petition in favor of this candidate. According to dissonance theory, signing such a petition would produce discomfort that could result in a more favorable evaluation of the candidate in an effort to restore consistency.

Although early dissonance research was generally supportive of the theory, several competing formulations were proposed. Although it is now clear that many of the behaviors described by Festinger induce in people an 'unpleasant

tension,' just as the theory predicts, current research has begun to focus more on understanding the precise cause of that tension. For example, some have questioned Festinger's view that inconsistency per se produces tension in many people. Rather, some argue that people must believe that by their behavior they have freely chosen to bring about some foreseeable negative consequence, or that the inconsistency involves a critical aspect of oneself or a threat to one's positive self-concept.

Peripheral Route Approaches

Each of the central route approaches described above assumes that attitude change results from people actively considering the merits of some position either in a fairly objective manner or in a biased way (such as when seeking to restore consistency). The next group of theories does not share this assumption. Instead, these theories suggest that people often prefer to conserve their limited cognitive resources and form or change attitudes with relatively little cognitive effort. The peripheral route focuses on eliciting attitude change without much thinking about information central to the merits of the attitude issue. Thus, the peripheral approaches deal with changes resulting from rewards, punishments, and affective experiences that are associated directly with the attitude object, or simple inferences that people draw about the appropriate attitude to adopt based on their own behavior or other simple cues in the persuasion environment.

Inference Approaches

Rather than effortfully examining and thinking about all of the issue-relevant information available, people can make an evaluative inference based on some meaningful subset of information. One popular inference approach is based on 'attribution theory' and holds that people come to infer underlying characteristics about themselves and others from the behaviors that they observe and the situational constraints imposed on these behaviors. Bem suggested that people sometimes have no special knowledge of their own internal states and simply infer their attitudes in a manner similar to that by which they infer the attitudes of others. In his *self-perception theory*, Bem reasoned that just as people assume that the behavior of others and the context in which it occurs provides information about the presumed attitudes of these people, so too would a person's own behavior provide information about the person's own attitude. Thus, a person might reason, 'since I signed Candidate Smith's petition, I must be in favor of her election.'

The attribution approach has also been useful in understanding the persuasion consequences of making inferences about relatively simple cues. For example, when external incentives (e.g., money) provide a salient explanation for a speaker's advocacy ('he was paid to say it'), the message is less effective than when a discounting external attribution is not possible. Research indicates that these simple attribution processes are most likely to influence attitudes when people are relatively unmotivated or unable to think carefully about the issue, such as when they have relatively little knowledge on the topic and the issue has few anticipated personal consequences.

Like the attributional framework, the *heuristic-systematic model* of persuasion postulates that, when people are not motivated or able to process all of the relevant information available, attitude change can result from the use of certain heuristics or rules of thumb that people have learned on the basis of past experience and observation. To the extent that various persuasion heuristics are available in memory, they may be invoked to evaluate persuasive communications. For example, either because of prior personal experience or explicit training, people can evaluate a message with many arguments by invoking the heuristic 'the more arguments, the more valid it is.' If so, no effortful learning or evaluation of the actual arguments presented is necessary for influence to occur.

Approaches Emphasizing Affect

The attribution and heuristic models focus on simple cognitive inferences that can modify attitudes. Other peripheral route theories emphasize the role of affective processes in attitude change. One of the most direct means of associating 'affect' with objects, issues, or people is through *classical conditioning*. In brief, conditioning occurs when an initially neutral stimulus (the conditioned stimulus, CS) is associated with another stimulus (the unconditioned stimulus, UCS) that is connected directly or through prior conditioning to some response (the unconditioned response, UCR). By pairing the UCS with the CS, the CS becomes able to elicit a conditioned response (CR) that is similar to the UCR. So, in Pavlov's initial conditioning studies, when food was paired over and over again with a bell, eventually the bell elicited salivation in the absence of food.

Considerable research has shown that attitudes can be influenced by pairing initially neutral objects with stimuli about which people already feel positively or negatively. For example, peoples' evaluations of words, other people, political slogans, consumer products, and persuasive communications have been modified by pairing them with such affect-producing stimuli as unpleasant odors and temperatures, the onset and offset of electric shock, harsh sounds, and elating and depressing films. People are especially susceptible to the simple transfer of affect from one stimulus to another when the likelihood of object-relevant thinking is rather low. Some recent research by Jones, Fazio, and Olson suggests that conditioning in the domain of attitudes (*evaluative conditioning*) occurs by means of a simple misattribution process. That is, although people are actually feeling unpleasant because of the UCS (e.g., an pleasant odor), they misattribute (confuse) this feeling as originating from the CS (e.g., the persuasive message).

Another procedure for modifying attitudes through simple affective means was identified by Robert Zajonc in his work on *mere exposure*. In this research, Zajonc and his colleagues have shown consistently that when objects are presented to an individual on repeated occasions, the mere exposure is capable of making the individuals' attitudes toward these objects more positive. Recent work on this phenomenon indicates that simple repetition of objects can lead to more positive evaluations even when people do not recognize that the objects are familiar. Mere exposure effects have been shown in a number of studies using a variety of stimuli such as polygons, tones, nonsense syllables, Chinese ideograms, photographs of faces, and foreign words. Interestingly, what these stimuli have in

common is that they tend to be meaningless and are relatively unlikely to elicit spontaneous thought. In fact, the simple affective process induced by mere exposure appears to be more successful in influencing attitudes when processing of the repeated stimuli is minimal. When more meaningful stimuli have been repeated such as words or sentences, mere exposure effects have been less common. Instead, when processing occurs with repetition, the increased exposures enhance the dominant cognitive response to the stimulus. Thus, repeating strong arguments tends to lead to more persuasion (at least to the point of tedium), and repeating weak arguments tends to lead to less persuasion.

A Dual Process Approach to Understanding Attitude Change

Although the theories just described continue to be useful in accounting for a variety of persuasion phenomena, much of the contemporary literature on attitude change is guided by one of the available 'dual process' models of judgment. For example, one of the earliest approaches of this type, the *Elaboration Likelihood Model* (ELM), was introduced by Petty and Cacioppo and represented an attempt to integrate the many seemingly conflicting findings in the persuasion literature under one conceptual umbrella by specifying a finite number of ways in which source, message, recipient, and contextual variables have an impact on attitude change (for reviews of the ELM, the related heuristic/systematic model, and other dual process approaches). The ELM is based on the notion that people want to form correct attitudes (i.e., those that will prove useful in functioning in the environment) as a result of exposure to a persuasive communication, but there are a variety of ways in which a reasonable position can be adopted.

The most effortful procedure for evaluating an advocacy involves drawing upon prior experience and knowledge to carefully scrutinize and think about all of the issue-relevant information available in the current environment along the dimensions that are perceived central to the merits of the attitude object. According to the ELM, attitudes formed or changed by this *central route* are postulated to be relatively persistent, predictive of behavior, and resistant to change until they are challenged by cogent contrary information along the dimension or dimensions perceived central to the merits of the object. However, it is neither adaptive nor possible for people to exert considerable mental effort in processing *all* of the persuasive information to which they are exposed. This does not mean that people never form attitudes when motivation and/or ability to think are low; in contrast, they may change via a peripheral route, wherein relatively simple associations, online inferences, and well-learned heuristics are utilized. For example, a person might be more persuaded by a message containing nine rather than three arguments because each of the arguments is evaluated and determined to be compelling (central route), or because the person simply counts the arguments and reasons and assumes 'the more the better' (peripheral route). Attitudes formed or changed by the central route processes are postulated to be relatively more persistent, resistant, and predictive of long-term behavior than those based on peripheral route processes. Thus, the ELM

holds that both central and peripheral processes are important for understanding attitude change, but their influence varies depending on the likelihood of thinking.

The ELM holds that there are many variables capable of affecting elaboration and influencing the route to persuasion. Some variables affect a person's motivation to process issue-relevant information (e.g., the personal relevance of the issue; personal accountability for a decision; whether the person is relatively high or low in need for cognition), whereas others affect their ability or opportunity to think about a message (e.g., the presence of distraction; the number of times the information is repeated; the amount of issue-relevant knowledge available). Some variables affect processing in a relatively objective manner (e.g., distraction disrupts whatever thoughts a person is having whether favorable or unfavorable to the proposal), whereas others influence elaboration in a biased fashion (e.g., a positive mood makes positive thoughts more likely than negative thoughts when people are motivated and able to think). Biases can stem from ability factors (e.g., a biased knowledge store) and motivational factors (e.g., when a desire to maintain one's current attitude is more salient than one's desire to objectively consider new information).

Research on the ELM has shown that when the elaboration likelihood is high (e.g., high personal relevance, high knowledge of topic, simple message in print, no distractions, etc.), people typically know that they want and are able to evaluate the merits of the information presented, and they do so. When thinking is high, the number, valence, and confidence people have in their thoughts determine the extent of influence. The extensive thinking that people do can be relatively objective or biased. On the other hand, when the elaboration likelihood is low, people know that they do not want and/or are not able to carefully evaluate the merits of the information presented (or they do not even consider exerting effort). Thus, if any evaluation is formed, it is likely to be the result of relatively simple associations or inferences (e.g., agreement with an expert source; counting the number of arguments presented). When the elaboration likelihood is moderate (e.g., uncertain personal relevance, moderate knowledge, moderate complexity, etc.), however, people may be unsure as to whether the message warrants or needs scrutiny, and whether or not they are capable of providing this analysis. In these situations, they may examine the persuasion context for indications (e.g., is the source credible?) as to whether or not they should attempt to process the message.

There are at least two important implications of the ELM. First, the model holds that any one variable can produce persuasion by different processes in different situations. For example, putting people in a positive mood can influence attitudes because of a simple inference process when the likelihood of thinking is low (e.g., 'I feel good so I must like it'), bias thinking when the likelihood of thinking is high (i.e., making positive interpretations more likely than negative ones), and influence the extent of thinking when it is not already constrained to be high or low (e.g., thinking about an unpleasant message less when happy than when sad). In addition to considering the extent of thinking, it is also important to consider the timing of key persuasion variables such as whether they are salient before or after message processing. For example, if a person is motivated and able to think about

a message, inducing happiness prior to the message will likely lead to biased thinking about the message. However, when happiness is induced right after message exposure, it is likely to affect the confidence people have in the thoughts that they have already generated. Thus, by considering the likelihood of thinking and the timing of persuasion variables, the mechanism by which the variable affects attitudes can be understood. Second, as explained next, the ELM holds that the mechanism of persuasion has implications for the strength of the changed attitude. The ELM holds that not all attitude changes of the same magnitude are equal. Specifically, thoughtful attitude changes (central route) tend to be more consequential than nonthoughtful changes (peripheral route).

Consequences of Attitude Changes Produced by Different Processes

It is now clear that there are a variety of processes by which attitudes can be changed, and that the different processes dominate in different situations. That is, some attitude change processes dominate when motivation and ability to think are high, but other change processes dominate when motivation and ability to think are low. Research suggests that attitudes formed by different processes often have different characteristics. For example, *persistence* of persuasion refers to the extent to which attitude changes endure over time. When attitude change is based on extensive issue-relevant thinking, it tends to persist longer than when it is not. However, multiple exposures to positive cues can also produce relatively persistent attitudes.

Resistance refers to the extent to which attitude change is capable of surviving an attack from contrary information. Attitudes are more resistant the stronger the attack they can withstand. Although attitude persistence and resistance tend to co-occur, their potential independence is shown conclusively in William McGuire's work on cultural truisms. Truisms such as 'you should brush your teeth after every meal' tend to be highly persistent in a vacuum, but very susceptible to influence when challenged. People have very little practice in defending truisms because they have never been attacked. These beliefs were likely formed with little issue-relevant thinking at a time during childhood when extensive thinking was relatively unlikely. Instead, the truisms were probably presented repeatedly by powerful, likable, and expert sources. As noted above, the continual pairing of an attitude with positive cues may produce a relatively persistent opinion, but it may not prove resistant when attacked. The resistance of cultural truisms and other attitudes can be improved by motivating and enabling people to defend their positions in advance of a challenging communication. One such *inoculation treatment* involves exposing people to a few pieces of counterattitudinal information prior to the threatening communication and showing them how to refute it. The inoculation procedure does not change the valence of a person's initial attitude, but it makes it stronger. Other persuasion treatments that seem ineffective in changing the valence of attitudes might nonetheless be effective in modifying the strength of the attitude, making it more or less enduring, resistant, or predictive of behavior than it was initially.

Perhaps the most important consequence of attitudes changed by high rather than low thought processes is that these attitudes are more likely to predict and guide behavior. There are several reasons for this. First, as noted above, high thought attitudes are more likely to be stable over time so that they will be available to guide behavior when the opportunity arises. Second, however, attitudes based on high amounts of thought are also held with greater confidence, making people more willing to act on these attitudes. Interestingly, recent research by Barden and Petty shows that if attitude confidence is increased even in the absence of enhanced thinking, people are more willing to act on these attitudes, providing a relatively low thought way to increase attitude strength.

Summary

In sum, contemporary persuasion theories hold that changes in attitudes can come about through a variety of processes which imbue them with a multiplicity of characteristics and render them capable of inducing a diversity of consequences. According to the popular dual process logic, the processes emphasized by the central route theories should be largely responsible for attitude change when a person's motivation and ability to scrutinize issue-relevant information is high. In contrast, the peripheral route processes should become more dominant as either motivation or ability to think is attenuated. This framework allows understanding and prediction of what variables affect attitudes and in what general situations. It also permits understanding and prediction of the consequences of attitude change. It is now accepted that all attitudes can be based on cognitive, affective, and behavioral information, and that any one variable can have an impact on persuasion by invoking different processes in different situations. Finally, attitudes that appear identical when measured can be quite different in their underlying basis or structure and thus can be quite different in their temporal persistence, resistance, or in their ability to predict behavior. Work on attitude change to the present has focused on the intrapsychic processes responsible for change in adult populations mostly in Western cultures. Future research is needed on the interpersonal processes responsible

for attitude change, and the potentially different mechanisms that produce change in different population groups (e.g., children vs. elderly individuals, those in individualistic vs. collectivist cultures). In addition, as the field matures, current theories are ripe for exportation to important applied domains such as health promotion (e.g., AIDS education), political participation (e.g., determinants of voter choice), and others.

Attitude Formation

M A Olson and R V Kendrick, University of Tennessee, Knoxville, TN, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Attitude Positive and negative evaluations of things, people, and concepts.

Implicit cognition Cognitive processes that operate efficiently and involuntarily, and often without the awareness of the perceiver.

Priming Happens when exposure to a stimulus influences responses to another stimulus, often in the absence of awareness.

Tripartite model A method of categorizing different attitude formation processes into affect (emotions), cognitions (beliefs), and information about attitude-related behavior.

Introduction and Relevant Distinctions

Attitudes are positive and negative evaluations of things, people, and concepts. A person might, for example, feel positively toward his or her mother, value his or her car for its reliability, be suspicious of foreigners, and constantly crave chocolate. All of these are attitudes in that they imply positive/approach tendencies or negative/avoidance tendencies and involve summaries of the value of the object. Such precomputed summary judgments of attitude objects are functional in that they help prepare the individual for action so that one does not need to deliberately make important decisions from scratch every time a behavioral opportunity arises. In other words, because people know what they like and dislike, they can spend less time pondering what to buy and consume, for whom to vote, how to behave, and with whom to affiliate. They need only consult their attitudes toward the relevant object and act in accordance with it. Indeed, attitudes have been considered 'ready aids' for sizing up the world and how to live in it, and it is difficult to imagine how people could function without having a grasp of the things that benefit and sustain them and things that could potentially hinder or harm them.

The attitudes people hold toward the objects in their world have immense personal and social consequences. Attitudes have been implicated in health behavior (e.g., attitudes toward regular physicals or safe sex practices), politics (e.g., attitudes toward general political ideologies or more specific political figures), consumer behavior (e.g., attitudes toward various brands and products), and social conflict (e.g., attitudes toward various religious groups and ethnicities), among many other domains. Because attitudes are so relevant to such an array of life domains, and because they are thought to be important determinants of behaviors and judgments (at least under certain conditions), the attitude concept is one of the most well-studied concepts in the field of psychology. Hence, an understanding of the basic origins of attitudes is critical to understanding human psychology in a more general sense.

For most people, attitudes' origins are often understood on a per-case basis, whereby one simply attempts to identify the source of each attitude individually (e.g., 'I learned to like blue cheese from my mother,' or 'I like Volvo cars because of their safety record'), without considering broader themes. Social scientists consider such broader themes and, in so

doing, have provided some ways to organize attitude formation processes. The first and most prevalent is referred to as the tripartite approach, whereby attitudes' origins are considered in terms of affect (based on affect or emotion), cognition (based on belief or cognition), behavior (based on information derived from one's own behavior), or some combination of the three. More recently, researchers have distinguished between explicit origins, where attitudes are derived consciously through some sort of thoughtful and effortful process, and implicit origins, where attitudes form without conscious intent or awareness on the part of the person. In this article, attitude formation processes are discussed in terms of their tripartite and implicit versus explicit origins, with each being discussed in turn.

A final distinction is whether a given attitude is learned (either socially or through direct experience) or biologically derived (either genetically or through evolutionary processes). Although most attitudes of interest to social scientists are typically assumed to be learned, there is evidence that some attitudes are meaningfully influenced by biological processes relating to genetics and evolution. This article describes the main sources of attitudes as they have been studied by social scientists and considers some additional issues when pondering about the origins of attitudes.

Origins

Cognitive Origins

One way an individual may come to evaluate a particular object is through acquiring positive or negative beliefs about the object. One may read information outlining the significant, harmful health effects of smoking and consequently develop beliefs that cigarettes lead to negative outcomes such as lung cancer and emphysema. Attitudes can develop through this often thoughtful, 'rational' route as individuals acquire cognitions that inform them whether an attitude object leads to good or bad outcomes or possesses wanted or unwanted qualities.

The most prominent framework within which to understand the cognitive origins of attitudes is the expectancy-value model. The model claims that an attitude is a function of the expectancy that the object has certain attributes and the value attached to each of the perceived attributes of the attitude object. The *expectancy* is one's belief about whether the

attribute will occur, and the *value* represents one's evaluation of the attribute. For example, in forming an attitude toward smoking, one might think of various attributes of smoking cigarettes (that they cause cancer, make one appear cool), determine how (un)favorable they find each attribute, and then assess the likelihood that each will occur. I might believe that smoking cigarettes will make me look cool and that this outcome is quite good (high positive value) but is only marginally likely to occur (low expectancy). Additionally, I am keenly aware of adverts stating that smoking cigarettes leads to an increased risk of lung cancer, and I conclude that this is clearly a negative outcome (high negative value) that according to published statistics is likely to occur (high expectancy). These values and expectancies are then combined, yielding an overall attitude toward the object. In the aforementioned example, I really want to look cool but I do not want to get lung cancer. Since looking cool is quite positive yet not likely, and getting cancer is quite negative as well as likely, the net sum of my attitude should be negative. As one might imagine, this model represents a conscious, *explicit* process, requiring a certain degree of attention and deliberate effort.

Similar to the expectancy-value model is information integration theory. This model states that as new object-relevant information is learned, it gets added to existing thoughts and beliefs about the object, and the result of this integration produces an attitude. At first, each piece of new information is added in a way similar to the expectancy-value model. However, in this process, the potential (un)favorability of each new attribute is evaluated, and this evaluation is combined with a judgment about the importance of the attribute in forming the attitude. Once we determine how we think about the attributes of an attitude object and how important each attribute is in determining the attitude, they can then be integrated with current attitudes and beliefs to form new attitudes. For example, I may learn that smoking leads to a risk of developing emphysema, an unfavorable outcome, which I deem as unimportant (perhaps because this consequence occurs in the distant future). However, if I already possess thoughts that smoking will make me feel relaxed – a likeable outcome that I place more value on because it is so immediate – then it will comprise a larger portion of my complete attitude toward smoking. This last point touches on an important distinction between the value-expectancy model and the information integration model. Information integration theory acknowledges that when forming attitudes toward objects, not all pieces of information are entered into the equation equally. Rather, some beliefs are learned earlier, or may be seen as more important, and therefore have more influence on information learned later.

Among other explicit, belief-based approaches to attitude formation are the reception-yielding model and the cognitive-response model. Both of these models are less concerned with calculations in their descriptions of how attitudes form and focus rather on the explicit reactions to people's thoughts about what they learn about attitude objects. The reception-yielding model describes a two-stage process where one initially receives object-relevant information and then chooses to either yield to it (i.e., change one's evaluation of the object in light of the new information) or reject it (i.e., maintain one's evaluation of the object despite the new information). Considering the previous smoking example, when deciding how I feel

about smoking, I might read the surgeon general's warning about birth defects caused by smoking while pregnant (reception) and then adjust my attitude toward smoking due to this potential health risk (yield). Although this model has been primarily applied to attitude change, it can be used to describe how people perceive information and form attitudes from scratch based on their own thoughts about what they learn. Thus, this approach helps us understand the origins of attitudes based not simply on what people learn about an object but how they respond to what they learn.

The cognitive-response model presents another process by which attitudes form in an active, deliberate, and explicit manner. When we encounter an attitude object, we tend to actively relate qualities and information about the object to existing thoughts. The process of relating new bits of information to those already held results in cognitive responses concerning the attitude object, and the extent to which these responses are (un)favorable determines our overall evaluation of the object. When I learn that cigarettes are expensive, for example, I relate this new, negatively evaluated thought to my preexisting thought that cigarettes also make one smell bad. Taken together, I conclude that there are more negative aspects of smoking (cost and interpersonal consequences) than there are positive qualities (it feels pleasurable), and I form an overall negative attitude toward smoking.

A more recent development in the literature on the cognitive origins of attitudes is the metacognitive model (MCM). According to the MCM, one considers the various qualities of the object, but also considers the truth value of each of his or her beliefs about the object. One might, for example, consider some beliefs about the object to be more certain than others. Therefore, it is possible to have contradictory cognitions about an object, with some cognitions labeled as valid (presumably allowing these attributes to exert greater influence) and others labeled invalid (presumably not influencing one's overall attitude). Interestingly, the application of these so-called validity tags requires some amount of effort, and in the absence of such effort (as when one has little time or energy to think), all cognitions are available to influence one's attitude, even those that one might not believe to be true. I may possess the negative cognition that cigarettes cause cancer, but I supplement this belief with an invalidity tag (i.e., 'this is not applicable because it only applies to long-term smokers and I have only been smoking recently and plan to quit'), so when asked, I might claim to have a positive attitude toward smoking, even though I still harbor some negative beliefs about it.

The aforementioned descriptions of cognitive routes to attitude formation all share a relative reliance on thoughtful conscious processes. It is worth noting that cognitive origins are called so because they have at their core cognition or beliefs about the attitude object. This fact, while implying that some minimum of explicit, deliberate effort be present during the formation process, still leaves open the possibility that attitudes can form through implicit, less-conscious forms of learning. Unconscious thought theory, for example, argues that one can process large amounts of information outside of conscious awareness, compared with the relatively small amount of information that can be consciously processed at one time. Unconscious thought has been shown to give individuals the ability to process large amounts of information, perhaps allowing for

attitudes to form by consolidating cognitions even in the absence of any deliberate or conscious intentions. When bombarded with complex information about an object, it often becomes difficult to weigh the pros and cons using the more explicit manners discussed previously. Unconscious thought provides the possibility of taking large amounts of object-relevant information and, in essence, letting the powerful, unconscious parts of the brain do the work, yielding an overall evaluation of the attitude object that is presented to consciousness later as a gut feeling.

Lastly, the value-account model outlines another cognitive yet implicit process by which attitudes have been shown to arise. Overall evaluation of objects attitudes can be characterized as value accounts comprising the positive or negative values associated with the various attributes of the object. When new information is obtained, it gets incorporated into the account, and the value, or evaluation, of the account linked to the object changes the overall value or attitude toward the object. This process has been shown to function even outside of deliberate control, such that individuals who are engaged in another task designed to deprive them of cognitive resources are still able to detect valence information concerning an attitude object, and this information has been shown to influence overall evaluations of the attitude objects. Applied practically, if I have an overall positive attitude toward cigarette smoking (a positive value) and am exposed repeatedly to antismoking billboards describing the number of deaths caused every year by smoking, my attitude should become more negative due to the incorporation of negative-valued information, even though the bulk of my attention is fixed on the task of driving and not on deliberately processing public health bulletins.

Affective Origins

In addition to thoughts, attitudes can also form from the emotional responses that we experience when we encounter an attitude object. For example, I may experience a pleasurable feeling while smoking a cigarette, and this affect could lead me to have a positive attitude toward smoking. Or, I might think about the negative health effects of long-term smoking such as lung cancer or death, and I experience a distinctly negative attitude instead. These examples highlight several ways that affect can be used to form attitudes toward objects. It is worth noting that the aforementioned first example derives solely from an emotional response, but the second example is based on an emotional experience felt in response to a cognition concerning the attitude object. This highlights the fact that affective origins can be directly experienced or derived secondarily from an object quality. In this section, we focus on affect, independent of whether it is in response to a thought about the object. Later, we address how affective responses lead to attitude formation and then we consider three processes that lead to affectively derived attitudes: operant conditioning, evaluative (a form of classical) conditioning, and mere exposure. Operant conditioning, a process by which the frequency of a response is increased following a positive outcome and decreased following a negative outcome, can provide one mechanism for the formation of affectively based attitudes. If interaction with the attitude object causes a positive emotional response, then the evaluation of the attitude object will

become more positive and this connection will strengthen, resulting in a positive general attitude. Research has shown that individuals who were reinforced when recalling favorable responses toward an object (via hearing 'good' in response to these recollections) later demonstrated more positive attitudes toward the object, compared to unreinforced participants. If every time I smoke a cigarette and I am reinforced with a positive feeling from nicotine, the act of smoking will be reinforced, resulting in a stronger positive attitude toward smoking. Conversely, if every time I light a cigarette everyone leaves the room, the likelihood of my smoking will decrease and I will develop a negative attitude toward it. Thus, attitudes can be formed by experiencing positive or negative outcomes based on our attitudinal responses, and the more often one's responses are reinforced, the more likely that attitude will manifest itself in the future.

Operant conditioning tends to occur in an explicit fashion with one consciously perceiving the reinforcing outcomes of relevant behavior. Classical conditioning, while similar to operant conditioning, does not require that the person respond to an attitude object. Instead, the connection between an object and an affective evaluation develops by simply observing the pairings between an attitude object and a positively or negatively evaluated stimulus. Observing these pairings creates an association between the previously neutral object and the valence of the object with which it is paired. For example, researchers created positive and negative attitudes toward two names ('Ed' and 'George') by visually presenting these names to participants on index cards while having them repeat aloud positive or negative adjectives that were paired consistently with either name. Importantly, this occurred even though there was no meaningful relationship between the names and the adjectives. When considering our smoking example, repeatedly noticing advertisements containing attractive models engaged in smoking behavior can lead to a change in one's attitude toward smoking due to the transfer of the positive affect associated with the attractive model to the cigarette brand. This can occur in an explicit fashion where one is consciously aware of the pairings of the attitude object (cigarettes) and the valences stimuli (attractive model).

Research on a variant of classical conditioning – evaluative conditioning – has shown that attitudes can form via affective connections between an object and another, valenced object, without conscious awareness of this relationship. Like classical conditioning, evaluative conditioning happens when a previously neutral object takes on the valence of stimuli that co-occur with the previously neutral object. Studies have shown that participants who view a novel object repeatedly paired with positive stimuli will later evaluate the novel object more positively, whereas novel objects repeatedly paired with negative stimuli will come to be viewed more negatively. There has been some debate concerning whether this process of attitude formation occurs in an explicit fashion where awareness of the connection between attitude objects and valenced associates is necessary, or whether it can occur implicitly, in the absence of such awareness. Recent work seems to indicate that it depends. Explicit awareness of the repeated pairings of neutral objects with strongly positive or negative stimuli leads an individual to form consciously held beliefs concerning the relationship between the two. However, if one remains unaware of the

repeated contingencies between a neutral object and a valenced stimuli, then the affect from the valenced stimuli can be implicitly misattributed to the previously neutral object, resulting in an attitude, the origins of which remain obscured to the attitude holder. If every time I sit next to an ashtray, my sense of smell is insulted by the foul stench of old cigarette smoke, I am likely to associate smoking with the negative feelings elicited by the smell of smoke, and whether I become conscious of the association between the negative affect and smoking will determine whether this attitude stems from a propositional, explicit process or an implicit, misattributional process. Research on the 'mere exposure' effect has also shown that simply increasing the familiarity of an attitude object can create more positive attitudes toward the object. In a study that presented Turkish words or Chinese symbols to participants in increasing frequency, those who observed more repetitions of the words or symbols showed a more favorable attitude toward them compared to others who saw the stimuli infrequently. This is due to a phenomenon known as 'perceptual fluency,' that is, greater ease at perceiving an object upon subsequent encounters, which is interpreted as liking for the object. Thus, the more familiar one is with the attitude object, the more likely one is to have a positive evaluation of it. So, if I choose to smoke, in the absence of other considerations, I am likely to prefer a brand of cigarettes that I have been exposed to in the past more than a brand I have never before encountered, even if I am unable to consciously recall which brand I have seen more often in adverts. Similar to the conditioning research described previously, mere exposure research outlines a way attitudes can form due to affect alone, without reliance on cognitions regarding an object's attributes, and often in the absence of explicit awareness of the underlying process.

Behavioral Origins

In situations where we lack either a cognitive or affective basis for an attitude, we can infer an attitude by observing our past behavior toward the object in a process of self-perception. When the internal cues that might otherwise normally lead to an attitude are weak, we instead make inferences regarding our behavior much like an outside observer would make. Consider our earlier example. I may not have any solid beliefs about the benefits or hazards of smoking, nor does the idea of smoking elicit any salient emotion. However, I may recall that I have smoked in the past, and I therefore conclude that I must have a positive attitude toward smoking – why else would I have behaved so? This scenario exemplifies how attitudes can have a behavioral genesis whereby our attitudes fall in line with our self-perceived actions.

Research on cognitive dissonance provides a framework to understand how attitudes can stem from past behaviors toward an attitude object when one has preexisting evaluative knowledge of the object. Cognitive dissonance occurs when an individual experiences an inconsistency between thoughts and behaviors concerning a target object. This state of dissonance is characterized by a negative state of arousal, which the individual seeks to correct by restoring consonance between the attitude and the behavior. If my behaviors include smoking cigarettes and I possess cognitions that cigarettes can lead to cancer, I would be susceptible to the negative affect created by

the conflict between my thoughts and behavior. To restore consistency, I can either quit smoking, thus realigning my thoughts and behaviors, or change my cognitions concerning the health risks of smoking (e.g., arguing that only heavy smokers will develop cancer) so that the cognitive component of my attitude toward smoking is no longer in conflict with my actions related to smoking. Thus, the behavior informs the attitude.

Similar research has shown that we are often nonconsciously tuned into subtle bodily gestures that inform us as to how we feel about an object. In a seminal study on the behavioral antecedents of attitude formation, participants held pencils in their mouths while viewing cartoons and were asked to rate how funny they felt the cartoons were. Some participants held the pencil with their lips, simulating a frown, while others held it with their teeth, simulating a smile. Participants who exhibited a smile while viewing the cartoons rated them as funnier than those who frowned. In a related research, participants induced to nod their heads while perceiving social stimuli rated those stimuli more positively than stimuli perceived while they were made to shake their head from side to side. Thus, in the absence of an obvious external reason for behavior, we infer an internal one, and this attribution can result in a new attitude that is consistent with our actions.

Self-perception, and its effects on attitude formation from our overt behavior, can have the opposite effect if it is applied when one already possesses an attitude. Researchers led preschoolers to engage in an enjoyable activity (drawing with magic markers) and promised some children a reward for participating in the activity while providing no reward for other children. When later given the chance to engage in the activity, children given the reward spent only half as much time coloring with the markers as did children who had not been given a reward. The explanation rests on an overjustification effect, where children who had played while anticipating a reward must have perceived that they did so because of the reward, whereas the others perceived that they engaged in the behavior simply because they liked it.

Biological Origins

Many social attitudes (e.g., racial, political, and interpersonal attitudes) probably are learned, as shown by the wide and easily observed varieties of attitudes in such areas. However, universal attitudes that show little cultural variation (e.g., xenophobia or a preference for sweet foods) can also be observed, suggesting biological origins. Moreover, cultural variation in a given attitude does not itself rule out a role for biological origins, as biological processes must interact with experience to produce a given attitude or behavior. Interest in the biological origins of attitudes has waxed and waned in the social sciences, and those advocating an evolutionary perspective have been attacked by critics for a variety of reasons, not the least of which is the notion that evidence for biological origins of attitudes might be taken as evidence of 'fixedness' (the impossibility of change). Others have voiced concern that evidence of biological origins might be misconstrued as justification for the existence of a given attitude or trait (the 'what is natural must be good' argument, also known as the adaptationist fallacy).

Evolutionary supporters tend to focus on mate preferences as examples of evolved attitudes. For example, owing to their greater costs to produce offspring, women are thought to be 'choosier' in selecting a mate and prefer a mate who shows evidence of both willingness and ability to invest in the health of the woman and her offspring. Men, however, are more likely to prefer a greater number of mates and be less careful about their mate choices, because their investment in offspring production is less. Moreover, men prefer potential mates with outward indicators of fertility, such as a waist-hip ratio of about 0.80, which has been shown to lead to more successful offspring production. Cross-cultural data on attitudes toward potential marriage partners consistently support this reasoning.

Flexibility in mate preferences is in line with an evolutionary perspective as well, as women will tend to show an increased preference for mates of high genetic value (e.g., more attractive men), as well as more aggressive and competitive mates, during the most fertile points of the menstrual cycle. Preferences for a mate who is willing and able to provide resources do not vary as a function of the menstrual cycle.

Little progress has been made in addressing more social scientific-oriented attitudes (e.g., racial and political attitudes) from an evolutionary perspective. There are some exceptions, however, including some research suggesting that racial prejudice may be a natural extension of an evolved preference for people who appear more similar to oneself. Another simple extension of evolutionary approaches to attitude research involves food preferences. Mammals, which acquire immediate energy from the ingestion of sugars and starches and long-term storable energy from fats, have likely evolved a taste for both. Hence, positive evaluations of foods high in sugars and fats are likely to have evolved components.

Other biological approaches to the study of attitude formation come from behavioral genetics research. Here, studies of identical twins who were either reared in similar or different environments have come to show that some attitudes are linked to genetics. For example, attitudes toward jazz, the death penalty, and some political ideologies have been shown to have genetic components, whereas attitudes toward coeducation have not. Attitudes may have heritable components because of their links to other traits with clear evidence for heritability (e.g., intelligence, openness). For example, because intelligence is somewhat genetically determined, attitudes related to intelligence may be at least partially determined by genes. Because a preference for jazz music is associated with intelligence, and intelligence has genetic components, a preference for jazz is indirectly linked to genetics. Similar arguments can be made about other biologically determined traits such as physique and preferences for various physical activities. Indeed, recent twin research suggests that one of the more studied social attitudes – prejudice – may have genetic components.

Regarding their implicit versus explicit origins, a preexisting biologically based tendency toward a given set of attitudes may suggest a more implicit basis. Indeed, people are seldom able to explain why they prefer sweet and fatty foods, or members of their own group, without referring back to their attitude in a circular fashion. However, people are certainly aware of their food preferences, and most social scientists would agree that they are also aware of their prejudices, whether they wish to admit them publicly or not. Thus, we must consider what

we mean by 'implicit.' Here, researchers typically refer to an attitude as implicit if one is unaware of its origins, its influence on judgments and behavior, or both. Attitudes partially determined by biology probably meet these criteria, as people have a difficult time generating the underlying reason – the foundation – for their food preferences, preferences for their own groups, etc. Similarly, it was mentioned that men tend to prefer a certain waist-hip ratio in women, but most would be unable to explain the evolutionary origins of their preference for more shapely feminine forms. Hence, biologically determined attitudes are liable to have implicit origins, although many of them are certainly further molded by culture and personal experience.

Additional Considerations

The question of how attitudes form has been thoroughly investigated for several decades by social scientists, but it is difficult to isolate this origins question from several other relevant issues. Thus, the final section discusses additional concepts related to attitude formation in the hopes of providing a broader context.

First, we have covered the different attitude formation processes individually, but we must also point out that such processes are likely to combine and interact in real-world attitude formation situations, and some research has investigated these more complex situations. It is also likely that the different formation processes are mutually reinforcing in natural environments, such as when one uses one's affective reactions to an object as cause to seek positive cognitively oriented information about it. Similarly, one's biological predispositions to prefer sweet foods are often reinforced by cultural information that encourages the consumption of sugary foods. However, interesting situations arise when two or more formation processes conflict. We have already mentioned the case of cognitive dissonance, where knowledge of one's behavior contradicts either other beliefs or other affective reactions regarding an object. Conflict also arises when affective and cognitive reactions disagree, such as when one feels warmly toward an object he or she believes has negative effects (e.g., smoking or an unhealthy relationship partner). Such situations are usually unstable and prompt discomfort in the perceiver that he or she is motivated to reduce.

Attitudes are also related to other social constructs studied by social scientists, including morals, values, impression formation, and social judgment. Morals and values have been considered classes of attitudes that relate to interpersonal conduct. Impression formation is a bit broader than attitude in that it involves not only the question of whether we come to like someone, but also whether we think of the individual as having specific traits (e.g., introversion, extroversion, etc.). Social judgments are made at a specific point in time, whereas attitudes, potentially among other information, are brought to bear on a specific case, such as when someone judges a particular politician as qualified to hold public office. Judgments are single cognitive acts, whereas attitudes are thought to have some longevity in the person's mind. Thus, answers to questions about the origins of attitudes can also be found in these literatures.

Although this article is about attitude formation, another article in this volume is directly relevant. Although the concepts differ in that the former addresses how attitudes come about without the existence of a prior attitude and the latter addresses how one's attitudinal position can change over time, in reality, the research paradigms and theories used to describe these processes differ only trivially. Indeed, most persuasion research involves cases where no attitude existed prior to exposure to a persuasive message. Hence, most persuasion research directly informs attitude formation research.

Attitudes also vary in important ways, and attitude formation processes have implications for these other attitudinal qualities. For example, attitudes vary in strength, that is, their persistence over time, their ability to predict behavior, and their resistance to counter-persuasion attempts. Stronger attitudes are more likely to form from direct experience with the attitude object as opposed to hearsay or indirect experience. Affectively based attitudes also tend to be better predictors of behavior in many domains, particularly regarding political attitudes and voting behavior. However, evidence from persuasion research indicates that attitudes formed through more thoughtful processes are often stronger. There is also some evidence that attitudes of a biological origin are less malleable.

An attitude's ability to predict behavior is part of its appeal to psychologists, but one should not assume that attitudes should always predict behavior. Specific theories describe when attitudes are likely to predict behavior, and some argue that an attitude's origin must be taken into account when considering whether it might predict behavior. For example, because people are less able to articulate the bases of implicitly formed attitudes, they are less likely to notice their influence. Implicit attitudes are then likely to leak out into one's behavior without one's awareness. For example, racial prejudice, if formed gradually through socialization processes that one rarely acknowledges, is likely to appear in one's less-controllable behavior. For example, in one study, Black participants were able to detect racial prejudice in Whites' nonverbal behavior. Controllable behavior is less likely to be influenced by implicitly formed attitudes and is instead more influenced by explicitly held attitudes.

In conclusion, fundamental goals of the science of psychology include the ability to explain and predict human behavior.

Because attitudes are so central to achieving these goals, attitudes hold a central place in psychology. Further, an understanding of an attitude's origins is useful in understanding its later influences on behavior. This article has addressed several formation processes – affective, cognitive, behavioral, and biological, as well as implicit and explicit. Although the power of each of these formation processes is appreciated by social scientists generally, there is still considerable debate about the role of each (e.g., whether implicit or explicit formation processes are more pervasive). The further reading section provides examples of such debates, as well as more thorough treatments of attitude formation processes in general.

Glossary

Actor–observer effect Attributing other people's behavior to dispositions, but one's own similar behavior to the situation.

Attributional complexity Highly developed attributional knowledge structures.

Causal attribution An inference about why an event or behavior occurred.

Causal uncertainty Doubt about one's abilities in the area of attribution.

Correspondence bias Attributing an event that can be explained by the situation to dispositions.

Dispositional attribution Something about the person caused the behavior.

Implicit theories Beliefs about the fixed or malleable nature of attributes.

Self-handicapping Creating an obstacle that makes it difficult to attribute failure to low ability.

Self-serving attributions Attributing one's successes to dispositions and failures to situational factors.

Situational attribution Something about the person's environment caused the behavior.

Introduction

Causal attribution involves identifying one or more factors as being responsible for bringing about a particular behavior or outcome. In short, it is the answer to the question 'why?' Research has found that this type of thinking can occur spontaneously when we observe another person's behavior. When we overhear a person shouting at a coworker, we may wonder why the person is shouting: Is it because he or she is just a rude person or was the person provoked somehow? Attributions are especially common when we are confronted with an unexpected or negative event. If a spouse suddenly announced that he or she wanted a divorce, the partner would want to know why. If a student failed a test, he or she would want to know why.

Note that there is no single, overarching theory of attribution. Rather, the literature about attribution consists of complementary theories that approach different aspects of the attribution process. The classical theories identify different types of attributions and specify the conditions under which each type should be drawn. Researchers then discovered that people often exhibit various attributional biases. They began to devote their attention to explaining why these biases occur. Contemporary theories focus on the cognitive processes that underlie the attribution process, differentiating the steps that occur automatically from those that take more effort. Increasing attention to individual and cultural differences in attribution has shed light on how basic beliefs about people and various motivations can influence the attributions people make. And lastly, a final set of theories illustrates the implications that different types of attributions have for motivation, well-being, academic performance, and marital satisfaction.

Classical Theories

Heider (1958)

Heider argued that we can learn a lot by examining lay people's understanding of the causes of action. It is their understanding,

right or wrong, that will influence their thoughts, feelings, and behavior. He also argued that causal understanding plays an important role in life. When people attribute transient events to stable underlying factors, they feel that they can predict and control their outcomes.

Heider distinguished between two sets of causes: person and environment. One type of person factor is power, which includes ability, self-confidence, mood, and fatigue. Another person factor is trying, which includes intentions and exertion. Environmental factors include task difficulty, luck, and opportunity. Of primary importance, according to Heider, is understanding the causes of intentional behavior. Intentional behavior occurs when a person consciously or unconsciously tries to bring about a particular consequence. When we can attribute such intentional behavior to stable underlying factors, such as ability or task difficulty, we gain a sense of prediction and control over future outcomes.

How do we know when it is appropriate to attribute an outcome to ability? The level of exertion can be used as a cue. Greater exertion is necessary when power is low or difficulty is high. To keep up with a professional marathon runner, for example, the average person would have to exert a great deal of effort. Thus, when perceivers observe a person successfully perform a difficult task with great ease, they might infer that the person has a high level of ability.

Heider's analysis of attribution sparked a great deal of interest. The task for subsequent researchers was to translate Heider's ideas into hypotheses that could be tested in the laboratory.

Jones and Davis (1965)

Jones and Davis focused on how perceivers infer intentions, and corresponding dispositions, from a person's choices. They argued that perceivers consider the effects of an action and try to figure out which effects were intended (rather than simply incidental or accidental). Perceivers also consider whether the actor was capable of bringing about the effects.

If they conclude that one or more effect was intentionally produced, they then try to figure out what it tells them about the person. They compare the chosen action with other possible unchosen actions. Perceivers attend to non-common effects, or the unique attributes of a chosen alternative. For example, imagine a person choosing from a set of computers or job candidates. If all computers in the set are of the same brand, or if all of the job candidates have expertise in the same area, these factors cannot help a perceiver understand why a person chose one over another. But if the chosen computer is the only one of a particular brand (e.g., the only Mac), or if the chosen candidate is the only one with a particular type of expertise (e.g., the only health psychologist), this factor can potentially tell perceivers something about the person who made the selection.

The social desirability of the effects, or how desirable a particular feature is, also matters. If a choice has several unique attributes, people typically assume that the factor attracting the person to that option was the more desirable one. For example, if the computer chosen was the only Mac and the most expensive, people would assume that the person chose the computer because it was a Mac, not because it was the most expensive. In terms of what one learns about the target, however, more unusual choices and behaviors are more diagnostic. If a person does what anyone else would have done, perceivers do not learn much. But if a target's behavior diverges from that of the average person, perceivers are more likely to draw an inference about the correspondent's disposition.

Kelley (1967)

Kelley's model describes how perceivers analyze behavioral information; typically about a person interacting with a social or nonsocial stimulus. Perceivers consider whether the person's reaction is similar when compared to different people (consensus), stimuli (distinctiveness), and occasions (consistency). Depending upon the information they gather or infer, perceivers may then attribute the reaction to something stable about the person or the entity.

As an example, perceivers may learn that Jennifer likes her English professor. They would then analyze whether the effect (liking) covaries with the person (Jennifer), the stimulus (the English professor), or the particular occasion. Do other people like the English professor? Does Jennifer like her other professors? Has Jennifer always liked this professor? When the cause is present, the effect should be present; when the cause is absent, the effect should be absent. If we find that other people do not like the English professor (low consensus), Jennifer likes her other professors (low distinctiveness), and Jennifer has always liked the English professor (high consistency), we would draw a dispositional inference: something about Jennifer is causing her to like the English professor. However, if we find that other people like the English professor (high consensus), Jennifer does not like her other professors (high distinctiveness), and Jennifer has always liked the English professor (high consistency), we would draw an external attribution: something about the English professor is causing Jennifer to like him or her. Other potential outcomes would lead to attributions of some combination of the person, the stimulus, and/or the particular circumstances.

Abnormal conditions focus model

An alternative way of understanding the role of consensus, distinctiveness, and consistency information in attribution comes from the abnormal conditions focus model. It posits that perceivers contrast a target event with other events, identify any abnormal feature(s) of the target event, and use the abnormal feature(s) to explain the target event's occurrence. When few other people react the same way to a stimulus (low consensus), the target person seems abnormal. For instance, if someone loves a relatively unpopular activity such as filling out a tax return or doing laundry, we may conclude it is due to something peculiar about the person. When a target person responds differently to other stimuli (high distinctiveness), the target stimulus seems abnormal. If a person likes everyone except for one particular coworker, for example, we would wonder about the coworker. When the target person responds differently to the target stimulus over time (low consistency), the present circumstances seem abnormal. If a person does not usually enjoy opera but enjoys it on a specific occasion, we would look to the occasion for an explanation. Perceivers also bring real world knowledge to the table. If an event is an ordinary occurrence (a scripted event that is high consensus, low distinctiveness, high consistency), nothing seems abnormal, and thus, the event does not need to be explained. If we learned that someone ordered food when they were at a restaurant, for example, we would not experience a pressing need to figure out why.

Summary

The classical attribution theories reviewed above established an interest in determining when perceivers attribute intentional behavior to something stable about the person (e.g., abilities or dispositions) or something stable about the situation (e.g., task difficulty or the nature of the stimulus). Each theorist focused on different potential determinants: Heider on the relationships between ability, task difficulty, and exertion, Jones and Davis on the outcomes of various choice options, and Kelley on other potential reactions as a function of differing actors, stimuli, and occasions. Common to all theories, however, is the assumption that it is not always appropriate to conclude that a person's behavior is due to some stable, inner disposition. However, as the next section reveals, people sometimes draw such conclusions even when a person's behavior can be completely explained by the situation.

Biases

Perceivers do not always follow logical rules or use all of the available information when making attributions. This section will review three widely studied biases in the attribution process: the correspondence bias, the actor-observer effect, and self-serving attributions. All of these biases involve a tendency to favor either dispositional or situational attributions for certain types of events.

Correspondence Bias

Logically speaking, people should not attribute a behavior to a corresponding disposition when the situation can explain

the behavior. For example, if a person writes arguments in favor of Fidel Castro after being instructed to do so by his or her debate advisor, a perceiver should not conclude that the author truly likes Fidel Castro. If a person is nervous while discussing anxiety-inducing topics, a perceiver should not conclude that the person is dispositionally anxious. However, studies have found that perceivers continue to draw dispositional inferences in such cases. This tendency is referred to as the correspondence bias, or the fundamental attribution error.

One reason for the bias is that perceivers are sometimes unaware of situational factors or the target's perception of them. If they are unaware that the topics are anxiety-inducing or that the author felt compelled to comply with the debate advisor's request, they cannot be expected to take these factors into account. Additionally, even if perceivers are aware of the situation, they may underestimate its power. They may mistakenly think, for instance, that most people would refuse to write arguments that conflicted with their beliefs. However, even if they were to recognize the full strength of the situation, that knowledge could bias their perceptions of behavior. Knowing that the person is discussing anxiety-inducing topics could make the person's behavior seem more anxious than it would otherwise seem. This type of influence is more likely to occur when the behavior is somewhat ambiguous. Lastly, as I will explain later, it can require greater effort on the part of the perceiver to factor in situational information. Thus, if perceivers are either unmotivated or unable to think carefully, they would not be expected to adjust their attributions in light of situational information.

Another factor that can encourage people to draw dispositional inferences is the motivation to maintain a belief in a just world. When another person experiences a negative outcome (e.g., homelessness, assault), blaming the person allows the perceiver to keep believing that the world is just and fair. It also can create a false sense of security; perceivers may believe that as long as they take the right precautions, they will be able to prevent negative outcomes.

Actor–Observer Effect

Although perceivers are likely to underweight situational information when explaining someone else's behavior, they are better at taking it into account when explaining their own behavior. For example, one study found that when interacting with another person, people attributed their own behavior to the situation, but their partner's behavior to his or her personal characteristics. This is known as the actor–observer effect. Researchers have discussed several reasons for this effect. First, actors are more aware of their feelings, intentions, prior situational factors, and past behavior than are observers. Second, situational factors are more salient to actors whereas behavior is more salient to observers. When engaged in an interpersonal interaction, we may further be cognitively occupied, unable to estimate the effect that we are having on the other person. We may also focus on how the other person differs from us since the environment is shared. Lastly, our tendency to see others primarily in dispositional terms may be sustained when we have limited opportunities to observe them across a variety of situations.

Self-Serving Attributions

Some researchers have argued that the motivation to feel good about oneself can affect the extent to which actors attribute their behavior and outcomes to situational factors. This motivation can lead people to make internal attributions for their positive outcomes and behaviors, and external attributions for their negative outcomes and behaviors. For example, one study found that participants who lost a game attributed their negative outcome less to skill and more to luck than did their opponents. Conversely, participants who won the game attributed their positive outcome more to skill and less to luck, compared to their opponents. Other researchers have argued that results like this can be explained without drawing on motivation. For instance, actors may perceive that their behaviors are connected to a greater extent with their positive outcomes than with their negative outcomes. Additionally, given that people typically intend to succeed and expect success, negative outcomes may be unexpected, and thus attributed to situational factors such as bad luck.

Automatic and Controlled Components

The classical attribution models reviewed in the first part of the article were primarily descriptive. Contemporary models delve into the underlying cognitive processes. Specifically, they break the attribution process into different stages or systems. They distinguish between relatively automatic processes and more controlled processes. Automatic processes are those that are efficient, unintentional, involuntary, or occur outside of awareness. Controlled processes are just the opposite: effortful, intentional, voluntary, and aware. These dual process models shed additional light on attributional biases, especially the correspondence bias. I will first describe three prominent dual process models, and then discuss two lines of research that illustrate specific issues relevant to the automatic and controlled ends of the processing spectrum.

Gilbert's Model

Gilbert's model of person perception focuses on the efficiency of different stages of the attribution process. According to his model, people first categorize behavior (e.g., she is being rude) and then characterize the person in dispositional terms (e.g., she is a rude person). These two stages are relatively automatic (efficient). The third stage involves factoring in the situation (e.g., she was just insulted), and it requires greater cognitive effort. Thus, if perceivers are unmotivated or unable to think carefully, they will not make it to the third stage. This model helps us predict when the correspondence bias is especially likely to occur: whenever perceivers lack the motivation or ability to engage in the final stage of processing.

A common methodology used to test Gilbert's model places some perceivers under cognitive load by having them rehearse a series of digits while learning about and rating a target person. Their judgments will be the product of only automatic stages (categorization and characterization), as they do not have the cognitive resources available to engage in the controlled stage (factoring in the situation). Researchers then

compare their judgments to judgments made by undistracted perceivers. Such studies typically find that cognitive load prevents perceivers from factoring in situational information.

However, other researchers have noted that situational information is not inherently more difficult to consider. If it is particularly salient, even distracted perceivers can use it to explain behavior. Additionally, if a perceiver's initial goal is to figure out the situation, he or she can automatically categorize the behavior (e.g., she is being rude) and characterize the situation (e.g., this is an aggravating situation). In the latter case, factoring in dispositional factors requires greater effort.

Trope's Model

Trope's model of person perception can easily accommodate the finding that people sometimes make relatively automatic situational attributions. In his model, perceivers automatically identify behavior and then engage in either diagnostic or pseudodiagnostic attributional reasoning. Diagnostic reasoning involves thinking about multiple potential causes (dispositions and situations), and it requires motivation and ability. Pseudodiagnostic reasoning is easier, but it focuses on a single cause (disposition or situation). So when situational information is made especially salient, it can be the focus of pseudodiagnostic reasoning, which can take place even under cognitive load.

Trope's model also goes into more detail about how salient information about the person and the situation can bias the early, relatively automatic stage of behavior identification. For instance, studies have found that perceivers will judge an ambiguous expression as sadder if they think a person was at a funeral when the picture was taken. This is an example of an assimilation effect, where perceivers see the behavior in line with the context (sad situation, sad expression). However, contrast effects can also occur, where judgments move away from the context. Several studies have found that exposure to a highly successful performance can make a subsequent performance seem less successful. This effect happens when perceivers are under cognitive load, indicating that it is automatic. Indeed, when perceivers are not under cognitive load, they correct for the influence. The latter finding also indicates that perceivers may correct for a number of factors (e.g., exposure to other targets) and not just situational factors when they are motivated and able.

Social Neuroscience Approach

Building on their interest in the automatic and controlled components of attribution, researchers have recently turned their attention to the neural substrates of attribution. They have proposed an X-system that carries out automatic, reflexive operations, and a C-system that carries out reflective, controlled operations. According to this model, the lateral temporal cortex, amygdala, and basal ganglia are involved in the X-system. Current experience is processed in a stream of consciousness fashion, interpreted through the lens of relevant past experience and current goals. The C-system comes online when the anterior cingulate sounds an alarm, indicating that further processing is needed. The prefrontal cortex and hippocampus then help perceivers use symbolic logic to make sense

of existing events. The social neuroscience approach opens up a new realm of possibilities for understanding and studying attribution.

Spontaneous Trait Inferences

Research on spontaneous trait inferences bears on the automatic side of the processing continuum, but focuses more on intentionality and awareness rather than efficiency. This research examines whether people spontaneously infer corresponding traits as causes of behavior. For example, if I read that Bob gave Sarah half of his sandwich, I may spontaneously infer the trait 'generosity.' Participants in these studies are typically asked to read sentences that describe behaviors, and then are prompted to recall the sentences with one of a number of prompts: the corresponding trait term (generous), the gist of the behavior (shared), or words that are semantically related to parts of the sentence (bread). Numerous studies have found that the trait terms help participants recall the sentences, suggesting that participants spontaneously inferred the traits when reading the behavior. This occurred even though participants had not been instructed to form impressions and even when the sentences were presented as a distracter task, indicating that the inferences were unintentional. Furthermore, participants tended to be unaware that they were drawing trait inferences. Thus, this research supports the idea that parts of the attribution process can occur automatically.

Trait-Behavior Relations

Research on trait-behavior relations allows us to better understand the corrections that may occur at the controlled end of the processing continuum. That is, to fully understand correction, we need to think about different kinds of traits and how they map onto behavior. When dealing with capacities or abilities, like intelligence or athletic ability, highly skilled people may perform well or poorly (e.g., if they are not trying), but unskilled people will typically perform poorly (assuming the task is at least moderately difficult). A poor performance, then, could be due to lack of capacity, or to situational factors such as direct instruction from others to perform poorly or the motivation to save an opponent from embarrassment. However, because an unskilled person is not capable of executing a highly skilled performance, a highly successful performance is diagnostic of high ability. Thus, even if perceivers are motivated to correct their dispositional inferences for any relevant situational factors, a consultation of their trait-behavior theories would tell them it is logical to assume that a highly successful performance is due to high ability, even if situational factors also encouraged success (e.g., trying to impress an audience or wanting to win a cash prize).

A similar asymmetry occurs with morality-related traits such as honesty. In this case, however, it is the immoral person who exhibits a greater range of behaviors. This type of person may behave morally some of the time and immorally at other times. However, a moral person should behave morally at all times. We learn more about a person, then, when we observe an immoral behavior. Even if a situational factor encouraged immoral behavior (e.g., another person suggested that the target person lie or steal), perceivers may not adjust their

dispositional inferences. Instead, they may maintain that a person who commits immoral acts is immoral. Moral behavior is more ambiguous, though, so perceivers would be more likely to correct their dispositional inferences in light of relevant situational pressures.

Perceiver Differences

Thus far, perceivers have been treated as interchangeable. Given certain information and certain processing constraints, perceivers will follow similar processes and arrive at similar conclusions. Indeed, that is the social psychological approach – to look for commonalities in people’s responses to social stimuli. However, we gain a deeper understanding of the attribution process by examining how perceivers differ from one another in experience and motivation. This section will examine individual and cultural differences in attribution.

Individual Differences

Researchers have identified a number of individual differences that are directly relevant to attribution. I will focus here on three: attributional complexity, causal uncertainty, and implicit theories about attributes. These constructs have been found to moderate classic attribution effects, such as the correspondence bias.

Attributional complexity

Attributional complexity includes a high level of interest in causal explanations, a preference for more complex, abstract, and temporally distal explanations, greater thought about the attribution process, and greater awareness of the influence that people have on each other. Psychology majors are higher in attributional complexity than natural science majors. There is also some evidence that women are higher in attributional complexity than men. People who are high in attributional complexity generate more causes when describing a friend’s personality, and when making attributions for hypothetical events, they prefer explanations that address more than one potential cause. Additionally, one study found that people who are high in attributional complexity are less susceptible to the correspondence bias. Their more intricate causal schemas make them more sensitive to situational constraints when judging others.

Causal uncertainty

Causal uncertainty refers to doubts about one’s ability to understand the causes of events in the social world. Such doubts can be triggered by a loss of perceived control over events in one’s life, and once in place, causal uncertainty can further undermine a person’s sense of control. Men and women do not differ in their levels of causal uncertainty, but causal uncertainty is associated with depression, anxiety, and low self-esteem. Because it threatens control and causes one to feel bad, people are highly motivated to resolve causal uncertainty. As long as they think there is some chance that their efforts will pay off, causally uncertain perceivers should attempt to improve their understanding of events. They may start with relatively automatic strategies for understanding and

progress to more effort-intensive strategies if needed. Automatic strategies could include accessing stored schemas and heuristics. Controlled strategies could include gathering and carefully processing causally relevant information. Consistent with the idea that they use controlled processing to improve their understanding, studies have revealed that individuals who are high in causal uncertainty are less susceptible to the correspondence bias. As long as their cognitive load does not prevent them from doing so, they carefully consider situational constraints when judging others.

Implicit theories

Implicit theories refer to people’s beliefs about the nature of attributes such as personality, intelligence, and morality. Entity theorists think that such attributes are fixed, whereas incremental theorists think that they are malleable. These beliefs have implications for the attribution process. Entity theorists place a high value on dispositional inferences and readily draw them based on small samples of behavior. Furthermore, they tend to generalize to broader attributes and assume those attributes will remain relatively stable over time. To entity theorists, dispositional inferences provide an explanation for why a particular behavior or outcome occurred. Incremental theorists draw dispositional inferences as well, but they are more responsive to new contradictory information, they generalize less, and assume less stability. They focus more on the situational context and a person’s strategy, effort, goals, and intentions. To incremental theorists, dispositional inferences simply summarize a person’s behavior in a particular situation.

Researchers have examined how these differing beliefs affect judgments about the self and others. Implicit theories predict responses to setbacks. When people receive news that they performed poorly on a test, entity theorists draw negative, global inferences about their abilities, while incremental theorists focus more on strategy and effort. When judging another person’s negative behaviors, entity theorists draw more global and stable negative dispositional inferences and recommend greater punishment. More troubling, they more readily draw inferences about morality from a person’s appearance, and base their verdicts upon these inferences rather than the strength of evidence presented in a criminal case. Thus, implicit theories about the malleability of attributes, which differ across individuals and domains, help us predict the extent to which perceivers will draw correspondent dispositional inferences from behavioral information.

Cultural Differences

Just as individuals differ from one another in attributionally relevant beliefs, so do cultures. Different thinking styles prevail in western (European American) and eastern (East Asian) cultures. People in western cultures tend to think analytically, focusing on objects and individuals. People in eastern cultures tend to think holistically, focusing on the context in which objects and individuals are located. These styles affect the ways in which people in the two types of cultures view themselves and others. Westerners use more abstract traits to describe themselves and others, whereas Easterners refer more to specific contexts and social identities. Furthermore, a number of studies have revealed that Easterners are less susceptible

to the correspondence bias than are Westerners when situational constraints are made salient (e.g., they just experienced the same situational constraint themselves). However, when situational constraint information is available but not salient, both groups show the correspondence bias.

In some respects, Easterners and Westerners share similar views of dispositions. They have similar conceptualizations of personality and predict that people engaging in a certain type of behavior once will engage in similar types of behavior in the future. Furthermore, when dispositional and contextual explanations are assessed separately, Easterners and Westerners typically differ in the amount of contextual explanation, but not always in the amount of dispositional explanation. However, there are subtle differences in their views of dispositions. Easterners are more like incremental theorists, while Westerners are like entity theorists. Thus, Easterners see dispositions as malleable, and they also acknowledge the role of the context in shaping dispositions. Lastly, Easterners are more likely than Westerners to attribute causality to a group, rather than to an individual.

In sum, while basic social psychological research provides a good starting point for common biases in the attribution process, research on individual and cultural differences sheds light on moderating factors. Individuals who are high in attributional complexity or causal uncertainty, or who subscribe to an incremental theory or Eastern culture are more likely to consider situational constraints on behavior.

Implications

Motivation and Psychological Well-Being

Up until now, I have focused primarily on the degree to which perceivers see the cause of a behavior or outcome as internal or external. However, there are meaningful differences within these two general categories. Some factors (ability, task difficulty) are more stable than others (effort, luck). In addition, some factors (effort) can be controlled more easily than others (luck). Lastly, some factors (social skills) affect a broader range of events than others (ability to remember names).

These dimensions affect a person's motivation level as well as their overall psychological well-being. The attributions people make for an unsuccessful performance (e.g., a low test score or negative job evaluation) can greatly affect their motivation. If people attribute the failure to insufficient effort (an internal, unstable, and controllable factor), improvement will seem possible and motivation can be maintained. However, if they attribute the failure to a lack of intelligence (an internal, stable, uncontrollable factor), improvement will seem unlikely and motivation may decline. Research has revealed that people who are depressed tend to make the latter type of attribution, and furthermore think the cause will affect many other outcomes. This stands in contrast to the self-serving attributions mentioned earlier, where people attribute failures to external factors.

Self-Handicapping

People sometimes try to manipulate plausible attributions in order to prevent people from attributing their failure to a lack

of ability. Specifically, when individuals doubt their ability to succeed, they sometimes withdraw effort or engage in an activity that interferes with their performance. Because any one of these factors can explain a failure, it becomes more difficult to attribute the failure to a lack of ability. This type of behavior is known as self-handicapping. As one might imagine, it can have negative implications for performance in the classroom and beyond.

Marital Satisfaction

Attributions can also affect how we feel about the important people in our lives. Research has revealed that the type of attributions married people make about their spouses' behaviors are associated with their levels of marital satisfaction, emotions, and behavior. Relationship researchers have distinguished between *causal* attributions, or judgments about who or what brought about an event, and attributions of *responsibility* and *blame*, or judgments about who is accountable and at fault for an event, respectively. These attributions tend to build on each other, with internal attributions potentially leading to responsibility attributions, and responsibility attributions potentially leading to blame attributions. However, in marriage, responsibility and blame tend to co-occur. To measure causal attributions, researchers have presented individuals with hypothetical negative partner behaviors and asked them to rate the extent to which something about the partner caused the behavior (locus), as well as whether the reason will change (stability) and affect other parts of their marriage (globality). Unsatisfied individuals tend to attribute negative partner behaviors to causes that are internal (something about the partner), stable (not likely to change), and global (will affect many other areas). Responsibility/blame attributions are assessed by having individuals rate whether the negative partner behaviors were intentional, selfishly motivated, and blameworthy. Greater responsibility/blame attributions are associated with less marital satisfaction, and during an interaction, greater anger (wives only) and whining (husbands and wives).

Findings from longitudinal studies have supported the idea that a negative attributional style predicts decreases in marital satisfaction over time. There is also some evidence for the opposite path as well: low satisfaction sometimes predicts the development of a more negative attributional style over time. Importantly, these relationships held up when related variables such as depression were controlled.

Conclusion

Over 50 years of attribution research has shed much light on the processes people use to understand the causes of events, the biases they exhibit along the way, the beliefs that impact people's attributions, and the implications of particular attributions for important domains. We see that people can spontaneously and efficiently draw dispositional inferences about others. Sometimes they stop here, and if they have neglected relevant situational information, they would be said to have shown the correspondence bias. Perceivers are more likely to factor in situational constraints if they are motivated and able (due to accuracy motivation, attributional complexity, causal

uncertainty, lack of cognitive load), if the situational information is salient, and if their beliefs encourage such a consideration (incremental theories, Eastern cultures, trait-behavior relations). Furthermore, we see that certain types of attributions can enhance functioning. Specifically, attributing a negative performance to a lack of effort, rather than ability leaves room for improvement. Attributing negative partner behavior to external, unstable, and specific factors helps people maintain positive views of their relationships. Finally, we see the difficulties that people face when they lack confidence in their ability to understand the causes of events. This relatively new research on causal uncertainty supports assertions that Heider and others have made that understanding why events occur is critical for a sense of prediction and control over one's environment.

Glossary

Diagnostic criteria The established guidelines for a specific diagnosis that include the specific behaviors, the course of symptom development, and characteristics an individual must exhibit.

fMRI Functional magnetic resonance imaging, used to observe brain functioning.

Prevalence The number of people in the population who have a particular characteristic or diagnosis. Often expressed as the observed number per 10 000 people.

Stereotyped A rigid repetition of a specific behavior or activity that is often nonfunctional.

Stress A negative physical or emotional reaction to events or series of events in the environment that may or not produce similar effects in other individuals.

Stressor An event or series of events or interactions that can precipitate a negative emotional or physical reaction.

Perspective

Leo Kanner first described the syndrome of autism in the early 1940s. There are long historical roots to the conceptualization of severe early childhood disturbance, primarily referring to dementia and intellectual limitations. A few detailed accounts of individual cases, such as Itard's classic description of the wild boy of Aveyron, provide clear examples of the confusion that existed as to how to best conceptualize severe pathology in children. Descriptions of educational programs in the mid-1800s have fascinating detail of treatment programs and individuals who today would most likely be diagnosed as having autism. The term autistic was first used by Eugene Bleuler in the early 1900s to describe a specific thought process characterized by poor logic and a detachment from reality, but was not in reference to a specific disorder.

These historical accounts were at times very systematic descriptions and provide interesting continuity to the present. What was lacking was effective formal differentiation or diagnostic criteria. Kanner is credited for identifying the syndrome and asserting its distinguishing characteristics that set it apart from other severe disorder categories of the time. He provided clear description of an initial group of eight boys and three girls, drawn from the very large pool of his clinical experience as a psychiatrist at John Hopkins. He chose the term 'autism' to describe his observations, a term also associated with the description of social withdrawal in schizophrenia. However, Kanner's perspective was quite different. Unfortunately, there still persists a popular but simplistic image of individuals with autism solely as being withdrawn and retreating from social interaction. Kanner used the description 'aloof' to describe the type of social interactions, and lack thereof, that he observed. 'Aloof' better describes the feeling of detachment often observed in social interactions of individuals with autism, connoting more of a detachment than withdrawal in the emotional sense.

Kanner identified almost a dozen specific characteristics that he associated with the syndrome he termed early infantile autism. Some of these were: aloofness, excellent rote memory, echolalia, pronoun reversal, an intense desire to maintain sameness, alert

expression, poor eye contact, appearance of being deaf, no anticipatory reaching out from infancy, lack of social and communication initiation, normal intelligence (as assessed by the Seguin Form Board), and normal motor coordination.

In his description of the 11 children that he presented, he noted considerable variation in the number and severity of behaviors observed, but he conceptualized the syndrome as primarily an 'autistic disturbance of affective contact' and later he utilized the term 'early infantile autism.' Importantly, however, he saw the primary feature as the inability to relate to other people and situations from infancy. He specifically contrasted his syndrome with others such as Heller's dementia infantilis and DeSanctis' dementia praecocissima in that these are characterized by a period of normal development prior to symptom onset. In contrast, Kanner stressed the presence of symptoms from infancy: hence the use of the term 'early infantile autism.' This emphasis on the presence of autism from birth was maintained by Kanner when he stated almost 30 years later that the primary characteristics for autism were '(a) the children's inability from the beginning of life to relate themselves to people and situations in the ordinary way and (b) an anxiously obsessive desire for the preservation of sameness.' However, as various researchers have pointed out, by focusing on just the social isolation and preservation of sameness, this reduced the number of symptoms thought to be part of the syndrome, and may have inadvertently led to overly broad diagnostic criteria.

Diagnosis

Terminology

As listed in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) of the American Psychiatric Association, the current standard for diagnosis, the pervasive development disorders (PDDs) include: autistic disorder, Asperger's disorder, Pervasive developmental disorder-not otherwise specified (PDD-NOS), Rett's disorder, and childhood disintegrative disorder. With a very rapid rise in the diagnosis of autistic disorder over the past two

decades, the attention directed at the PDDs has increased. However, the terms used to describe the disorders within the PDDs have grown imprecise. Terms such as 'autism spectrum disorders' and 'ASD,' which do not appear in the DSM-IV-TR, are often used as if they were a diagnosis, are frequently used interchangeably with PDD and autistic disorder. The lack of clarity when using such terms creates confusion, particularly among consumers. The inconsistent use of such terms is not limited to just the popular media, but is also observed in professional writings. Websites and publications often use the term ASD to describe individuals without specifying which DSM diagnostic categories individuals actually fall into, and in what proportion, for the research article or description presented. In addition, national organizations such as the National Institute of Mental Health (NIMH) and the American Academy of Pediatrics differ in their use of the term ASD. The NIMH includes all of the disorders within the PDDs as part of their definition of ASD whereas the American Academy of Pediatrics includes only autistic disorder, Asperger's disorder, and PDD-NOS under their use of the term ASD. **Figure 1** illustrates the DSM-IV-TR PDD categories and the partial overlap of the term ASD by the two organizations.

A related problem is the use of descriptive labels for presumed subcategories of autistic disorder that also have yet to be adequately defined. For example, the terms high-functioning autism and low-functioning autism are widely used, often in the context of presumed severity and prognosis; yet they have no reference in the DSM-IV TR. The term high-functioning autism typically is used to refer to individuals with a diagnosis of autistic disorder who have adequate verbal language abilities and an average or above-average level of cognitive ability. Individuals described as having high-functioning autism present with symptoms that are clinically similar in a number of ways to that of individuals with Asperger's disorder. However, there is strong debate in the field as to whether there are meaningful clinical and prognostic differences between individuals diagnosed with Asperger's disorder and those described as having high-functioning autism. This is an important area of research that has begun to receive more attention, as it might have implications for the study of etiology, response to treatment, type of treatment recommended, and prognosis. Currently the term high-functioning as a qualifier for autism is not consistently defined and creates potential diagnostic overlap. This can lead to problems when interpreting research and clinical descriptions.

Related to this concern, proposals for subtyping within autistic disorder, which could be essential for both clinical and etiological research, have come primarily from clinical observation. Perhaps the most cited proposed subtyping comes from Lorna Wing and her colleagues who describe three subtypes: aloof, passive, and active-but-odd, to explain observations as to the variation in types of social deficits. Recent research questions the validity of these specific categories, but does support the presence of subtypes, with replication of research findings required for more precise specification.

Symptomatology

The three most prevalent PDDs are autistic disorder, Asperger's disorder, and PDD-NOS, which from here forward will be referred to as ASD. While they each have separate diagnostic criteria, the DSM-IV-TR outlines three core characteristics of interest that are associated with these three disorders. These include:

- Impairment in social interaction
- Impairment in communication (specifically as used in social situations)
- Stereotypic, repetitive behaviors, and restricted interests

Diagnostically, the difference between the disorders lies in the severity and nature of each of these core characteristics and their pattern. **Table 1** provides a comparison of the three disorders across the three core characteristics. A description of the specific behaviors associated with each of the core characteristics of interest follows.

Impairment in social interaction

Kanner's initial description of autism highlighted the deficits in social interaction as central to the disorder. Currently, these deficits are still considered to be the most important of the core deficits. Some have argued that these social interaction deficits, because of their specific manner of expression and pervasive nature, are what differentiate ASD from other clinical populations who also show social interaction problems.

As listed in the DSM-IV-TR, impairments in social interaction include: (1) deficits in nonverbal behaviors such as eye-to-eye gaze, facial expression, and gestures to regulate social interaction; (2) failure to develop peer relationships

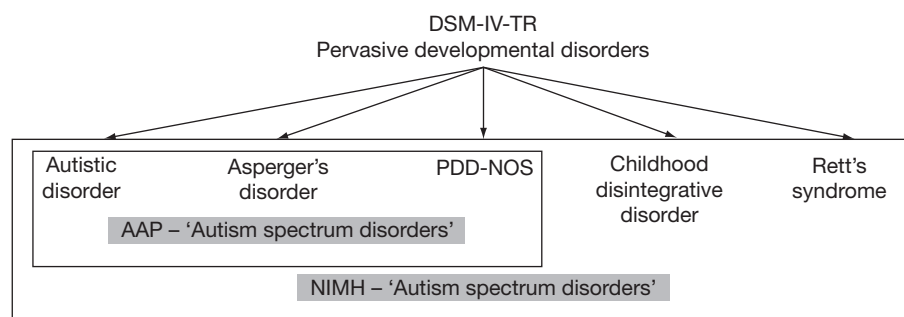

Figure 1 A comparison of definitions of autism spectrum disorders.

Table 1 A comparison of core diagnostic characteristics for autistic disorder, Asperger's disorder, and PDD-NOS

	<i>Autistic disorder</i>	<i>Asperger's disorder</i>	<i>PDD-NOS</i>
Age considerations	Delay in at least one area is present prior to the age of 3.	After 36 months	None specified
Marked impairment in social skills	At least two of the following must be present: <ul style="list-style-type: none"> – Marked impairment in the use of multiple nonverbal behaviors (eye-to-eye gaze, facial expression, body postures, and gestures) to regulate social interaction – Failure to develop peer relationships appropriate to developmental level – Lack of spontaneous seeking to share enjoyment, interests, or achievements with others – Lack of social or emotional reciprocity 	Same criteria as autistic disorder	Severe and pervasive impairment in development of social interaction
Marked impairment in communication	At least one of the following must be present: <ul style="list-style-type: none"> – Delay in, or total lack of, the development of spoken language (without attempts compensate through alternative means) – Marked impairment in the ability to initiate or sustain conversation with others – Stereotyped and repetitive use of language or idiosyncratic language – Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level 	No clinically significant delay in language development present	Impairment in either verbal and/or nonverbal communication skills and/or presence of stereotyped behavior, interests, and activities
Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities	At least two of the following must be present: <ul style="list-style-type: none"> – Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus – Apparently inflexible adherence to specific, nonfunctional routines or rituals – Stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole-body movements) – Persistent preoccupation with parts of objects 	Same criteria as autistic disorder	Presence of stereotyped behavior, interests, and activities and/or impairment in either verbal and/or nonverbal communication skills
Other considerations	Behavior not better accounted for by Rett's disorder or childhood disintegrative disorder	<ul style="list-style-type: none"> – Behavior causes clinically significant impairment in social, occupational, or other important areas of functioning – No clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior, and curiosity about the environment in childhood – Criteria not met for another specific PDD or schizophrenia 	Criteria not met for a specific PDD, schizophrenia, schizotypal personality disorder or avoidant personality disorder

appropriate to developmental level; (3) lack of spontaneous seeking to share enjoyment and interests (e.g., by a lack of showing, bringing, or pointing out objects of interest); and (4) lack of social or emotional reciprocity.

Social deficits observed in children with ASD include difficulties understanding the facial expressions of others, initiating social interactions, responding to the social bids of others, and responding to the emotions of others. Research has also

identified specific social behaviors that differentiate children with ASD from typically developing children at 2 years of age. These behaviors include:

- decreased attention to the voices of others (e.g., failing to respond to their name when called);
- the use of another's body as a tool (e.g., taking another's hand and putting it on a toy in an attempt to have the person turn it on);
- little to no interest in other children (e.g., preferring to engage in isolated play when with other children, failure to initiate social interactions with peers, indifference to the activities of other children);
- limited use of pointing to communicate with others;
- deficits with understanding gestures;
- lack of seeking to share enjoyment with others (e.g., not showing items of interest to an adult or peer or directing the attention of others to events in their environment).

Joint attention behaviors have been an area of particular interest for researchers and clinicians studying social deficits in ASD as it has been proposed that this specific deficit of joint attention is specific to ASD and not observed typically in other clinical populations. Joint attention has been described as using gestures and mutual eye gaze to share interest, enjoyment, and attention. Examples of these joint attention behaviors include: a child shifting his or her gaze between an interesting object and a familiar person, combining gaze shift and pointing to direct another individual's attention to an object of interest in the environment, or showing a toy to someone as part of initiating a social interaction. Whereas typically developing children begin to exhibit joint attention behaviors around 15 months of age, joint attention deficits tend to be a characteristic of individuals with ASD throughout their lives. Other behaviors observed early in the social development of typical children that are problematic in individuals with ASD include, but are not limited to: imitation, social play, friendship-seeking behavior, comfort seeking, responding to the facial expressions of others, and cooperative play.

Striking in some, the social deficits in others with ASD are more subtle. For example, individuals with Asperger's disorder display many of the social difficulties described above, but in particular have a difficulty identifying and interpreting the social cues of others. Some research has shown that some individuals with Asperger's can learn skills, such as how to correctly identify emotions and other social cues. However, they often have difficulty using those skills in their everyday environment, making the development of friendships and maintenance of social relationships difficult. Complicating the picture further, individuals with Asperger's possess typical cognitive and verbal abilities. They are often aware of the fact that they are socially different from others, and it is not uncommon for them to express frustration with these issues, placing them at risk for a number of other issues including lower academic achievement, depression, and anxiety. Further, the changing nature and often emotional intensity of adult social and sexual relationships present great difficulty for individuals with Asperger's disorder.

Impairment in communication

The communication deficits observed in individuals with ASD can vary. A delay in the development in expressive language is

observed in some, others may never develop meaningful speech, and some may have no delay in the development of speech but have difficulty with the more pragmatic aspects of conversation. It is often estimated that up to 50% of individuals with autistic disorder do not develop spoken language, whereas to receive a diagnosis of Asperger's disorder, individuals must not have had any delays in the development of spoken language.

It is estimated that a majority of individuals with ASD fail to develop spoken language. Whereas children with speech delays typically compensate for their difficulties through the use of nonverbal communication (e.g., physical gestures, pointing, eye contact), individuals with ASD do not. For individuals with autistic disorder, these areas of nonverbal communication are either absent or noticeably impaired throughout their development. A large body of research has been devoted to assessing and developing methodologies to teach individuals with ASD, who do not have spoken language, alternative methods (e.g., sign language, pictures) of communication. A number of different strategies have been successful for teaching individuals with ASD to communicate their wants and needs. However, even when these individuals acquire an alternative means of communication, the use of communication to initiate social interactions and conversations tends to remain deficient.

The language of individuals who develop expressive speech is often rote, repetitive and can be lacking in communicative meaning. Echolalia is a characteristic of speech patterns in the majority of individuals with autistic disorder. Echolalia is the repetition of the speech of another person or oneself and it can be immediate (i.e., repeating a word, phrase, or sentence immediately after it is spoken by someone else) or delayed (i.e., repeating speech heard in the past). Although echolalia often appears to be unrelated to an individual's environment, there is some question in the field as to whether there is a communicative function of echolalia for individuals with ASD.

When functional language does develop, pragmatic deficits often persist. Such deficits include: difficulties with 'turn-taking' in conversation, and preoccupation with one conversational topic. For example, individuals with Asperger's disorder have the verbal abilities to carry on a conversation but typically choose to keep the conversation focused on a specific topic of interest, be indifferent to requests to change topics, and have difficulty taking turns in the conversation.

The prosody and intonation of speech are also impaired in individuals with ASD. Prosody, the rhythm of spoken language, helps a speaker add specific meaning to a phrase or sentence. For example, when asking a question, most individuals raise their voice slightly at the end of the sentence, helping a conversational partner understand the intent of a sentence or phrase. Individuals with ASD typically have abnormal intonation and use of rhythm and stress in speech production. Other characteristic speech abnormalities include pronoun reversals, articulation difficulties, and idiosyncratic use of speech, including the development and use of neologisms.

Stereotyped and repetitive behavior

The broad category of restricted and repetitive behaviors in individuals with ASD includes self-stimulatory behavior (e.g., repetitive finger movements, gazing at lights, rocking,

toe walking), stereotypical motor behavior (e.g., posturing), preoccupation with objects and activities, insistency with sameness or inflexibility in routines, and restrictive interest in objects or activities. Parents of young children with ASD may notice that their children play with toys in an odd manner. Rather than using cars or blocks for pretend play, children with ASD may prefer to line up toys according to attributes such as shape, size, or color. Children with ASD may also become preoccupied with one part of a toy and their toy play may become restricted (e.g., spinning the wheel of a toy truck over and over). In addition, individuals may develop interests in specific types of toys or collections, which are greater in intensity than seen with typically developing individuals.

When compared, the toy play of individuals with ASD shows clear differences from the play of typically developing children. Children with autism exhibit limited functional and symbolic play, atypical play preferences, lack of creativity and flexibility in their play, and limited capacity for imitation. Children with ASD also use less appropriate, less varied, and more repetitive play. Changes in routines can also be difficult for individuals with ASD. Children with ASD often exhibit a desire for sameness in their environment. Disruptions in daily routines, or changes in their environment (e.g., rearranging furniture in a common room) can precipitate behavior problems (e.g., crying, tantrum throwing) in children with ASD.

Repetitive behavior in individuals with ASD may also manifest itself as a persistent, focused, and intense preoccupation. For example, an individual may become fixated on learning everything there is to know about train schedules. For others, it may be clocks, maps, radios, or a particular sports team. These focused interests differ from hobbies or more typical interests of others, by their exclusive focus. For example, many typically developing individuals are passionate about a particular sports team. They enjoy watching their team play, talking to others about the team, wearing the team colors, and reading about them. An individual with ASD who is fixated on that same team may know all of the numbers for every player who has been on that team and their home towns, but does not necessarily enjoy watching the team play, and cannot carry on a conversation about that team beyond what numbers the players wore or from where they came. Individuals with ASD might talk at length about a specific area of interest, even after the conversational partner has displayed disinterest in the topic or attempted to change the topic of conversation. Further, the typical fan, no matter how devoted, is able to carry on social conversations on other topics, whereas the individual with ASD often has great difficulty in exhibiting this type of flexibility.

Prevalence

For decades after Kanner's publication, autism was thought to be extremely rare. In the 1960s, it was estimated to affect less than 1% of the population. Research conducted in the 1980s and 1990s presented a different picture with prevalence rates almost 10 times what were reported previously. Most recent figures released from the Center for Disease Control report the prevalence rates of ASD between 45/10 000 and 67/10 000. While the prevalence statistics have changed over time, the ratio of diagnosis between boys and girls has remained fairly

consistent. It is estimated that the rate of ASD is 3–4 times higher in boys than in girls. The increase in prevalence statistics has led some to conclude that we are experiencing an epidemic while others make arguments that the explosive increase in the prevalence of ASD does not reflect a single cause epidemic in the typical sense, but rather may be the result of changing diagnostic criteria, diagnostic substitution, early identification programs, increased services specific for individuals with ASD, and increased awareness.

Changes in Diagnostic Criteria

In the 1950s Kanner and Eisenberg published a list of criteria for early infantile autism. Their criteria included aloofness and indifference to others, and an intense resistance to change in the child's own repetitive routines. They also specified that these behaviors needed to be present before 24 months of age.

Michael Rutter, a researcher working primarily in Great Britain, suggested in 1978 modifications for the definition of childhood autism. He presented four criteria: (1) Impaired social development, which has a number of special characteristics out of keeping with the child's intellectual level; (2) Delayed and deviant language development that also has certain defined features and is out of keeping with the child's intellectual level; (3) Insistence on sameness as shown by stereotyped play patterns, abnormal preoccupations, or resistance to change; and (4) Onset before 30 months. Rutter further gave examples of the behaviors based on his own research and clinical experience, as well as on Kanner's descriptions.

Autism was formally recognized in the DSM, in 1980, with the publication of the Diagnostic and Statistical Manual Third Edition (DSM-III). Referred to as Infantile Autism, it was included under a new class of disorders – the PDDs. To receive a diagnosis, individuals had to meet six mandatory diagnostic criteria. The criteria included onset before 30 months of age; a pervasive lack of responsiveness to other people; gross deficits in language development; when speech is present, peculiar speech patterns such as immediate and delayed echolalia, metaphorical language, and pronoun reversal; bizarre responses to various aspects of the environment (e.g., resistance to change, peculiar interest in or attachments to objects); and the absence of delusions, hallucinations, loosening of associations, and incoherence as observed in individuals diagnosed with schizophrenia.

Seven years later, the diagnostic criteria were modified with the publication of the revised edition of the DSM-III (DSM-III-R). Now referred to as autistic disorder, the diagnostic criteria were divided into three main categories (impairment in reciprocal social interaction, impairment in verbal and non-verbal communication, and restrictive repertoire of activities and interests) with specific behaviors (16 total) listed under each one. To receive a diagnosis of autistic disorder, individuals had to exhibit at least 8 of the 16 behaviors listed, with two from the reciprocal social interaction category and at least one from each of the other categories. Onset also needed to occur in infancy or early childhood. Described earlier, the criteria were further modified with both the publication of the DSM-IV and the DSM-IV-TR.

Studies comparing DSM-III to DSM-IV have found that the DSM-IV broadened the diagnostic criteria of autistic disorder.

To examine the effect that changes in the diagnostic criteria could have on prevalence, research has been conducted in which the DSM-III and DSM-IV criteria are applied to a sample population. Research comparing the diagnostic criteria of the two versions has revealed that the application of the DSM-IV criteria resulted in significant increases in diagnosed cases of autistic disorder over the DSM-III criteria.

If one examines the prevalence rates for autism over the last two decades, one can see a direct relationship between the date of publication of DSM-IV, in 1994, and DSM-IV-TR, in 2000, and a corresponding significant increase in prevalence rates in the United States. In addition, studies have found that when case definitions and identification methods are held constant, no significant increase in diagnosis is observed. While it appears a relationship may exist between changes in diagnostic criteria and prevalence of autism, it is not likely the sole cause of the observed increase.

Diagnostic Substitution

In addition to changes in diagnostic criteria, researchers have examined the possible influence of diagnostic substitution and the increase in the prevalence of autism. The premise of 'diagnostic substitution' is that an individual who would typically receive a specific diagnosis would now receive a different diagnosis because of changes in social acceptability, consumer preference and selection of diagnostician, differential availability of services based upon diagnostic classification, and lessening concern about the need for specific differential diagnosis.

If in fact diagnostic substitution is influencing the prevalence rate of autism, the observed increase in the prevalence of autism would coincide with a similar decrease in the prevalence of some other disability (or disabilities). This, in fact, has been reported by numerous researchers, indicating that substitution may be occurring for the diagnosis of mental retardation.

Public Awareness of Autism and Early Identification

Awareness and publicity of autism has increased dramatically during the last two decades. A review of the archives of Time Magazine revealed a considerable increase in the number of stories published about autism. Between 1980 and 1989, three articles were published about autism. Between 1990 and 1999, the number of articles increased to 11 including 2 cover stories. Between 2000 and 2009, Time Magazine has published 73 articles about autism including 6 cover stories.

Earlier identification and detection of autism has also been suggested to be a factor in the observed increase in the prevalence of autism. Improved diagnostic assessments and increased awareness have been suggested to play a role in the early detection and diagnosis of the disorder. In the last two decades, the number of assessment measures and procedures has increased dramatically with regard to both the diagnostic process and screening. As would be expected, research has indicated that the mean age of diagnosis of autism and start of service delivery has declined over this period.

There is no denying that there has been an increase in the prevalence of ASD over time. Whether the increase is due to factors such as changing diagnostic criteria or better

identification, or multiple other factors is unclear. Continued research in this area as well as the etiological roots of ASD will help develop a better understanding of its prevalence.

Etiology

To date, the specific causes of ASD remain unknown. Hypotheses about the etiology of ASD have ranged from psychological, to environmental, to biological. However, research focused on genetic and neurobiological factors has been most promising. More than 15 genes have been implicated in the etiology of ASD. Information obtained from twin studies provides further support for the role of genetic factors in the development of ASD. In studies with monozygotic twins, the median concordance rate for autistic disorder is reported to be as high as 90%. The prevalence of ASD among nontwin siblings of children with ASD is also significantly higher than that of the general population, with estimates ranging from 4% to 8%. In addition, phenotypic studies have revealed that characteristics such as rigidity, social anxiety, and communication difficulties are seen more frequently in relatives of individuals with ASD compared to controls.

While the current research supports a biological link in the development of ASD, the data on the specifics of the link is less clear. Multiple genes have been implicated in the development of ASD including chromosomes 2, 7, 13, 15, 16, and 17 and the X chromosome. Neuroanatomical features that have been hypothesized to be linked to ASD include abnormal functioning of the brain stem, cortex, cerebellum, hippocampus, and amygdala. There is also evidence suggesting that the brain is enlarged in children with autism. However, the implications of brain enlargement have yet to be determined. Lastly, some research has implicated neurotransmitter abnormalities in individuals with ASD. Specifically, abnormalities in serotonin and GABA levels have been found in some individuals with ASD.

A major difficulty in drawing conclusions from the current research evidence from the neurobiology and neuroimaging fields is that the sample size is still small and is typically biased towards the individuals with ASD who are considered 'higher functioning.' This is understandable given that the behavioral issues that many individuals with ASD exhibit prevent them from participating in intensive assessments such as functional magnetic resonance imaging (fMRI). However, the absence of data from individuals with more challenging behaviors makes generalizing the results of such studies difficult. Advancement in the research methods used to collect this type of data is needed to help researchers collect information from a broader population and develop a better understanding of the etiological roots of ASD. It cannot be underscored enough that the ASD represent a heterogeneous population and that there are likely multiple pathways in its development.

Treatment Challenges

Individuals with ASD present with three core characteristics: (1) impairment in social interactions, (2) impairment in communication, and (3) stereotyped or repetitive behavior. Thus, a comprehensive treatment program needs to address these core

areas and the individual differences in the expression of related problems. Elements that must be included as components of a comprehensive treatment program include child-focused instruction, family focused support, addressing the multiple skill domains, and intensive educational instruction (e.g., lasting throughout a school day, and occurring across multiple settings), and the program typically continues over a period of months or years. Often, a distinction is made between treatment and education for individuals with ASD. This is a false dichotomy. School, work, home, and community, should all be seen as the various settings in which comprehensive treatment must be applied. The focus of this section is not to describe all of the many hundreds of interventions promoted for individuals with ASD but to discuss the challenges parents and practitioners face in developing comprehensive treatment programs. In particular, the myriad of treatment options, parental stress, and accessibility to services are discussed. Lastly, because of the extreme heterogeneity in ASD, it is important to state explicitly that not all individuals with ASD require, nor desire, treatment intervention.

Treatment Options

When a simple Internet search is performed with 'autism spectrum disorders' and 'intervention' or 'treatment' as the search terms, over two million results are found. Search results run the gamut from intensive behavior therapy to restrictive diets and horse back riding. The number of different approaches and options available for treating individuals with ASD can be overwhelming for parents and practitioners trying to do the best they can for their children. Researchers are recognizing this concern and have begun publishing scientific reviews of the benefits of different treatment options. Between the research that has been conducted and the methodology-based systematic literature reviews, there is convergence and agreement that interventions based on the principles of the extensive research in basic learning and the applied research in behavioral approaches to comprehensive intervention (behavior therapy, applied behavior analysis, cognitive-behavior therapy) are the most effective. Such reviews have also found that the majority of treatment approaches promoted for ASD lack empirical evidence of effectiveness, and some have been identified as potentially harmful. Further, while not all treatment approaches identified as 'ineffective' are harmful, they can come at a significant cost with respect to time commitment that then reduces a family's ability to devote time to other important activities and also typically have a significant monetary cost.

Parental Stress

Parents of all children experience varying levels of stress. However, having a child with special needs has been associated with increased levels of stress among parents. Further, it has been reported that parents of children with ASD experience significantly higher levels of stress than parents of children with other disorders. In particular, primary caregivers (e.g., mothers) typically experience more stress than other family members (e.g., fathers, grandparents).

Factors that have been associated with parental stress in children with ASD range from child-specific characteristics

(e.g., communication difficulties, social impairments, disruptive behaviors) to making decisions about treatment options for their child. Increased attention has been directed at developing interventions to reduce parental stress as well as address the source of the stressors. Interventions to address parental stress reactions (e.g., cognitive and behavioral programs for coping and relaxation) and interventions to address source of stressors (e.g., parent education programs in behavioral management techniques, provision of information about and help attaining community resources such as respite care) have been reported to be effective in reducing overall levels of stress in parents of children with ASD. Reducing parent stress is an important, but often neglected, element of treatment for children with ASD, and research has suggested that helping parents alleviate stress can improve treatment outcomes through greater effective parent participation in intervention programs.

Access to Services

Access to appropriate treatment is often problematic for parents as well as those professionals assisting in implementing comprehensive intervention. A number of factors may interfere with access to quality treatment including monetary cost, geographic location, and availability of qualified providers. The standards of care and practice, particularly with respect to educational services, vary significantly across states and within states.

Families trying to obtain services are faced with the problem of availability of service providers. With the increase in the number of individuals needing services, families are often faced with extensive waiting lists to receive appropriate services or with the choice of accepting services that are inadequate with respect to intensity and/or the evidence base for the intervention offered. Research on treatment for individuals with ASD has indicated that early and intensive treatment is associated with better long-term outcomes. However, individuals and families can be left waiting for months and, in some cases, even years to receive appropriate treatment.

The most effective interventions for individuals with ASD are often quite time and resource intensive. Interventions based on the principles of behavioral approaches have received the most consistent and extensive research support in addressing the needs of individuals with ASD. However, comprehensive intervention involving this approach for individuals with severe needs can involve between 25 and 40 h a week of direct services. Research has demonstrated that such comprehensive behavioral services are associated with significantly better outcomes and are more cost-effective in the long term. Currently, there are no universal standards or regulations in place to determine who is responsible for the costs associated with ASD (e.g., insurance company vs. school district vs. family).

Autobiographical Remembering and the Self

J J Skowronski, Northern Illinois University, DeKalb, IL, USA

Glossary

A positivity bias in recall The tendency to remember positive autobiographical events better than negative autobiographical events, or to generate false memories for positive autobiographical events; sometimes reversed in the service of current self-positivity.

Autobiographical memory A memory system consisting of episodes recollected from an individual's life, based on a combination of episodic (personal experiences and specific objects, people and events experienced at a particular time and place) and semantic (general knowledge and facts about the world) memory.

Episodic memory The element of the memory system that includes specifics about when and where an event occurred, thought to be accompanied by the sense that an event is relived or reexperienced.

Infantile amnesia A fairly universal observation is that many individuals fail to recall much from the time of their early childhood; it used to be believed that such failure reflected failures in the structural or processing capabilities of children, but more recent research suggests that the failure lies in retrieval failure, not in a failure of storage.

Meaning-making People sometimes try to make the world meaningful; to do so, they often construct a narrative that places events into a story-like context. Such narratives have implications for autobiographical memory: negative events that are part of narratives that have the theme of overcoming

or redemption may be well recalled because the negative event is critical to the theme of the story.

Procedural memory The memory that reflects the acquisition of skills, often thought to be represented in nonsymbolic forms and to reflect implicit knowledge (e.g., knowledge that it not cognitively accessible).

Self-enhancement motivation The motivation that the self has to view itself in a positive light; can cause negativity biases in recall when the current self benefits from recalling autobiographical events in an especially negative light.

Semantic memory The knowledge that is remembered in a fashion such that it is known, but not reexperienced.

Typically, such knowledge refers to general knowledge about the world, but it can also refer to knowledge about the self.

Symbolic self The self's capacity to consider itself as a concept or as an object of consideration.

The reminiscence bump The tendency to recall autobiographical events from the adolescent and young adult years; one reason may be that these years are crucial to the development of the self.

The self A collection of mental structures that comprise an individual's identity. These structures can be quite diverse and multidimensional, so that different aspects of the self can become activated in different contexts or by different goals. Current views of the self in psychology position the self as playing an integral part in human motivation, cognition, and affect.

An issue that has often been the focus of interest about the self (an ability that reflects humans' possession of a *symbolic self*) concerns the nature of the relation between one's personal identity and memory of one's own personal past. This interest is evident in the speculations offered by many philosophers. For example, John Locke directly linked the self to memories of the personal past (*Essay Concerning Human Understanding*; 1975/1689, Book II, Chapter 27). Locke argued that selfhood existed entirely in such memories: That a person found identity in the extension of consciousness backward in time, and that the person's identity reflected those parts of the past that could be remembered. An extension of this idea is that a person who remembers nothing of his or her past has no identity.

Interest in the extent to which selfhood is linked to autobiographical memory has extended into modern-day psychological theory and research, and it has led to the development of a huge and diverse literature. One exciting element of this literature is that it is truly a reflection of cross-disciplinary efforts in psychology, with major contributions coming from researchers in many of psychology's major subfields. This literature obviously cannot be adequately reviewed in this modestly sized article. Instead, our goal in this article is to selectively

highlight findings and ideas that illustrate some of the themes that have emerged from theory and research into the relation between autobiographical memory and the self.

One of these modern themes pursues the Locke thesis: Is autobiographical memory necessary for the presence of a sense of self? However, this is not the only line of research that pursues links between the self and autobiographical memory. Considerable work has addressed the extent to which the current self directs and affects autobiographical memories to serve the purposes of the current self, causing them to be remembered, forgotten, distorted, or to even be entirely fabricated. Yet, other scholarship has focused on the mechanisms underlying such effects. For example, one line of work focuses how an individual's attempts at meaning-making might affect recall of events from the personal past and how the self-concept might direct those attempts at meaning-making. Another line considers the role that social processes might play in the interplay between the self and autobiographical memory. The remainder of this article attempts to provide an entrée into the area of autobiographical memory and the self by describing just some of the research that has been conducted in each of these subareas.

Is Autobiographical Memory Necessary for Individuals to Experience a Sense of Personal Identity?

We begin by discussing the issue that was raised by Locke: Is the sense of self, or the sense of personal identity, dependent on the ability to recall one's personal past? Modern psychological scholarship (which is reviewed in more detail by others) suggests that the answer to this question is 'no.'

Understanding this answer requires a brief overview of how psychologists currently think about memory. One widely held view is that long-term memory reflects the action of multiple systems. For example, one system is thought to contain procedural memories and another is thought to contain declarative memories. Procedural memory involves learning and retention in the body's action systems, reflecting the acquisition and retention of motor, perceptual, and cognitive skills (e.g., knowing how to swim). Such knowledge is often represented in a nonconscious, nonsemantic form. Certainly, while one can listen to and acquire a description of how to engage in a given activity, acquisition of such descriptions clearly are not sufficient to learn how to engage in the actions themselves. To learn how to perform the activity, one has to engage in, and practice the activity. That ability to *do* stuff reflects the learning that has occurred in the procedural memory system.

In comparison, it is thought that the declarative memory system is the repository of symbolic and semantic knowledge about the world. Tulving, among others, argues that the declarative memory system contains two subtypes of information (perhaps residing in separate subsystems): semantic memories and episodic memories. Semantic memories reflect relatively generic knowledge about the world (e.g., DeKalb is a city in Illinois). Such memories typically are not accompanied by recall of when or where the memory was acquired; rather, they are retrieved without such information.

In contrast, episodic memories contain such specifics. Examples of episodic memories (e.g., from one of the chapter authors) are a memory of hitting a walk-off home run in a little league baseball game and a memory of throwing a hanging curveball in a college baseball game that was hit by an opposing batter for a walk-off home run.

The key to these memories being classified as episodic is that they have a 're-living' quality that includes the notion that the events were experienced by the self at a particular point in space and time. Certainly, a rememberer can 'know' things about themselves in a way that reflects semantic memory. However, that same knowledge can also be recalled in a way that, at least to some extent, provides a sense of reexperiencing the event. Such a memory is exemplified by Proust when he writes about an encounter with a Petit Madeline given to him by his mother. Proust indicates that when his mother offered him the little cake, he retrieved 'a feeling of inexplicable happiness' and a childhood memory of Saturday mornings in Combray where his Aunt Leone used to give him a Madeleine after first dipping it in her own cup of tea. Proust describes such a memory by saying that "It is a complete fragment of the past, with its original 'perfume,' that is for a moment given back to us." By definition, episodic memories have this 'reliving' quality.

In modern terminology, Locke's assertion about the necessary link between memory for the personal past and a sense of identity can be framed in terms of episodic memory: Is the

ability to retrieve such memories crucial to an individual's sense of identity or a sense of self? The answer appears to be 'no.' A moment's reflection should reveal why this should be the case. The semantic memory system can contain a lot of self-relevant information that is important to the sense of self. While some of this information might reflect the symbolic system's encoding of self-events (I know that I hit a home run), other information may reflect higher-order conceptual knowledge (e.g., I believe that I am lazy; other people think I am driven; I am a golfer). Hence, it seems reasonable that disruption of the ability to 're-live' the specific events contained in episodic memory should have no effect on those components of self-knowledge that reflect semantic memory.

Indeed, this proposition is now supported by considerable research. Even people who exhibit total amnesia for events from their personal past can describe their own personal characteristics both reliably and accurately. For instance, Clive Wearing, an accomplished musician who suffered viral encephalitis-induced episodic memory loss in 1985, has retained both his musical ability and his personality, including a profound and often-professed love for his wife. Such observations would seem to at least partially refute Locke's notion that one cannot have a sense of self without access to autobiographical memories (or, at least, to the episodic variety).

However, the fact that episodic memories are not necessary for the possession of a sense of self does not mean that such memories are unimportant to the sense of self. For example, as illustrated by their observations of the patient D.B. Klein, et al. note that episodic memory seems to be required for a sense of continuity in personal identity across time.

Another way in which the autobiographical memory is important to the self lies in the extent to which the self uses memory to maintain and promote the current self. For example, the Self-Memory System outlined by Conway proposes that the self-system works to maintain the self's 'status quo,' as well as working to maintain the extent to which the self perceives goal coherence. Conway speculates that control processes of the working self may act on the stored corpus of autobiographical event knowledge in the service of such maintenance, doing so by means of editing memory content and by generating false memories. Such ideas imply that the self plays an important role in the ability to recall events from one's personal past. It is to this idea that we turn our attention in the next section.

Does the Self Direct, Affect, or Alter the Content of the Autobiographical Memories That Can Be Recalled?

Event Valence and Memory for the Personal Past

One example of this notion of selectivity lies in the potential relation between event valence and recall, sometimes expressed in the widespread belief that people remember the past through 'rose-colored glasses.' In more precise terms, this idea suggests that there may be a *positivity bias* in the content of memory such that when trying to remember the events of their lives, people's memories tend to retain the positive and eliminate the negative.

The hypothesis that such a positivity bias may emerge in autobiographical memory can be generated from modern

thinking about the self. The argument is that the powerful motivations of self-enhancement and self-protection, as well as both cognitive tendencies and motivational tendencies toward self-consistency for those who think positively about themselves, should generally work to promote recall of positive autobiographical memories and to diminish recall of negative autobiographical memories. Moreover, psychologists have detailed a large set of mental mechanisms that can work to produce such positivity biases in recall. Indeed, the results of many studies have evinced some form of a positivity bias. Such results induced Walker, Skowronski, and Thompson to confidently declare that "Life is pleasant – and memory helps keep it that way."

These biases can be manifest in different ways. One manifestation of the positivity bias is that people tend to *selectively remember* the positive and *selectively forget* the negative. For example, D'Argembeau and Van der Linden asked participants to recall positive and negative events that involved self-evaluations (i.e., pride and shame) and positive and negative events that involved evaluations about others (i.e., admiration and contempt). The results showed that for events that involve self-evaluations, people reported a subjective remembrance of positive events with more details than they did negative events; this outcome did not occur for events that involved evaluations of others. A study by Skowronski, Betz, Thompson, and Shannon similarly found that people exhibited positivity biases in self-reported self-memory that were not evident in memories about others (in fact, the memories about others evinced a *negativity bias*).

A second way in which the positivity bias in memories of the personal past can be manifest relies on *distortions* in memory. In one type of distortion, events are misrecalled to be more positive (or less negative) than warranted when compared to the objective historical record. One example comes from Bahrick, Hall, and Berger, who reported that college students remembered more As than were present on their high school transcripts. A second example comes from a study conducted by Croyle, Loftus, Barger, Sun, Hart, and Gettig, the results of which suggested that people misrecalled (minimized) both their cholesterol scores and the cardiovascular risk categories into which they were placed; those who received the most undesirable test results were most likely to evince evidence of this distortion (for results with similar implications, see Christensen, Wood, & Barrett).

These memory tendencies seem to be present at an early age. For example, Wilson, Smith, H.S. Ross, and M. Ross interviewed pairs of siblings to assess memories for their sibling disputes. Although describing the same episodes, both older (M age = 7.0) and younger (M age = 4.4) siblings ascribed more serious transgressions to the other than to themselves.

However, a thorough review suggests that the autobiographical memory data are not always entirely congruent with the presence of a hedonic valence effect in recall. Such inconsistency emerged in an early review of the literature conducted by Meltzer and again in a later review reported by Matlin and Stang. Indeed, modern studies that look for evidence of a positivity bias in memory sometimes continue to fail to find evidence of the effect.

Additional pessimism about consistency of the positivity effect in memory comes from results provided by researchers who have studied the relation between trauma and memory.

One of these researchers suggests that the available evidence shows that traumatic events are essentially unforgettable. However, results from such studies are not definitive: They cannot rule out the possibility that, despite their negativity, such events are well recalled because of their extremity. Indeed, studies consistently show that event extremity is much more strongly predictive of recall than event valence. Nonetheless, such results do pose a challenge to the idea that self-related processing of autobiographical events will tend to promote positivity in recall.

Skowronski notes that such inconsistencies can be at least partially resolved by a focus on the mental structures, processes, and mechanisms that are involved in processing autobiographical memories. Such an idea is wonderfully exemplified by the work of Wilson, M. Ross, and their colleagues. The work produced by these researchers suggests that the self-enhancement and self-protective motives that often serve to maintain the positivity of the *current self* can sometimes produce a negativity bias in memory for past events. The Wilson and M. Ross team suggests that this can occur as a consequence of the meaning-making activities in which people engage as events are retrospectively considered and rehearsed.

For example, one way in which one might glorify one's current ability to play golf is to remember how bad one was at the activity when one started to play the game. A parable can be constructed from such events, one that says: "Look at how far I've come – I never broke 120 when I started, but now I break 90 almost every time." This exact effect has been observed in the research conducted by the Wilson and M. Ross team: People reconstruct their memories of their early performance levels, and such reconstructions often reflect performance that is worse than is objectively suggested by the historical record. Similar results were reported by Dewhurst and Marlborough, who reported that students who surpassed their target grade sometimes exaggerated how anxious they had been prior to the exam. Echoing the conclusion of the Wilson and M. Ross team, Dewhurst and Marlborough attributed these findings to the action of the motives of self-enhancement and self-protection that bias the recall of preexam anxiety in the direction that maximizes current self-esteem.

The implication of such research is that the self-enhancing or self-protective goals of accentuating the positive do not always eliminate memory for the negative – in the right circumstances, when it benefits the current self, these goals can actually maintain, enhance, or distort memory for negative life events. However, given the way that memory becomes framed over time, remembering the negative actually has at least one positive effect – it makes the current self feel good. More important to the current article, though, is the idea that regardless of whether they are positive or negative, these memory biases occur *because of the influence of the self*. The consistency, protection, and enhancement motives that are activated by the current self in a given situation cause differential cognitive treatment of memories of an individual's personal past. It is this differential treatment that is responsible for biased recall of autobiographical information.

The Reminiscence Bump

Other data link the self to recall by showing that the extent to which an event is important to the self is related to memory for

the event. A fine example of this effect comes from research examining the reminiscence bump. The reminiscence bump effect shows that when recalling events from their personal past, people tend to produce a disproportionately high proportion of memories for events that occur roughly between the ages of 10 and 30. Presumably, this is a time that is crucial to the emergence of an individual's self-concept, and the events that are remembered during such periods may bear special significance to the self.

Consistent with this view, one study has shown that bump memories were found to be more novel, more important for identity development, more distinct, and more likely to involve developmental transitions than memories from other age periods. The content of the memories in the bump period is more likely to be positive than negative, an outcome that arguably is also consistent with the action of the self on memory. Other studies have shown that reminiscence bumps are not always restricted to their typical age range, but can emerge during any period of substantial life transition that is likely to cause significant changes to an individual's self-conception. Thus, as with the valence biases in memory, these studies document the fact that memory of the personal past is strongly related to an individual's identity.

Mechanisms that May be Related to the Recall of Events from the Personal Past

Meaning-Making

What are some of the mechanisms that might be responsible for the relations between the self and memory of the personal past? Clearly, there are a host of cognitive mechanisms that may be relevant. However, one mechanism that has received considerable recent empirical attention reflects the cognitive efforts that one undertakes to make sense of one's life. Such meaning-making seems to be a routine activity, and as such, has the potential to affect memory for many negative autobiographical events that might become incorporated into the life story.

Such processing is exemplified by the results of a recent study by Ritchie, Skowronski, Hartnett, Wells, and Walker. This paper examined events that changed their affective tenor over time, moving from negative to positive, or vice versa. The authors argue that such changes might occur because of the way in which events become reinterpreted in the light of subsequent life events. For example, consider the plight of a person who had been denied her tenure in her first academic job. Such an event might have been crushing when it happened, but later, as the person's life progressed, the event might be viewed in a different light. For example, the person might have obtained a second job that was a perfect fit for them. As the person reflects on and tries to understand her own life, the tenure denial (I was crushed) may come to be viewed positively (in the end, it was the best thing that could have happened to me).

In such a case, one would likely not expect memory for the original event to be diminished. In fact, one might expect that because of the high relevance of the entire event sequence, memory for the tenure denial event might actually be quite good and might strongly persist over time. Indeed, the story

becomes even more important to the self, (e.g., illustrating self-resilience) if the crushing nature of the tenure denial is emphasized.

Certainly, then, mental activity such as meaning-making and event reprocessing might be responsible for the fact that not all negative events are poorly recalled. When such negative events are essential to a life story that helps to ascribe meaning to events, those negative events may be recalled quite well. These considerations suggest that, more generally, a full understanding of how the self affects autobiographical memory necessitates an understanding of how an event fits into the personal narratives that people use to make sense of their lives (an idea anticipated by Singer).

Social Mechanisms

However, it is also the case that these meaning-making activities may not solely be for private consumption. People also need to explain themselves to others, and the need to concoct such public explanations may affect the meaning-making process.

Consistent with this proposition, data indicate that people often relate autobiographical event descriptions to one another in the course of those conversations. Moreover, some data suggest that social rehearsals occur at least as often as, and perhaps more often than, other rehearsal types. For example, in each of the two studies reported by Walker et al., participants listed autobiographical events that occurred within the last 6 months. After listing the events, participants were asked to estimate the number of times that they had rehearsed each event for one of the several different reasons (e.g., to remember the details of the events, to reexperience the emotions associated with the events, to better understand the events, to talk about the events to others, or the events were thought of involuntarily). In both studies, the most frequent reason that people rehearsed events was for the purpose of talking to others, and its reported frequency was significantly greater than any other reason.

Consideration of the social underpinnings of autobiographical event rehearsal adds additional complexity to the study of autobiographical memory, for different motives may drive the public presentation of different kinds of memories. Certainly, one might expect the need for others to view the self positively to motivate the selective self-presentation of positive events over negative events, a process that might be expected to push autobiographical memory toward positivity. However, sometimes in social circumstances, one needs to tell an interesting story, and stories can be especially entertaining when they involve themes such as overcoming obstacles (a theme that often appears from studies of meaning-making). Moreover, sometimes one can ultimately gain benefit by presenting one's foibles to others (e.g., self-deprecating humor might serve the purpose of ingratiation), which suggests that, at least under some circumstances, one might be motivated to relate one's negative life experiences to others. Thus, as in the M. Ross research, it may be that enhanced recall of negative personal life events may be a consequence of the need to enhance the current positivity of the self; that need sometimes induces rehearsal of negative events for the purpose of relating those events to others.

However, the effects of public event disclosures may go beyond the moderation of positivity effects in recall. For example, Skowronski and Walker suggest that other elements of social interactions that might affect autobiographical public self-presentations are the Grice conversational norms to be *relevant*, to be *informative*, and to be *brief*. These norms should not only work toward selectivity in the rehearsal of autobiographical memories, but they might also work toward distorting their content. This can happen in two ways. The norm to be brief may cause people to omit many details from their event descriptions; such omissions might cause those details to be permanently inaccessible when the memory is retrieved. Moreover, people may sometimes add event details, or fabricate events entirely, in the service of telling a good story. When the story is told often enough, a storyteller may experience a false memory because of a failure to accurately engage in reality monitoring: The storyteller may ultimately lose track of the fact that an event element was self-fabricated, coming to believe that the fabricated element was true (though this may not always occur).

The social nature of remembering has also been explored from a developmental perspective. In fact, the themes of social interaction and narrative construction have been remarkably combined in a program of research that has examined the emergence of the self as it related to the emergence of the capacity to produce early autobiographical memories. Until the middle 1980s, it was widely believed that autobiographical memory emerged relatively late in development. One example of this came from the literature on literature detailing *infantile amnesia*. Observations suggested that this amnesia was widespread. These observations led scholars to believe that such children did not report such memories simply because they lacked the cognitive mechanisms to do so. This apple cart was upset by research that began to emerge in the late 1970s. Researchers in these studies began to ask 3- and 4-year-old children to report what happens in the course of everyday events and routines. The children could do so, and readily provided rich reports of their experiences. As it has evolved, this research has now demonstrated conclusively that young children do have considerable memory for significant life events.

There have been a number of intriguing lines of research that have emerged from these examinations of early autobiographical memory. One of these lines of research links frequent social discourse with parents to both the emergence of autobiographical memory reporting capabilities and to the emergence of a personal identity. The scholars in this area argue that through participating in joint reminiscing with parents, young children develop a sense of subjective perspective on their personal past. These scholars argue that, even more importantly, through participating in adult-guided conversations about their past that are replete with information about their inner mental life, children come to develop a subjective sense of self.

Part of this thesis revolves around the idea that reminiscing is not just about what happened, but what happened *to the actor* (the 'me'). This necessitates distinguishing what happened to the self from what happens in the world at large. It is thought that a child's interaction with parents about the child's own life events aids the development of this self-perspective, especially to the extent that such activity promotes the inclusion of the child's thoughts, feelings, and evaluations of the past in their autobiographical memories.

In a rather ironic sense, these scholars have moved back, at least a bit, toward Locke's idea that autobiographical memory is essential to the sense of self. While we have argued that considerable data suggest that autobiographical memory (at least in its episodic form) does not appear to be necessary for adults to maintain a sense of identity, those data do not preclude the possibility that the recall of the personal past as is reflected in child discussions with parents is important to the development of a personal identity. It should be emphasized that it seems to be the social nature of these interactions, not the emergence of language itself, that is the driving force behind these findings. Indeed, developmental psychology scholars have provided impressive evidence that links such interactions to personal identity. For example, considerable data now show that maternal style early in development has a substantial effect on children's emerging ability to recall their own past, and that this effect emerges over a relatively long developmental period. For example, data provided by Reese, Haden, and Fivush, showed that the ways in which mothers reminisce with their young preschool children continued to affect children's memory skills more than 2 years later.

One important idea outlined by these scholars is the notion that it is discourse with caregivers that contributes to the development of a sense of time in autobiographical memory. That is, it is thought that talking about experienced events with parents whose narrative styles induce a child to incorporate memory fragments into coherent narratives of the past provides not only a way for the child to organize memory for future recall, but also a scaffold for understanding the order and specific locations of personal time, an element that is essential to autobiographical memory.

This temporal element is also essential to the sense of self. As noted earlier in this article, one contribution that autobiographical memory does make to the self is that it helps to provide information about both stability and change in the self. Thus, the content of the self is closely connected to the sense of a personal past, and discourse with caregivers can help children to develop the understanding that it was the same self that exists in the present that experienced an event in the past. Moreover, the ability to report autobiographical events is closely tied to evidence that a child has acquired a sense of self. For example, Harley and Reese measured children's self-recognition with the mirror test at age 1½ years and used it as a predictor of children's memory reports with mothers and experimenters at ages 2 and 2½ years. Children's memory reports with mothers and experimenters varied as a function of their earlier self-recognition skill, with early recognizers engaging in more interactions with mothers and with experimenters over time. Additional analyses showed that the initial importance of self-recognition was mediated by maternal reminiscing style when children were 2 years old: Children who recognized themselves earlier in the mirror test had mothers who responded with increased elaborations in past event conversations with children at age 2 years, and maternal reminiscing style directly predicted children's later memory reports.

In summarizing the 2002 'state of the art,' Reese argued that the data collected up to that point showed that social factors, such as parental reminiscing style, interacted with children's self-understanding to produce autobiographical memory. She also argued that such effects occurred for at least two reasons.

First, parents' talk about personally relevant past events may be an important source of information for children's self-understanding. Second, children may not be able to benefit from increased self-understanding in their retention of autobiographical memories unless they have the added elaborative and evaluative support from their parents in understanding past events. Such ideas clearly support the contention that one must incorporate social variables when attempting to understand the relations between the self and autobiographical memory.

Coda

Scholars who are interested in the relation between the self and autobiographical memory have a daunting task. This task begins with gaining an appropriate understanding and appreciation of the philosophical issues relevant to the topic, represented in this article by the works of Locke and Grice. This task continues by keeping abreast of developments in the area, which means monitoring literatures across many of psychology's subareas, especially social psychology, developmental psychology, cognitive psychology, personality psychology, clinical psychology, and neuroscience. Finally, to contribute empirical scholarship in this area, one needs to be open to multiple methodologies and analytic techniques. The information presented in this article merely samples the field and is obviously substantially influenced by the research programs, interests, and explanatory stories preferred by the article's authors. While the task is daunting, it is likely that their payoff is substantial. For one, assimilating the scholarship in this area will contribute to a broad view of psychology and will perhaps allow one to better appreciate the methods, areas, and approaches that might characterize the subareas that differ from one's own specialty. Moreover, we believe that the interdisciplinary nature of the area continues to make it a fertile ground for scholars who want to pursue new avenues of research into this relation. We hope that this article may serve to stimulate interest in such research, and we look forward to examining the products of such research in the years to come.

Avoidant Personality Disorder

C A Sanislow, E E Bartolini, and E C Zoloth, Wesleyan University, Middletown, CT, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Anhedonia A mental health symptom, commonly seen in mood disorders and schizophrenia-related disorders, involving the inability to experience pleasure from enjoyable activities.

Comorbidity The presence of two or more psychiatric diagnoses found simultaneously in the same individual. Comorbidity may reflect the presence of two distinct pathologies, but may also reflect imperfect diagnostic categories.

Distress disorders A higher order classification of the broad range of anxiety and depressive disorders.

DSM The *Diagnostic and Statistical Manual of Mental Disorders* (current version: *Diagnostic and Statistical Manual of Mental Disorders*, 4th revision, text revision, or DSM-IV-TR) is published by the American Psychiatric Association and provides a multiaxial classification system for mental disorders, with personality disorders such as APD listed under Axis II disorders.

FFM The Five Factor Model of personality describes five broad personality domains: openness, conscientiousness,

extraversion, agreeableness, and neuroticism. Each domain has six facets descriptive of lower-order personality traits.

Generalized social phobia A subtype of social phobia marked by a fear of social situations across all aspects of the social world. GSP is very closely linked to APD.

ICD The *International Statistical Classification of Diseases and Related Health Problems* (current version: *International Classification of Diseases*, 10th Revision, Clinical Modification, or ICD-10-CM) is published by the World Health Organization and provides a classification system for a broad range of medical symptoms and conditions, including mental health diagnoses. It is widely used internationally but is less common within the United States.

SASB Structural Analysis of Social Behavior, a model of personality based on interpersonal theory that describes patterns of behavior, suggests origins of maladaptive interpersonal behavior, and guides psychotherapy process.

Social anxiety disorder The term introduced in the DSM-IV as an alternative name for social phobia.

Social phobia A disorder marked by an enduring fear of social situations and the embarrassment that may result from participation in social interactions.

Introduction

When does anxiety in interpersonal situations become pathological, and what makes it so? Clearly, functional impairment is an important element. For personality disorders in general, there is the assumption that there are clinically significant deficits in both the self and interpersonal relationships. For avoidant personality disorder (APD) self-definition encompasses a desire for affiliation hobbled by a sense of personal inadequacy, and intense fears of interpersonal rejection stemming from a heightened sensitivity to criticism from others is another key feature, leading to social detachment that is perhaps the most obvious clinical feature of APD. In broader terms, the feelings of the person suffering APD have been described as anxiety, and the behaviors as shyness, suggesting overlap with other forms of psychopathology. Historically, one thing that differentiates APD from other forms of psychopathology, however, is that APD is characterized by isolative interpersonal behaviors combined with a desire to be close to others that is stilted by fears of rejection.

Diagnosis

APD affects about 1–2% of the general population, and is frequently present among patients in outpatient psychiatric clinics, often ranging between 10% and 20% of the cases. Personality pathology corresponding to APD is included in

the two major diagnostic manuals for psychiatric diagnosis of mental disorders: the tenth edition of the *International Statistical Classification of Diseases*, or the 'ICD-10,' which is published by the World Health Organization, and the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders*, or the 'DSM-IV-TR,' which is published by the American Psychiatric Association. Both diagnostic manuals specify avoidant personality pathology as chronic and enduring. The actual diagnosis 'APD' is listed among DSM-IV-TR personality disorders, whereas the corresponding diagnosis in ICD-10 is 'Anxious (Avoidant) Personality.' The DSM-IV-TR diagnostic criteria are shown in [Table 1](#), and criteria from the ICD-10 in [Table 2](#). (The 'TR' in DSM-IV-TR stands for 'Text Revision.' The fourth edition of the DSM, published in 1994, was updated in 2000 by revisions to the 'text' describing some diagnoses; however, none of the diagnostic criteria were altered).

DSM Definition and Criteria

In the DSM-IV-TR, APD (code number 301.82) is characterized by a "...pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation..." (p. 718). The diagnostic title 'Avoidant Personality Disorder' was first introduced into official diagnostic nomenclature with the DSM-III, which was published in 1980. Within the DSM (DSM-III through DSM-IV-TR) Axis II, APD resides in 'Cluster C' of the Personality Disorders, along with Dependent and

Table 1 DSM-IV-TR diagnostic criteria for avoidant personality disorder

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

- (1) avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection
- (2) is unwilling to get involved with people unless certain of being liked
- (3) shows restraint within intimate relationships because of the fear of being shamed or ridiculed
- (4) is preoccupied with being criticized or rejected in social situations
- (5) is inhibited in new interpersonal situations because of feelings of inadequacy
- (6) views self as socially inept, personally unappealing, or inferior to others
- (7) is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual for Mental Disorders*, 4th edn., text revision, p. 721. Washington, DC: American Psychiatric Association.

Table 2 ICD-10 diagnostic criteria for anxious (avoidant) personality disorder

Anxious (avoidant) personality disorder is characterized by at least four of the following:

- (1) Persistent and pervasive feelings of tension and apprehension
- (2) Belief that oneself is socially inept, personally unappealing, or inferior to others
- (3) Excessive preoccupation about being criticized or rejected in social situations
- (4) Unwillingness to get involved with people unless certain of being liked
- (5) Restrictions in lifestyle because of need of security
- (6) Avoidance of social or occupational activities that involve significant interpersonal contact, because of fear of criticism, disapproval, or rejection

Source: World Health Organization (1992) *The International Statistical Classification of Disease (ICD)*, 10th edn., pp. 155–156. Geneva: World Health Organization.

Obsessive–Compulsive Personality Disorders. Personality disorders in this cluster share features of internalizing distress including anxiousness and fearfulness. As is the case with all personality disorders in the DSM-IV-TR, there is for APD the general requirement of “. . . an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture and is manifest in at least two of the following areas: cognition, affectivity, interpersonal functioning, or impulse control. . .” (p. 686).

Of the seven criteria for the DSM-IV-TR APD shown in **Table 1**, at least four are required for a patient to meet the diagnostic threshold. The first criterion, ‘avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection,’ may apply to work or school. Often a person suffering from APD will limit their educational opportunities, and they are likely to choose an occupation where interpersonal contact is minimal. They

will also avoid working in teams, preferring to do things themselves. This is to be distinguished from the perfectionism aspect in obsessive–compulsive personality disorder, in which people prefer to work alone because their standards are so high they believe that others would bring the work down.

The second criterion, ‘is unwilling to get involved with people unless certain of being liked,’ is based on a preoccupation with feelings of inadequacy. This preoccupation essentially creates a cognitive disturbance that interferes with interpersonal interactions in novel social situations. An avoidant person will deal with this by being reticent and reluctant to ‘make the first move.’ This is unlike the case of dependent personality disorder (DPD) where a person is reticent based on fears that differentiating their opinions from another will destroy or otherwise damage the relationship. For avoidants, the fear is the confirmation of their own perceptions of inadequacy.

The third criterion, ‘shows restraint within intimate relationships because of the fear of being shamed or ridiculed,’ is also driven by the fear of being criticized. Being avoidant means always being petrified about what is to them, ‘deep, dark, secrets’ that, if revealed, would almost certainly invite ridicule. Even a slight teasing might be perceived as humiliating. For these reasons, APD is often associated with a great deal of secretive behavior that is, for the most part, irrational, except for the fact that it brings a needed security even in the ‘closest’ relationships. In contrast, such restraint observed at the clinical surface with DSM-IV-TR ‘Cluster A’ (odd, eccentric) personality disorders such as schizoid, schizotypal, or paranoid, is better attributed to an indifference to intimacy (schizoid) or paranoid fears underlying secretive behavior (schizotypal and paranoid).

The fourth criterion, ‘is preoccupied with being criticized or rejected in social situations,’ at the first blush may appear similar to the DSM-IV-TR Axis I clinical syndrome of social phobia. Clearly, anxiety in a social situation is the hallmark of this criterion. For avoidants, any aspect of their being is fair game, from their hairstyle and clothing to their ideas and intellect. In contrast to social phobia, anxiety associated with avoidant personality disorder is not situation specific, but wide-ranging across all areas of the social world. It is not, for example, limited to situations where they might be called on to speak in front of others. A variant of social phobia, generalized social phobia, interestingly appears to diagnostically cooccur with greater frequency than the simple type, and will be considered in greater detail in a later portion of this article.

The fifth criterion, ‘is inhibited in new interpersonal situations because of feelings of inadequacy,’ represents more than mere cautiousness. Often it involves social comparisons that may have no basis in reality, for instance, the feeling that others whom the avoidant person is with are smarter, more successful, have better relationships, better family life, a better job, etc. Again, rooted in this criterion is the idea of being ‘less of a person’ across multiple domains. Here again, with APD, the person will unfortunately hold back information about himself or herself, information that might actually lead to the experience of being liked or respected by others if it weren’t for this inhibition or competing cognitive process of evaluation of self and others.

The sixth criterion, 'views self as socially inept, personally unappealing, or inferior to others,' is a pervasive inferiority complex that includes the beliefs that one is not at all likeable and possesses no social skills. The insecurity that accompanies these feelings of awkwardness is paired with the belief that others will always judge or otherwise evaluate them negatively. Here, it is important to distinguish this criterion from cognitive features of depressive disorders. For depressive disorders, whether they are shorter in duration but intense, such as the case of major depression, or longer in duration but less intense, such as dysthymic disorder, the key distinction is that in APD, these feelings of ineptness and being unlikeable are independent of depressive mood states. In other words, the depressed mood may come and go or otherwise vacillate, but with APD, the inferiority remains constant.

The seventh criterion, 'is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing,' translates to 'never be the first to express deeper feelings.' Thus, the risk is not about 'risk-taking behavior' as might be found in people with antisocial tendencies or thrill seekers. For APD, the risk is much more pedestrian and mundane. The person will be loath to reveal feelings that may expose him or her, whether positive or negative. Even if someone has a positive feeling, the typical approach would be to wait for the other to share the feeling or observation and then to agree with that observation rather than risk the certain humiliation that would come with a 'stupid' disclosure that was 'off the mark.'

ICD Definition and Criteria

The ICD-10 diagnosis, anxious (avoidant) personality disorder (code number F60.6) is very similar to that of DSM-IV-TR, despite the slight variation in the title. As with the DSM-IV-TR, anxious PD features must meet the accepted general criteria for personality disorder including characteristic and enduring disturbances in a person's inner experience and behavior that is outside the accepted norm. Disturbances in specific processes that impede functioning may include cognition, affect, impulse control, and interpersonal relatedness. In the ICD-10, the behaviors must also be seen as maladaptive and inflexible, evidence personal distress or otherwise have an adverse impact, and be of long duration and not attributable to other mental or organic disorders.

Comparing the APD criteria from the ICD-10 to the DSM-IV-TR reveals many similarities and a few differences. On the whole, the criteria appear to be tapping an isomorphic construct. Both require four criteria for a diagnosis, though the ICD-10 has total of six possible criteria compared to seven in the DSM-IV-TR. Comparing [Tables 1](#) and [2](#), reveals an almost direct correspondence of ICD-10 to DSM-IV-TR criteria (ICD-10 #2 to DSM-IV-TR #5, ICD-10 #3 to DSM-IV-TR #4, ICD-10 #4 to DSM-IV-TR #2, and ICD-10 #6 to DSM-IV-TR #1). Of the two remaining ICD-10 criteria (#s 1 and 6), criterion #6, 'Restrictions in lifestyle because of need of security,' roughly approximates DSM-IV-TR criterion #7, 'is unusually reluctant to take personal risks or engage in new activities because they may prove embarrassing,' and may also partially capture DSM-IV-TR criterion #6, 'is inhibited in new interpersonal situations

because of feelings of inadequacy.' A subtle difference is that the ICD-10 focuses on 'security' which is in contrast to the DSM-IV-TR focus on 'embarrassment' or 'feelings of inadequacy.' Finally, the first ICD-10 criterion #1, 'Persistent and pervasive feelings of tension and apprehension,' appears to tap a more general construct of anxiety. In contrast, DSM-IV-TR attempts to focus more specifically on anxiety related to a negative concept of self.

In the version of the ICD-10 updated in the year 2007, there is a general description of anxious [avoidant] personality disorder that reads as follows:

Personality disorder characterized by feelings of tension and apprehension, insecurity, and inferiority. There is a continuous yearning to be liked and accepted, a hypersensitivity to rejection and criticism with restricted personal attachments, and a tendency to avoid certain activities by habitual exaggeration of the potential dangers or risks in everyday situations. (Chapter V of Version 2007 published on the Web)

In Version 2007 of the Web-based ICD-10, there are no specific criteria lists for any of the personality disorders, hinting at a shift to more prototypic representations or descriptions of personality pathology. This is consistent with future plans for the APD diagnosis in the next edition of the DSM.

ICD-11, DSM-5, and the Future of APD

Both the ICD-11 and the DSM-5 are under revision at the time this article is going to press, and so there are many uncertainties about the future diagnostic conceptualizations of APD. Though still subject to further revisions, a general model of personality disorders for the DSM-5 has been developed and informs the likely diagnostic future of APD in this manual. While the DSM-IV had conceptualized personality disorders in terms of essential features, the committee developing DSM-5 is considering a prototypic model in which specific domains or facets may be characteristics of multiple disorders.

The DSM-IV opens the discussion of APD in terms of its key feature, namely, a "pervasive pattern of special inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation." This idea of a disorder having one 'essential feature' is different from the DSM-5, which opens with the phrase "Individuals who match this personality disorder type" and also later uses the phrase "individuals resembling this type," both of which illustrate prototypic description rather than one derived from a polythetic collection of an essential number of criteria.

One proposal is to change the diagnostic system from a categorical system to a hybrid prototype-dimensional system based on a prototype rating and ratings on six-domain trait dimensions. The first component is an assessment of where an individual fits in the five severity levels of personality functioning using the Self and Interpersonal Functioning Continuum. This assessment of level of personality functioning was not a part of the DSM-IV, as historically the diagnosis of a functional impairment was seen as sufficient evidence of a personality disorder without a quantitative rating of disturbance. The second component is the prototype rating system. Each personality disorder has a prototypic description that emphasizes typical deficits and features of the disorder. Patients are

compared to the prototype in terms of how well they match the description, and a rating from 1 (no match) to 5 (very good match) is made. The description of the APD prototype is shown in [Table 3](#).

The second component of the proposed personality disorder diagnosis for DSM-5 has roots in trait theories of personality, including the Five Factor Model developed by Thomas Widiger, Paul Costa, and many others. The resulting DSM-5 model is a 'hybrid' system that combines specific personality disorder 'types' along with ratings for traits and functioning. Traits relevant to APD in the DSM-5 rating system include the tendency to feel responsible for bad things that happen, anhedonia, having difficulty allowing oneself to acknowledge or express wishes and emotions, and a desire to be recognized as unique. As shown in [Table 3](#), the traits are rated 0 (very little or not at all descriptive) to 3 (extremely descriptive). The American Psychiatric Association maintains a web site illustrating the diagnoses and keeping the field abreast of updates to the proposed revisions.

The future of APD, or anxious personality disorder, in the ICD-11 is less certain at this point in time. Mental disorders in general are among a handful of disorders that are a focal point for substantial revision. In contrast to the DSM, which focuses solely on mental disorders, the ICD covers all disease-related classification and the 'Mental and Behavioral Disorders' is but one component of the manual. Empirical studies on the structure of mental disorders are being presented to the work group for ICD Mental and Behavioral Disorders led by Dr. Steven Hyman, and there exists the possibility for substantial revision, including folding the symptoms of personality disorders into clinical syndromes. These considerations stem from questions raised by overlapping features of psychopathology and personality disorders in the current form of diagnoses, which call for new ways to examine and parse clinical symptoms to better address the problem of diagnostic comorbidity, a problem for many disorders including APD to which we now turn.

Comorbidity

Like APD, fear or avoidance of social situations and fear of possible scrutiny characterize social phobia, an Axis I disorder, in the DSM-IV-TR. However, the social situations tend to be more circumscribed for social phobia than for APD. Still, there is considerable diagnostic overlap between APD and social phobia, especially the generalized subtype of social phobia where a number of social settings are associated with an anxious state. In light of this overlap, and as the DSM moves more toward a dimensional approach, a key question reemerges: Does APD exist as part of a continuum, representing the more chronic, wide-ranging, and severe point on a spectrum of anxiety disturbance? In general, empirical results have supported the idea of a continuum model where APD is a more severe and pervasive form of 'social phobia' that is so longstanding that it has become integral to personality and interpersonal functioning. Perhaps it is an anchor point toward the more extreme end, with social phobia falling somewhere in the middle, and anxious behavior colloquially described as 'shyness' falling in the more mild, clinically insignificant end

of the continuum. In considering the continuum model, it is important to determine if it is merely quantitative differences that distinguish the two disorders.

Are APD and Social Phobia Separate Disorders?

The question of whether or not social phobia and APD are separate and distinct forms of psychopathology is a question that has plagued the field since the diagnosis was introduced in the 1980 DSM-III. Many studies have found overlap between APD and social phobia; this overlap may reflect shared or similar facets of the pathology, or it could be due to similarities in the descriptive criteria for the diagnoses. In the revisions from the DSM-III to DSM-IV-TR, there have been several adjustments to the criteria to reduce the diagnostic overlap and increase specificity. As previously described, the proposed revisions for the DSM-5 include reformulating APD as avoidant type; characterized by a 'negative sense of self, associated with a profound sense of inadequacy, and inhibition in establishing intimate interpersonal relationships,' specifying that, for APD, the social anxiety stems from the personal feeling of inadequacy.

Despite modifications and changes in wording and emphasis of criteria in DSM-III through DSM-IV, a trend for the cooccurrence of these two disorders has persisted. An apparent lack of qualitative differences leads researchers to hypothesize that the difference between the two is quantitative. Given similarities in criteria sets, this finding is somewhat intuitive and unsurprising as similar relations are also found between other Axis I and personality disorders. For APD, various research groups including the collaborative longitudinal personality study (CLPS) have reported significant associations with Axis I disorders, including social phobia, that have anxiety/inhibition as criteria. Several personality disorders also show this same association with related Axis I disorders with which they share criteria. A potential limitation in many of these studies is that data is derived from clinical samples that are comorbid for multiple Axis I and II disorders. However, other researchers, such as Chambless and colleagues have assessed impairment and distress among participants with the generalized type of social phobia, with and without APD, using self-report and observation and found no significant differences between the groups when they controlled for social phobia, thus supporting the continuum hypothesis.

To argue against the continuum model, it has been noted that higher levels of social avoidance, depressive symptoms, neuroticism, introversion, and social and occupational impairment were found for participants with generalized social phobia in combination with APD than for those participants with generalized social phobia alone. Thus it may be that APD differs from social phobia because it manifests itself in more severe cases of depression, introversion, and social and occupational impairment. Rettew has argued for a qualitative distinction between APD and social anxiety disorders, suggesting that widening the assessment scope to include nonsocial domains (introversion, passivity, fear of novelty, for example) would increase the likelihood of clarifying the distinction between APD and social phobia. Regardless of the outcome of this debate, two things seem clear. First, those with APD are

Table 3 Prototype description for avoidant personality disorder DSM-5 presently under consideration by the DSM task force

Prototype description

Individuals who match this personality disorder type have a negative sense of self, associated with a profound sense of inadequacy, and inhibition in establishing intimate interpersonal relationships. More specifically, they feel anxious, inadequate, inferior, socially inept, and personally unappealing; are easily ashamed or embarrassed; and are self-critical, often setting unrealistically high standards for themselves. At the same time, they may have a desire to be recognized by others as special and unique. Avoidant individuals are shy or reserved in social situations, avoid social and occupational situations because of fear of embarrassment or humiliation, and seek out situations that do not include other people. They are preoccupied with and very sensitive to being criticized or rejected by others and are reluctant to disclose personal information for fear of disapproval or rejection. They appear to lack basic interpersonal skills, resulting in few close friendships. Intimate relationships are avoided because of a general fear of attachments and intimacy, including sexual intimacy.

Individuals resembling this type tend to blame themselves or feel responsible for bad things that happen, and to find little or no pleasure, satisfaction, or enjoyment in life's activities. They also tend to be emotionally inhibited or constricted and have difficulty allowing themselves to acknowledge or express their wishes, emotions – both positive and negative – and impulses. Despite high standards, affected individuals may be passive and unassertive about pursuing personal goals or achieving successes, sometimes leading to aspirations or achievements below their potential. They are often risk-averse in new situations.

Traits

Domain	Facet	Description
Negative emotionality	Anxiousness	Having frequent, persistent, and intense feelings of nervousness/tenseness/ being on edge; worry and nervousness about the negative effects of past unpleasant experiences and future negative possibilities; feeling fearful and threatened by uncertainty
	Separation anxiety	Having fears of rejection by, and/or separation from, significant others; feeling distress when significant others are not present or readily available; active avoidance of separation from significant others, even at a cost to other areas of life
	Pessimism	Having a negative outlook on life; focusing on and accentuating the worst aspects of current and past experiences or circumstances; expecting the worst outcome
	Low self-esteem	Having a poor opinion of one's self and abilities; believing that one is worthless or useless; disliking or being dissatisfied with one's self; believing that one cannot do things or do them well
	Guilt/Shame	Having frequent and persistent feelings of guilt/ shame/ blameworthiness, even over minor matters; believing one deserves punishment for wrongdoing
Introversion	Intimacy avoidance	Disinterest in and avoidance of close relationships, interpersonal attachments, and intimate sexual relationships
	Social withdrawal	Preference for being alone to being with others; reticence in social situations; avoidance of social contacts and activity; lack of initiation of social contact
	Restricted affectivity	Lack of emotional experience and display; emotional reactions, when evident, are shallow and transitory; unemotional, even in normally emotionally arousing situations
	Anhedonia	Lack of enjoyment from, engagement in, or energy for life's experiences; deficit in the capacity to feel pleasure or take interest in things
	Social detachment	Indifference to or disinterest in local and worldly affairs; disinterest in social contacts and activity; interpersonal distance; having only impersonal relations and being taciturn with others (e.g., solely goal- or task-oriented interactions)
Compulsivity	Risk aversion	Complete lack of risk-taking; unwillingness even to consider taking even minimal risks; avoidance of activities that have even a small potential to cause injury or harm to oneself; strict adherence to behaviors to minimize health and other risks

Ratings are made on the prototype (1 = no match to 5 = very good match) and on the traits (0 = very little or not at all descriptive to 3 = extremely descriptive).

more severely impaired; whether or not the distinction is qualitative or quantitative is secondary. Second, it may be helpful to understand APD as a dysfunctional developmental adaptation to chronic social anxiety that, along with low self-worth, becomes folded into an individual's personhood.

In sum, the evolution of the criteria for APD from DSM-III to DSM-IV-TR, and beyond to those under consideration for DSM-5, places greater emphasis on the characteristics or traits of fear of novelty, passivity, and introversion, along with a poor sense of self and the expectation to draw the criticism from others. The proposed changes for APD emphasize introversion and avoidance of activities, including social situations, while criteria for social phobia emphasize the anxiety limited to what is felt in the midst of social situations.

There are several aspects among the APD criteria that highlight nonsocial factors, such as low self-esteem and guilt/shame. There is also an emphasis on behavior in intimate relationships in the criteria for APD that is not present in the social phobia. Additionally, criteria for social phobia highlight the reaction to social situations; fear and anxiety out of proportion to the danger presented by the situation, which is not discussed in APD definitions. These distinctions may eventually clarify qualitative differences, or may suggest personality traits that make individuals more vulnerable to anxiety. It is worth noting that differences in the criteria sets for APD and social phobia are not wholly mutually exclusive, and the rates of cooccurrence still merit investigation and raise questions about the Axis I and Axis II division in the DSM. This suggests

the possibility that there are core pathological elements that may be the same if diagnosis were based on a different level than the clinical reports and observation, for instance, neural, cognitive, or more basic temperamental features.

APD and Other Personality Disorders

Prior to the introduction of APD in the 1980 DSM-III, 'avoidant' personality was captured by the diagnosis of schizoid personality and the psychoanalytic construct of 'phobic character.' In 1969, Millon first argued for a distinct diagnostic construct for 'avoidant personality disorder' but it was not until the DSM-III that APD was officially cleaved from the old DSM I/II diagnosis of schizoid personality. Thus, among the personality disorders, APD and schizoid personality disorder share a close relationship based on their diagnostic lineage, though there have been efforts to distinguish the two. Both personality types tend to engage primarily in solitary as opposed to social activities, and appear aloof or inhibited in social situations. Although similar on this clinical symptom, the distinction between avoidant and schizoid personality disorders resides in motivation or desire for intimacy for APD, something that is said to be lacking in schizoid. In addition, there is a capacity, albeit an often unfulfilled capacity, for social attachment in APD that does not seem to be present for schizoid personality disorder. Unlike individuals with avoidant personality disorder, who intensely desire relationships and avoid them because of exaggerated fears of rejection, persons with schizoid personality disorder have little or no apparent interest in developing interpersonal relationships. In 1982, Millon clarified this distinction in motivation for attachment, and his distinction has been included in the criteria and the text description of APD in the DSM ever since. For schizoid, the motivation was passive, whereas for avoidant, it was active. Millon's distinction between active and passive detachment was central to the official introduction of avoidant personality disorder in DSM-III.

Like schizoid, those with schizotypal or paranoid personality disorder may also react negatively to the idea of interpersonal relationships. However, in both of these cases, the wariness in interpersonal relatedness is more apt to stem from paranoia rather than the hypervigilance for criticism common to APD or the indifference of schizoid. Schizoid, schizotypal, and paranoid personality disorders all reside in the DSM Cluster A 'odd-eccentric.' Though paranoid features connote a certain sense of fear, that type of reaction is based more on disordered thinking rather than anxious fear based on the anticipation of criticism, as is the case with APD.

Another personality disorder that may share some similarity on the clinical surface with APD is dependent personality disorder. Like APD, dependent personality disorder rests in the anxious or fearful 'Cluster C' of DSM Axis II personality disorders. Characteristic of both disorders are low self-esteem, rejection sensitivity, and an excessive need for reassurance. Both may be defined in terms of attachment anxiety. However, a key distinction of APD is that the anxiety is driven by a fear of rejection, whereas in the case of dependent personality the anxiety stems from fear of separation and/or rejection once a relationship has been established. Thus, with dependent

personality disorder, distress is clear in the midst of a close relationship or after a close relationship ends. Often, those with dependent personality disorder scurry to find a new relationship after one has ended. People suffering from APD, on the other hand, are slow to enter into new relationships.

Stability and Course

A primary distinction between Axis I and Axis II personality disorders in the DSM system is the chronic and enduring course of personality disorders relative to clinical syndromes on Axis I. This long-held assumption is part of the definition of personality disorders as chronic and enduring, which has been challenged with recent empirical studies that have examined the prospective course of personality disorders, such as the CLPS and the McLean Study for Adult Development. The general finding from both of these longitudinal, naturalistic studies is that personality disorders remit diagnostically much more often than was originally assumed. This pattern has been demonstrated specifically with APD in report from the CLPS led by Grilo (at the symptomatic level) and by Sanislow (at the construct level). However, other CLPS reports led by Skodol have shown that functional impairment, including social and occupational deficits, persist for APD and other personality disorders even though the symptom counts may drop below diagnostic threshold (true for other personality disorders, too). Thus, clinically significant impairments that impede the social relationships and occupational potential of those with APD remain evident over the long run.

DSM-IV-TR personality disorder criteria are a mixture of traits, symptoms, and behaviors, and it is reasonable to query if certain APD symptoms tend to persist more than others. In another CLPS report led by McGlashan, it was evident that certain APD criteria were more enduring than others. In assessments conducted 2 years later by clinical interviewers blind to the baseline diagnoses, the criteria 'feels inadequate' and 'socially inept' were the most persistent. 'Preoccupation with rejection,' 'need to be liked first,' and 'void risks for fear of embarrassment' continued to a moderate degree, while 'fears ridicule and shame' and 'avoids jobs with interpersonal contact' were the most likely to remit. Thus, the top two most persistent criteria include both a deficit in self and an interpersonal deficit. At the other end, the least persistent are tied to behavior in a specific situation (jobs with interpersonal contact) and fear-based anxiety (fear ridicule and shame). The more persistent are more global, representing general personality constructs, whereas the least persistent are based on behaviors (interpersonal jobs) and symptom based (fear). Like APD's Axis I counterpart, social phobia, these latter two criteria may be easier to overcome than one's sense of self or more global deficits in social skills.

Interpersonal Experiences, Development, and Risk for APD

Like other personality disorders, interpersonal problems are a critical feature of avoidant personality disorder. In fact, almost all DSM criteria for APD describe aspects of the interpersonal

problems generated and encountered by an individual with APD. The most articulate description of the interpersonal features of the APD symptoms are derived from Lorna Smith Benjamin's *structural analysis of social behavior* (SASB). The SASB codes patterns of interpersonal behavior of both the self and the other, and also codes for the patterns of interpersonal behavior that one has repeatedly experienced as they relate to how a person perceives or thinks about him or herself. Benjamin has applied this model to the DSM personality disorders, including APD, and has linked characteristic interpersonal patterns to APD criteria. From there, it is possible to trace back characteristic interpersonal experiences of the person suffering APD and to infer how they 'talk to' or otherwise treat themselves.

Interpersonal Origins of APD

According to Benjamin's interpersonal theory, the people with APD live in a state expecting degrading, humiliating attack. Their self-protective response to this possibility, which for them looms with certainty, is social withdrawal. This promotes a perception of others that borders on paranoid and a reliance on safety at home that can sap the resources of the few individuals with whom the person with APD does have a relationship. Benjamin describes these patterns in her book, *The Interpersonal Diagnosis of DSM-IV Personality Disorders*. The origins of this pattern of behavior require that the person had enough love and nurturance to form a good sense of self, and the difficult interpersonal transactions came during later stages of psychological development. For instance, "exhortations combined with degrading mockery" (p. 292) put a premium on the need to occlude any personal failings, thus leading to intense self-scrutiny along with vulnerability to criticism. For Benjamin, the *sine qua non* for APD is a "...defensive withdrawal out of fear of humiliation, attack, and rejection, and the wish for acceptance" (p. 298). Clearly, for professionals treating the persons with APD, it is important provide uncritical support while not pushing them too far, too fast.

Treatment

Individual therapy has historically been used as a treatment for APD. This type of therapy can be difficult for an avoidant, because the maladaptive behaviors and thought processes characteristic of APD interpersonal relationships also extend to the relationship with the therapist. Those with APD often fear being rejected by the therapist, tend to doubt the authenticity of the therapist's concern, and are likely to reject help. Therapists should take extreme care to avoid behavior that may be interpreted as judgmental, as the person with APD is generally sensitive to even mild criticism, and should be prepared for the patient to perceive the therapist as critical even if there is no real basis for this perception. Benjamin stresses that therapists should aim to provide 'accurate empathy' and 'warm support' in order to build trust. Once trust has been successfully established, the therapeutic relationship may serve as a testing ground for new coping skills. In the context of a 'safe' relationship, dysfunctional beliefs about the therapy relationship can be frankly examined, serving as a model for the patients to evaluate other relationships in their life.

Cognitive behavioral therapy (CBT) techniques, which encourage patients to identify the fears of rejection and criticism that underlie APD and then modify these distorted thought processes, have proven particularly helpful in the treatment of APD. Cognitive restructuring, for example, involves examining the patient's thoughts about the feared situations and challenging them. This technique is predicated on the theory that social anxiety arises from misconceptions about dangers that social situations pose and other false and overly negative cognitions. The process of cognitive restructuring includes identifying these negative beliefs, evaluating their accuracy, and recognizing possible alternatives to help address the overwhelming anxiety characteristic of patients with APD.

Behavioral therapy strategies to treat APD generally fall under two categories: graduated exposure and skills training. Exposure therapy rests on the idea that graduated exposure to the fear-provoking situation (in this case, social interaction) will help the individual overcome their fear and bring about behavioral change. For those suffering APD, exposure therapy typically involves learning relaxation techniques and then applying them to gradually higher-risk social situations both in and outside of therapy. This treatment is most effective when the patient is fully engaged in the threatening situation and is open to becoming fully immersed in the experience despite the negative emotions destined to arise. For the person with APD, this is difficult because it runs counter to instinctive avoidance of engaging in frightening social situations. The response by someone suffering from APD is not always obvious avoidance, and a patient may surreptitiously or unwittingly utilize maladaptive cognitive processing strategies to reduce their anxiety such as not fully attending to the stimuli meant to induce negative emotion. Thus, in the case where social anxiety has become bound with self-definition and esteem, exposure therapy may prove ineffective.

Social skills training is intended to directly address any interpersonal deficits the avoidant may exhibit. This strategy is predicated on the assumption that people with APD exhibit poor social skills, and that teaching them positive social skills will increase positive reactions from others and thus reduce anxiety. Much of this work has focused more specifically on shyness and related social deficits, and clinical researchers who have targeted the symptomatic aspects have demonstrated good results that are applicable to treatments aimed at APD. For instance, basic skills training in social behaviors such as assertiveness, eye contact, self-disclosure, nonverbal social cues, and listening skills are likely to invite positive, warm, and uncritical responses from others and thus help the person suffering from APD build confidence.

Both social skills training and graduated exposure therapy can be performed in a group or individualized setting, though there are obvious advantages for those patients who can tolerate group treatment as the results may more effectively generalize to other areas of the patients' lives. As with any therapeutic treatment, a personalized approach matched to the patient's needs is desirable, though much more research is needed on how to effectively identify needs and match those needs with different interventions.

Treatment Outcome Studies

Alden and colleagues conducted a rare study that specifically focused on group treatment for APD. They performed a

randomized controlled clinical trial investigating the efficacy of graduated exposure therapy alone versus graduated exposure with interpersonal skills training, and found that the APD patients who received both types of treatment had improved in reports of social reticence, social anxiety, and a wide variety of other measures, and that the gains had been maintained 3 months after treatment had ended. However, the treatment groups did not significantly differ from one another in terms of the amount of improvement, suggesting that the addition of social skills training did not increase the benefits of graduated exposure alone. Alden and colleagues later reexamined the data from their study and concluded that variations in the symptom patterns of APD may differentiate treatment response. The reanalysis showed that patients who exhibited more distrust and anger benefitted most from graduated exposure, while patients with problems asserting themselves were shown to benefit from both treatments, especially an intimacy-focused social skills training. Unfortunately, despite the gains made by the APD patients during treatment, the patients still functioned significantly below normal levels of social behavior at the conclusion of the 10 week treatment. The authors suggest that a longer period of treatment may be necessary to further increase progress. Research is also needed to compare the efficacy of group and individual therapy for APD, as Alden studied all treatments in a group setting.

Insights from Treatment of Social Anxiety

Scientific research on the clinical outcomes for treatment of the APD diagnosis per se is very limited. Other, related forms of anxiety, such as social phobia, have been more frequently studied and this more general work offers insights about techniques that may be effective for APD. Like APD, treatment for social anxiety often consists of CBT techniques such as cognitive restructuring, graduated exposure, relaxation techniques, and social skills training. Heimberg reviewed the efficacy of treatment for social anxiety looking at the efficacy of types of CBT as treatment for social anxiety. He reported that all types of CBT produce better effect sizes than no treatment control groups, and exposure alone and exposure plus cognitive restructuring produce similar, significant effect sizes, while social skills training, cognitive restructuring, and relaxation training all produce slightly less change than exposure-based interventions. No differences were found between individual and group treatments, and these gains were maintained at follow-up assessments. Another group of researchers, Alden and colleagues, looked at exposure alone versus exposure plus social skills training versus a waitlist control group for adults who reported impairment in various areas of social functioning, including experiencing extreme shyness. The group given the combination of exposure plus social skills training reported significantly improved functioning compared to other groups.

Pharmacotherapy

A number of studies have looked at the effectiveness of pharmacotherapy for social anxiety disorders, although results are inconclusive as to whether the benefits of medication are clinically significant over CBT and other psychotherapy

approaches. Antidepressants, particularly the SSRI's are the most studied and appear to be the most effective medication treatment, although antianxiety medications may provide short-term relief. Beta blockers are also often helpful. In comparative studies, most work demonstrates that medication groups and CBT groups improve about the same, and curiously, placebo groups also show significant improvement, though usually to a lesser degree. A combination of medication plus CBT is common in practice, but the efficacy of adding medication to CBT, relative to CBT alone, is not well studied enough to draw firm conclusions. Most important, studies examining longer-term outcomes of medication versus psychotherapy are needed.

Limits to Understanding APD Treatment from Other Disorders

Treatment for social anxiety appears to address some, but not all types of impairment in APD. It addresses the social impairment, and can thus be somewhat helpful in treating APD. In his review, Heimberg showed that one of the factors predicting outcomes of treatment is the severity of symptoms at pretreatment. Patients with both social anxiety disorder and APD tend to begin treatment more impaired than those with social anxiety alone, and while they showed improvement, they were still more impaired than patients with just social anxiety at posttreatment. Patients with the generalized type of social anxiety (the diagnosis of social anxiety most similar to APD) also tended to be more impaired, and CBT was less effective for this type than for those with the nongeneralized types of social anxiety. This result is not too surprising as treatment for social anxiety typically does not address nonsocial characteristics that typify APD, such as guilt/shame, avoidance of (nonsocial) activities, fear of novelty, and passivity.

Conclusion

Most diagnosticians and taxonomists of psychopathology and personality are well aware that these diagnoses are constructs that help us to organize patterns in myriad traits, symptoms, and behaviors and to recognize those features that coalesce and thus suggest some coherence. As such, diagnostic constructs such as APD provide a useful explanatory tool to help understand and communicate among professionals, and to develop, implement, and guide treatments. The APD diagnosis provides valuable clinical utility, but diagnostic systems are not perfect, in part because the diagnostic constructs themselves are not 'real' or natural kinds. Rather, diagnostic constructs are approximations of a hypothetical construct; one that itself is not directly observable or otherwise tangible. In the absence of an etiological understanding and the identification of a specific pathology (rather than a syndrome), problems such as diagnostic overlap are part of the course. Thus, it is important to bear in mind that the comorbidity with APD and Axis I disorders such as social phobia may be a matter of intensity, or that criteria overlap and comorbidity with other Axis II disorders such as schizoid personality disorder may reflect shared pathological mechanisms or more simply may be an artifact of our diagnostic architecture.

APD is a useful diagnostic construct that tells us about a person chronically suffering extreme levels of anxiety that stems

from a negative view of the self, as evident in social avoidance. While APD has manifest interpersonal 'symptoms,' it is equally a problem of one's own inner experience. Core to the disorder is the fear of being perceived as a failure, and this fear is so intense that it drives the person suffering from APD to isolation. The relief experienced from this self-imposed isolation can further reinforce the problem, and thus perpetuate a long-standing personality pattern from which it is difficult to break free.

The anticipated DSM-5 and ICD-11, along with a host of issues that the field is presently tackling, present challenges beyond human prescience when describing a diagnosis that may change or disappear altogether as knowledge advances. For instance, although the prototype description helps make clear the definition of APD, a trait approach to diagnosis may be favored in the DSM-5. Nonetheless, there are exciting possibilities of changes ahead, including whether dimensional approaches offer advantages over categorical approaches, or if an optimal number of factors or criteria better captures a form of personality-related pathology than does the DSM nomenclature that has persisted for the last three decades. Last, questions about the boundary between Axis I and II disorders have also been raised, for APD with social phobia. Future developments in personality pathology and psychiatric diagnosis are sure to be exciting, and whatever viewpoint one holds of the DSM system, it has in the last three decades yielded a wealth of empirical information to scaffold for future diagnostic efforts.

Glossary

Applied behavior analysis The application of principles of operant conditioning to the behavior of individuals in socially significant contexts.

Extinction Withholding reinforcement of a previously reinforced response, which results in a decrease of that response.

Operant behavior Behavior that is influenced by stimulus changes that follow its occurrence.

Punishment A process of behavior change by which a change in a stimulus event or condition that immediately

follows a response decreases the future frequency of that response.

Reinforcement A process of behavior change by which a change in a stimulus event or condition that immediately follows a response increases the future frequency of that response.

Selection by consequences Behaviors that produce favorable outcomes are more likely to be repeated and those that produce aversive outcomes are less likely to be repeated.

Three-term contingency The relation between an antecedent event, a target behavior, and a consequent event.

Introduction

Behavior analysis is a discipline with three primary branches: (a) behaviorism, which focuses on the world view or philosophy of behavior analysis; (b) the experimental analysis of behavior (EAB), which focuses on identifying and analyzing the basic principles and processes that explain behavior; and (c) applied behavior analysis (ABA), which focuses on solving problems of social importance using the principles and procedures of behavior analysis. Behavior analysis can be better understood by examining the history and philosophy of how behaviorism came to be.

Behavior analysis began as a school or subfield within the discipline of psychology. While the majority of psychologists in the early 1900s studied mental processes such as consciousness, John B. Watson argued that the proper subject matter was not states of mind or mental processes, but rather observable behavior. Thus, Watson created a new direction in the field of psychology by objectively studying behavior as a natural science consisting of direct observation of the relationship between environmental stimuli (S) and responses (R) which came to be known as S-R psychology.

One component of S-R psychology is respondent behavior, which is defined as behavior that is elicited by antecedent stimuli. In 1927, Ivan Pavlov, published a collection of experiments demonstrating that new stimuli can acquire the ability to elicit respondents. At the time of this experimentation, Pavlov was studying digestion using dogs as experimental subjects. In a well-documented paradigm, a tone signaled the availability of food. Although unintentional, Pavlov found that the dogs began to salivate when the tone occurred (i.e., before the food was presented) presumably because the dog had learned to 'expect' the forthcoming food. This line of research led to the development of a type of learning typically referred to as respondent (Pavlovian) conditioning. In Pavlov's basic respondent conditioning arrangement, the presence of food was termed an unconditioned stimulus (US), which elicited a reflexive response (in this case,

salivation) which was termed the unconditioned response (UR). Initially, the tone exerted no differential effect on the dog's behavior and was therefore referred to as a neutral stimulus (NS). However, after several trials in which the tone was presented just before the presentation of the food, the dogs began to salivate at the presence of the tone. Thus, through this pairing, the previous NS acquired characteristics of the US; thereby becoming a conditioned stimulus (CS). The salivation which followed the CS was referred to as the conditioned response (CR) to differentiate that this response (although topographically similar) was under the influence of a different stimulus (a tone as opposed to the presentation of the food).

The work of Pavlov was influential to many scholars. Among them was a young Harvard graduate student named B. F. Skinner. Skinner was interested in replicating much of Pavlov's work and began his doctoral work in the joint areas of psychology and physiology. After a great deal of work based upon Pavlov's findings, Skinner came to the conclusion that although respondent conditioning could explain why several behaviors occurred, it could not explain the majority of behaviors; especially those with no apparent antecedent causes in the environment. This conclusion drove Skinner to study other types of behavior (such as a rat's movement down a runway) and a near-continuous modification of his experimental methods (e.g., modifying devices so they recorded the rats' behavior). These modifications, in turn, led to the discovery of patterns of behavior among the rats such as how quickly a rat ate food after running or what occurred if the device failed to deliver food to the rat following running. Skinner observed that these patterns were predictable across organisms. Moreover, he observed that the organisms' behavior was not influenced by the prior stimuli that elicited a reflexive response; instead behavior seemed to be influenced by consequent stimuli (changes in the environment that occurred following behavior).

In 1938, Skinner published *The Behavior of Organisms* which summarized his laboratory research attempting to account for behavior that did not appear to be respondent. Skinner was

interested in the scientific account of all behavior, including those behaviors that appear to follow antecedent stimuli, not just those that appeared to be involuntary or reflexive. They are influenced by stimulus changes that have occurred after a behavior (i.e., a consequent stimulus) and are called operant behaviors. In other words, Skinner identified behavior that operated on the organism's environment to produce differential effects. He surmised that an organism's behavior was governed by a process of selection by consequences in which behaviors that produce desirable outcomes are repeated (or strengthened), whereas those that produce aversive outcomes are decreased (or weakened). In examining the effects of consequences on behavior, Skinner interpreted responding within the context of the operant three-term contingency (antecedent-behavior-consequence).

Skinner's laboratory findings led to the development of a new field of study which was referred to as the *experimental analysis of behavior*. This field produced its own set of experimental methods and (eventually) therapeutic practice as well as a fundamentally distinct conceptualization of behavior. Nevertheless, behavior analysis is often considered a subfield of psychology. Many would argue, however, that the field of behavior analysis differs considerably from the broad field of psychology. To illustrate, the basic tenets that distinguish behavior analysis from other areas of psychology include its emphasis on (a) behavior as the basic datum for the field rather than the psyche, the self, or other internal mental or metaphysical structures or phenomena; (b) continuity between publicly observable behavior and private events (e.g., thinking, feeling); (c) prediction and modification of the behavior of individuals (rather than groups); (d) environmental explanations of behavior; and (e) the study of behavior as a natural science. These basic principles of behavior analysis continue to define the work of behavior analysts and the separate domains of the EAB and ABA. Before considering these respective domains, a brief discussion of the underlying principles and concepts of behavior analysis will be reviewed.

Basic Principles of Behavior

Reinforcement may be considered the most important principle of behavior and is the key to behavior change. Reinforcement occurs when there is a change in a stimulus event or condition that immediately follows a response, which increases the future frequency of that response under similar conditions. The changes in stimuli that function as reinforcers can be described as either presenting a new stimulus into the environment or removing an already present stimulus from the environment.

Positive reinforcement occurs when a behavior is immediately followed by the *presentation* of a stimulus which, as a result, increases the future frequency of that behavior. For example, a rat pushes a lever in an operant chamber and receives a pellet of food. If the frequency of lever pressing increases, one can conclude that the presentation of the food pellet positively reinforced the lever-pressing behavior. A similar effect might be observed for the child who throws a tantrum in the department store. If the parent 'gives in' to the child's behavior by purchasing a toy, the future occurrence of

throwing a tantrum is strengthened such that the child may be more likely to throw a tantrum in the future to produce a desired outcome. (It should be noted that positive reinforcement is a technical term used to describe the effect of a contingency on the occurrence of a response. This is in contrast to the term 'reward' which is used to describe an item or activity presented to someone in an attempt to change behavior. That is, reinforcement is an effect demonstrated by an increase in behavior, whereas a reward is simply something presented to a person that may or may not affect their behavior).

When the frequency of a behavior increases because a stimulus in the environment has been removed, the process is referred to as negative reinforcement. Negative reinforcement is characterized by *escape* or *avoidance* contingencies in which the organism emits a response that either removes or avoids the presentation of an aversive stimulus. The concept of negative reinforcement can be demonstrated by revisiting the rat and operant chamber. For example, a low dose of electricity is sent through the floor of the operant chamber which gives a mild shock to the rat and when the rat pushes the lever the shock is terminated. If the frequency of lever presses in the presence of the shock increases, the lever press response has been negatively reinforced. In a more applied example, loosening one's belt following a large meal often results in the temporary attenuation of discomfort associated with eating too much. In this example, the response of loosening the belt is reinforced by the cessation of aversive stimulation (physical discomfort) which increases the future likelihood of this response in similar situations.

It is important to note that once a behavior has been established and strengthened with reinforcement, it is not necessary to reinforce that behavior on each occurrence. Many behaviors are maintained by intermittently reinforcing its occurrence. An intermittent schedule of reinforcement is a contingency of reinforcement in which some, but not all, occurrences of the behavior produce reinforcement. However, if reinforcement for a behavior that was previously reinforced is withheld for all occurrences, the frequency of that behavior will decrease to similar levels demonstrated prior to reinforcement or will cease altogether. This behavioral procedure is referred to as extinction.

Punishment is another principle of behavior that is defined based on its function. Punishment occurs when a change in a stimulus, event, or condition immediately follows a behavior and decreases the future frequency of that behavior. Like the process of reinforcement, punishment affects behavior through either the presentation or the removal of a stimulus. If an aversive stimulus is presented contingent on a particular behavior which results in a decrease in that behavior, positive punishment has occurred. For example, when a child runs into the street unsupervised, his mother reprimands him. Therefore, the frequency of child running into the street decreases. In contrast, negative punishment occurs when a stimulus (or access to forms of stimulation) is removed from the environment contingent upon a response, and decreases the future frequency of that response. An example of a negative punishment contingency can be demonstrated by a situation in which a child throws a toy. The mother then takes the toy away so he cannot play with it. In this example a preferred stimulus, the toy, is removed following inappropriate

behavior. Timeout is another example of a negative punishment contingency in that, while in timeout the individual cannot access sources of reinforcement. If a punishment contingency is removed, the behavior will ultimately reverse (increase) to levels near those seen prior to punishment. This process is called recovery from punishment.

Although punishment has been shown to be an effective procedure to decrease behavior, it can be argued that there are potential side effects and problems that occur when implementing punishment procedures. First, punishment can produce emotional and aggressive reactions. This is especially seen when positive punishment procedures are used when an aversive stimulus is presented as a consequence for a response. Second, inappropriate escape and avoidance behaviors may arise when a behavior is being punished. For example, a child may begin to lie or hide behaviors to avoid contacting the punishment contingency. Third, punishment may involve undesirable modeling of the punishing behavior. Finally, the decrease in the undesirable behavior of the person being punished may negatively reinforce the behavior of the punisher. In other words, the person implementing the punishment contingency may continue to implement punishment procedures more frequently in the future.

Critical variables for the use of both punishment and reinforcement are consistency and contiguity. A consequence should be implemented consistently to obtain the desired effect on behavior. If reinforcement is applied sporadically, the response will be more resistant to strengthening and less resistant to extinction. Likewise, if punishment is applied on a variable basis, the behavior will not decrease as quickly. Contiguity also plays a role in the efficacy of reinforcement and punishment procedures. Generally speaking, delayed consequences are less effective at changing behavior than are more immediate consequences.

Some behavior analysts argue that, from a functional perspective, reinforcement and punishment are the only principles needed to explain the basic effects of behavioral consequences. However, a number of factors may influence a response within behavioral contingencies. One such factor is the antecedent stimulus that signals the availability of reinforcement to occur. Such a stimulus is called a discriminative stimulus (S^D). For example, a friend asking 'How are you' acts as a S^D for you to say, 'I'm fine,' which is then reinforced by social approval. One would not say, 'I'm fine,' in the absence of another person asking how you are feeling. Likewise, stopping at a traffic signal is an example of behavior under the influence of a S^D . There is not physiological response governing this behavior; rather, our learning history dictates the relation between stopping or moving in the presence of red, yellow, or green lights. When a response comes under the control of some stimuli and not others, it is said to be under stimulus control (as in the case of stopping instead of driving in the presence of a red light).

Another factor that may potentially influence a response within a behavioral contingency is the reinforcing value of the consequence. A motivating operation (MO) refers to an environmental variable that alters the reinforcing effectiveness of a stimulus, event, or condition and alters the current frequency of all behavior that has been reinforced by that stimulus event or condition. A common example of an MO is food deprivation. Food deprivation acts as an MO that

increases the reinforcing effectiveness and value of food. Therefore, food deprivation evokes behavior that, in the past, has been reinforced with food. For example, the response of food ingestion (e.g., eating a sandwich) is more likely to occur when one has not eaten for several hours. It is unlikely that the sandwich will be highly reinforcing immediately after eating a large lunch.

Throughout the past 70 years, literally thousands of studies have supported the fundamental principles of behavior analysis through extensive empirical research carried out in both basic laboratory and applied settings. In the following sections, the focus of research and practice will be outlined for both EAB and ABA.

The Experimental Analysis of Behavior

As mentioned previously, the EAB began in 1938 with Skinner's, *The Behavior of Organisms*. The book summarized Skinner's laboratory research conducted from 1930 to 1937. In the early studies, Skinner primarily used animals (rats and pigeons) as subjects to demonstrate reliable functional relations between behavior and various environmental stimuli. He did this by systematically manipulating the arrangement and schedules of stimuli that precede and follow behaviors while recording the rate at which a single subject emits a given behavior in a controlled setting.

Because behavior analysts working in EAB are focused on basic laboratory research, studies are typically conducted in a well-controlled setting in which the researcher can control the conditions and environment under which the research occurs. When working with animals, operant chambers are used that typically consist of at least one operandum for the subject to manipulate (typically a lever or response key), and a device for reinforcement delivery. During a typical session in an operant chamber, the subject emits a specified response (e.g., lever press) which results in the delivery of a reinforcer (e.g., a food pellet). Skinner developed the operant chamber during the early years of his experimentation to measure the rate of responding and to study various schedules of reinforcement. Since Skinner began his work with operant chambers, thousands of studies examining the effects of changes in environmental stimuli prior to and preceding behavior have been conducted by behavior analysts. Such studies have examined differing schedules of reinforcement, novel or variable responding, allocation of responding or choice (commonly known as the matching law), the effects of different drugs on responding, and stimulus and discriminative control of responding, along with several other areas.

Since the development of the operant chamber, some behavior analysts have moved to conducting basic laboratory research with human participants as well. In recent years, research has focused on studying complex human behavior such as stimulus equivalence, choice, self-control, and the effects of drugs on the behavior of humans.

Applied Behavior Analysis

The general principles under which ABA was founded were developed (and continue to be refined) from the results of laboratory experiments conducted in EAB. Thus, many of the

principles that are applied to human behavior are the result of translational research in which laboratory findings have informed the development of novel applications. This translational link serves as the bridge between EAB and ABA.

ABA differs from EAB in that it is generally interpreted as a clinical discipline in which the general principles of learning and behavior are used to solve or improve problems of social relevance. Behavior analysts who work in ABA conduct research that assist in developing and evaluating practices directed toward the remedy of problems associated with socially significant behavior. Applied behavior analysts then use the results of the applied research to create and implement effective evidence-based procedures in more natural settings such as schools, home, and the community. Such work often focuses on behavioral problems that occur in particular settings and are associated with particular populations (e.g., autism or other developmental disabilities) as well as those that are within a large social context such as organizational behavior management. ABA also has been used to treat clinical behavioral problems such as anxiety, phobias, and depression.

Dimensions of ABA

Early in its development, applied behavior analysts worked primarily in the field of psychology and education. As described by Baer, Wolf, and Risley, there are seven dimensions of ABA that must be implemented in order to assure that effective interventions are developed and implemented. The seven dimensions are (1) applied, (2) behavioral, (3) analytic, (4) technological, (5) conceptually systematic, (6) effective, and (7) generalizable.

Applied behavior analysts select behaviors that are *applied*, meaning that they are socially meaningful and are currently of importance to the individual whose behavior is being modified. For example, if a child with a diagnosis of autism does not have verbal language in his repertoire, it would be more socially acceptable and appropriate to teach the child to request items (e.g., snacks, drinks, and toys) as compared to teaching the child to ride a bicycle. At any given time, a behavior analyst could modify numerous behaviors an individual emits. It is important to prioritize which behaviors are most important to modify. In addition to identifying target behaviors for individuals, behavior analysts must modify behaviors which will affect how behavior analysis is communicated to the media, the general public, and legislatures who fund services.

As described previously as one of the tenets of behaviorism, applied behavior analysts directly observe and manipulate *behavior*. They typically do not use indirect measures of behavior like self-report, interviews, or checklists. In addition, they do not attribute behavior as characteristics of inner qualities such as personality traits. Instead, they attempt to identify a function of the behavior by manipulating environmental variables and observing interactions between behavior and those variables.

Even when working in an applied setting in which the goal is to develop an intervention that will effectively increase or decrease a behavior, it is important to demonstrate experimental control via a systematic *analysis* of behavior. Experimental control is achieved when an experimenter demonstrates a functional (i.e., causal) relationship between environmental variables and a behavior. In ABA, experimental control is

demonstrated using various single-case experimental designs including the reversal, the multielement, and the multiple baseline design. These basic designs share three commonalities: (a) prediction – the anticipated outcome of future measurement, (b) verification – demonstration that the previous expectation of behavior would remain unchanged in the absence of an intervention, and (c) replication – repeating the previous changes in behavior via the introduction and removal of the intervention.

In addition to the analysis of an intervention through the use of a controlled research design, behavior analysts often track one or more dimensions of behavior to determine if an intervention is producing significant behavior changes. Measures such as the frequency (the number of times a behavior occurs), duration (the amount of time in which a behavior occurs), and latency (the measure of time from the onset of a stimulus to the start of a response) are used to track the behavioral progress of an individual. By repeatedly measuring and evaluating different dimensions of behavior, the behavior analyst can determine if changes are needed to the specified intervention.

An example of the *analysis* component of ABA can be demonstrated by the single-subject treatment analysis conducted within a reversal (ABAB) design that is depicted in [Figure 1](#). Each data point represents a 5-min session and sessions are presented along the x-axis in the order in which they were conducted. The y-axis depicts the percentage of each 5-min session in which inappropriate behavior was observed. An initial baseline was conducted to measure the occurrence of inappropriate behavior in the absence of an intervention. High levels of inappropriate behavior were observed ($M = 65.9\%$). On the basis of these data, one would predict that similar levels of responding would continue in the absence of an intervention (which was verified by the collection of each subsequent baseline data point). Conversely, one would predict that the introduction of an intervention would result in a change in behavior, which it did ($M = 6.9\%$). To ensure that the observed change in behavior was due to the intervention presented (as opposed to an extraneous influence), the treatment was withdrawn and the initial baseline pattern of responding was replicated ($M = 88.0\%$ during the second set of baseline data). Finally, the treatment effect was replicated when the intervention was reintroduced ($M = 14.6\%$ during the second set of treatment data).

In addition to selecting an appropriate design for evaluating a functional relation, it is important that behavior analysts are *technological*, meaning that they thoroughly and accurately describe the procedures they use when conducting experiments and implementing behavioral interventions. This information, which includes written procedures, operational definitions of target behaviors, and procedural integrity data, must be documented in a way that allows another individual to replicate the study after reading these documents.

The assessments and interventions that behavior analysts implement are applied in nature. However, these interventions, and the approaches used to develop the interventions, must be *conceptually systematic*. This means that they are based on the basic behavior principles that have been empirically validated over many years by scientists who conduct basic research on the behavioral theories of EAB. Examples of conceptually systematic intervention components are reinforcement, extinction, and schedules of reinforcement (described above).

Figure 1 Percentage of session during which inappropriate behavior occurred during the baseline and treatment conditions for Gail. Adapted with permission from Roane HS and Kelley ME (2008) Decreasing problem behavior associated with a walking program for an individual with developmental and physical disabilities. *Journal of Applied Behavior Analysis* 41: 423–428.

Many experiments that utilize group designs use statistics to determine if there are statistically significant differences between groups. Applied behavior analysts rarely use statistics to determine if behavior change is significant (although there are several statistical procedures for use with single-case research designs). Instead, behavior analysts determine the *effectiveness* of their procedures by evaluating their data, often through visual inspection, that is, whether the individual whose behavior was changed and the family, caregivers, and friends of the individual find the behavior change significant. Just because a behavior change is statistically significant does not mean that the change is socially significant. For example, a reduction of head banging from a rate of 12 per minute to 6 per minute may be statistically significant. However, the individual is still hitting her head ~360 times an hour. Consequently, this is not a socially acceptable level of reduction of head banging. A more significant reduction needs to occur in order to classify the intervention as effective. Typically, behavior analysts examine data visually to assess changes in the stability (relative degree of variability in the data), trend (direction of the behavior; either no trend, a therapeutic trend, or a countertherapeutic trend), and level of behavior across different experimental manipulations or interventions.

The last principle of ABA is that the findings must be *generalizable* to other settings, caregivers, or behaviors. If a child is treated at a clinic and the child's aggressive and disruptive behaviors are decreased to near-zero levels at the clinic, but at school and at home the child is still engaging in the problem behavior, then the behavior reduction has not generalized. Generalization is important because it is not beneficial to decrease a child's behavior in the clinic if he only spends a few hours of his week in that setting. The behavioral intervention is only beneficial if the intervention decreases the child's behavior across different settings when different caregivers implement it. The most effective way of ensuring that generalization occurs is to program it into the intervention.

Researchers and clinicians have been implementing the seven dimensions of ABA across several settings for years. Most notably, ABA has been implemented in educational and clinical settings with individuals with disabilities. However, interventions based on the principles of ABA have been implemented successfully in educational, clinical, sports, and business settings to address a wide range of behavioral issues. The following sections briefly describe the application of ABA in these areas.

Assessment and Treatment of Destructive Behavior

Destructive behavior (e.g., physical aggression, property destruction, self-injurious behavior, pica) is fairly common among individuals with developmental disabilities. Although the principles of ABA have been applied therapeutically to many types of behavior, one of the most notable utilizations of these methods has been within the context of the assessment and treatment of destructive behavior displayed by individuals with developmental disabilities. The following text describes the general course of assessment and treatment of these behaviors using principles of ABA.

Conducting a functional behavior assessment (FBA) is one of the most crucial components of behavioral interventions in educational and clinical settings. It allows a hypothesis to be made about the relationship between the environmental events and behavior. More specifically, it obtains information about the functions a behavior serves (i.e., the causal effects these behaviors have on altering the individual's environment). FBAs allow the behavior analyst to hypothesize what consequences an individual is obtaining for engaging in the problem behavior. There are three common FBA methods: (1) experimental functional analysis, (2) descriptive assessments, and (3) indirect assessments.

An experimental functional analysis is the most structured form of FBA. During a functional analysis, the antecedents

and consequences similar to those in the person's natural environment are experimentally arranged so that the effects on destructive behavior can be separately observed and measured. An experimental functional analysis is often referred to as an 'analog assessment' because, although the antecedents and consequences are similar to those in the natural environment, the assessment itself is not conducted in the natural environment. This allows the behavior analyst to control the environmental variables to better assess the conditions under which the destructive behavior occurs.

Typically, an experimental functional analysis comprises four separate conditions: contingent attention, contingent escape from demand, an alone condition, and a control condition. During the control condition, it is expected that destructive behavior will be low because reinforcement is freely available and no demands are placed on the individual. The four conditions are presented one at a time in a random sequence to determine which conditions result in highest levels of destructive behavior.

Although functional analyses result in clear demonstrations of variables that influence the occurrence of destructive behavior, there are some limitations as well. First, there is a risk of temporarily strengthening or increasing the destructive behavior because the individual is contacting reinforcing stimuli contingent on that behavior. It is also possible that the individual's destructive behavior may acquire new functions during the assessment. Second, it may not be optimal to assess some behaviors using a functional analysis (e.g., those behaviors that, although very serious, occur infrequently or those behaviors that are too dangerous to briefly reinforce). Third, although variables are contrived to simulate the natural setting during a functional analysis, the contrived setting may not detect the variables in the natural setting that are maintaining the destructive behavior.

If conducting an experimental functional analysis is either not feasible or optimal, a behavior analyst may choose to conduct either a descriptive FBA or indirect FBA. Similar to an experimental functional analysis, a descriptive FBA requires direct observation and measurement of the problem behavior; however, during a descriptive assessment, the observation of the behavior is in the natural environment. Hence, descriptive assessments involve observation of destructive behavior under naturally occurring variables that are not systematically arranged. If direct observation is not possible, an indirect FBA can be conducted. An indirect FBA encompasses methods that result in information about the behavior without directly observing that behavior. Such assessments include behavioral interviews with caregivers or teachers, behavioral checklists, rating scales, or questionnaires. Although indirect FBAs are helpful when the behavior cannot be observed, the information gathered must be taken with caution. Often, those being interviewed may have a personal relationship with the individual exhibiting the problem behavior. This may make it difficult to obtain an unbiased and accurate description of the problem behavior.

It is often important to develop an intervention that incorporates an individual's preferences for different activities, foods, etc. For many individuals, identifying preferred items and activities which can be incorporated into behavioral interventions as reinforcers is as easy as asking the individual or

significant others (i.e., caregivers, teachers, etc.) what kinds of things they like. However, identifying effective reinforcers for those individuals with severe disabilities may be more challenging. Fortunately, there are a variety of procedures supported by research that can be used to determine the stimuli an individual prefers as well as the conditions under which reinforcing values of the preferred stimuli change. Although a number of methods have been presented in the literature, most preference assessments involve measuring relative interaction with each stimulus and ordering the stimuli hierarchically in terms of relative level of interaction. In general, stimuli that are associated with higher levels of interaction (i.e., more preferred) function as more effective positive reinforcers.

Once an FBA and a stimulus preference assessment are conducted, a behavioral intervention is typically implemented. Behavioral interventions typically include extinguishing the problem behavior by stopping the delivery of the maintaining consequence identified by the FBA. As noted above, withholding a reinforcer that has previously been shown to maintain a response is a process referred to as extinction. In the context of destructive behavior, extinction would involve no longer delivering the reinforcer (identified in the FBA) following the target behavior. For example, if a child's physical aggression occurred because it resulted in others allowing him out of school work, extinction would be arranged such that the child would no longer be given a break from his work following instances of aggression (i.e., the response no longer produces the reinforcer). An FBA is useful because it indicates what variables to withhold during extinction. However, extinction as a solitary form of intervention is typically not recommended due to the possibility of negative side effects (i.e., an extinction 'burst' or an immediate worsening of behavior before it decreases). Thus, most FBA-based behavioral interventions involve the combined use of extinction and a process called differential reinforcement (DR). In a typical DR procedure, the reinforcer that has been found to maintain destructive behavior is delivered following some alternative response (or the omission of destructive behavior) and destructive behavior is placed on extinction. A commonly used DR approach is called functional communication training in which the individual is taught an alternative, appropriate form of communication which is reinforced while no longer providing reinforcement for the target destructive behavior. Using the above example, the child might be taught that in order to receive a brief break from working he must complete a problem first. Finally, once a treatment is developed to reduce the occurrence of destructive behavior, the treatment must be modified slightly such that it can be implemented in the individual's natural environment (a process referred to as treatment generalization). Again using the above example, the treatment might be gradually modified such that the child is required to complete one problem, then five problems, ten problems, etc. before a break is given (all the while destructive behavior is placed on extinction).

ABA and Autism

In recent years, the term 'applied behavior analysis' has become synonymous with a therapeutic approach targeting autism. Autism is a neurological disorder associated with

ritualistic and restricted engagement in activities and behaviors as well as impairments or abnormalities in a child's development in the areas of communication and social interaction. Although a number of procedures have been presented as potential treatments for autism, procedures based on the principles of ABA have received the most empirical support.

When used to refer to the treatment of autism, 'applied behavior analysis' is most often associated with a specific method of instruction (called discrete trial instruction, DTI) that was pioneered by Ivar Lovaas and colleagues at UCLA. The procedures involved in DTI are firmly grounded in the principles of ABA; however, it is incorrect to use the terms DTI and ABA as synonyms. That is, ABA as a field incorporates many different procedures beyond those utilized in DTI for individuals with autism. Moreover, there are additional behavioral procedures, also based upon principles of ABA, which are effective for teaching autistic individuals. The basic components of these procedures are described below.

In general, the strongest empirical support for the treatment of autism favors the use of early and intensive behavioral intervention (EIBI). In an EIBI program, the procedures from the field of ABA are used (a) to reduce the occurrence of problem behaviors associated with autism and (b) to replace those behaviors with appropriate communication, social skills, play skills, academic skills, and independent living skills. The basic procedures employed in an EIBI program involve rearranging the antecedent and consequent events in the environment such that appropriate behavior reoccurs and problem behavior is extinguished (i.e., the 'selection by consequences' paradigm presented by Skinner). Such treatment is developed by a practitioner with specialized training in ABA and is typically implemented at a 1:1 therapist to child ratio for ~20–40 h per week.

A number of empirical studies have found that ABA-based programs are consistently more effective than eclectic or play-based therapies and the use of ABA programs has been endorsed by a number of professional organizations. A critical review of the features and demonstrated efficacy of ABA-based treatment approaches for autism is beyond the scope of the current chapter; however, common procedures that are based on principles of ABA include: (a) DTI, (b) incidental teaching, (c) pivotal response training, (d) verbal behavior training, (e) natural language paradigm, (f) peer-mediated interventions, (g) precision teaching, and (h) errorless learning.

ABA in Other Areas of Focus

Although the principles of ABA are typically used in educational and clinical settings for individuals with developmental disabilities, these are not the only settings in which ABA has been implemented. Applied behavior analysts have shown that the same principles hold true and are effective in changing individuals' behaviors in organizational settings such as factories, restaurants, and retail. In addition, ABA has been shown to be effective with different populations such as adults with dementia, children with attention deficit/hyperactivity disorder, and athletes.

Conclusion

There are three branches of behavior analysis: behaviorism, experimental behavior analysis, and ABA. Behaviorism is the study of the philosophy and theories of behavior. The major tenants of behaviorism which collectively make it unique are that (a) behavior analysts view behavior as its own subject matter; (b) that private events are the function of the same environmental variables as public events; (c) that individuals, not groups, behave; (d) behavior is a function of variables in the environment; and (e) the study of behavior is a natural science. The purpose of the branch of the EAB is to further develop the basic principles of behavior analysis. The third branch of behavior analysis is ABA and its purpose is to implement the basic principles of behavior analysis in ways that result in socially significant changes for individuals in communities. There are seven dimensions of ABA, including: applied, behavioral, analytic, technological, conceptually systematic, effective, and generalizable. ABA is commonly implemented in educational and clinical settings with individuals with disabilities and this term is sometimes utilized (albeit inaccurately) as a label for a specific treatment for autism. However, the principles of ABA extend beyond individuals with developmental disabilities. ABA is an effective method of changing the behavior of many populations across many settings.

Glossary

Behavior genetics A scientific field that uses both quantitative genetics and molecular genetics to understand both the genetic and environmental contributions to individual variation in human behavior.

Gene The basic unit of inheritance, a section of DNA that codes for a particular product.

Gene–environment correlation When the genetic influences on a phenotype are correlated with the genetic influences on an environmental variable.

Gene–environment interaction When the effect of genes on a phenotype depends on exposure to a certain environment, and vice versa.

Heritability The proportion of total variance in a behavior or trait that varies among individuals in the population that can be attributed to genetic influences.

Nonshared environment Environmental experiences/influences on a phenotype that differ between family members.

Phenotype An observed characteristic of an individual, resulting from a combination of genetic and environmental influences.

Shared environment Environmental influences on a phenotype that are shared between family members and result in making them more similar.

Introduction

The characteristic ways that people think, feel, and behave constitute personality, and personality varies among people. Some people are more introverted, some more extroverted; some enjoy trying new experiences, while others are cautious, restrained, and stick to old habits. Psychologists have long been interested in understanding the reasons for this variation. One obvious place to look is the person's rearing environment, particularly the family. If an individual is more introverted, we might reasonably expect them to have, for instance, a mother who is also more introverted. However, when mother and child are biologically related, it becomes difficult to determine whether the child is introverted because of the genetic similarity to the mother, or if the learning processes and environments that the mother exposed her child to over the course of the child's younger years are the relevant causal factors.

Methods in behavior genetics for modeling genetic and environmental influences on human behavior are a fundamental tool for parsing out these possibilities. The field of behavior genetics, with its focus on twin and adoption studies and 'biometrical modeling' of these kinds of family data, was vitally important in demonstrating genetic influences on most behavioral traits long before the genome was sequenced. We can now say with reasonable certainty that individual differences in personality are influenced by genetic and environmental factors. Some may ask whether, in the era of molecular genetics, these biometric approaches are still necessary. In fact, biometric modeling of personality still has much to contribute, particularly as the field of molecular genetics struggles to find replicable results linking measured genes to personality traits.

Recently, the field of behavior genetics has extended earlier work that estimated the heritability (the magnitude of genetic influence) of personality. New focus on forms of gene–environment interplay – that is, how genetic and environmental factors interact and correlate – may have important implications

for understanding the etiology of personality. In this article, we provide a brief overview of biometric approaches, particularly using twin sample methodology, and how this work informs our understanding of the etiology of personality. We then present extensions of twin modeling that have implications for the structure of personality, links between personality and psychopathology, and connections between personality and environmental risk factors. Our goal is to provide the reader with a broad overview of conceptual and statistical issues related to the modeling of personality data in behavior genetics. Space limitations prevent us from providing a more in-depth treatment of the issues, but we refer interested parties to several excellent texts on behavior genetics.

Genetic and Environmental Influences on Personality Traits

Twin Studies

The most common method for examining genetic and environmental influences on personality variation involves the use of the twin study, thus we focus much of our discussion on this method and the findings from twin studies. Twins are nature's way of providing a natural experimental design to disentangle the relative influence of genes and the environment. Twins come in two varieties: identical (monozygotic, MZ) twins result from the splitting of one fertilized egg, and thus MZ twins share the same DNA/genes. Fraternal (dizygotic, DZ) twins result from two eggs being fertilized at the same time, and share on an average, half of their segregating genes. Biometric modeling takes advantage of the known degrees of genetic and environmental similarity between MZ and DZ twins, using the concordance between twin pairs to decompose the variance in a phenotype into percentages as explained by genes relative to environmental influence. Any phenotype in the human population that differs among individuals (e.g., a personality trait)

can be said to display 'phenotypic variance,' which is attributed to both genetic and environmental influences.

The basic goal of a univariate ('one variable') twin study is to estimate the relative influence of genes and environment. Biometric models separate the variation in a phenotype into three sources that, taken together, can be summed to account for the total variance of the phenotype. The first source of influence is genetic variance, or the amount that a phenotype differs among people because of genetic differences in the population. This source of influence is typically indexed with the heritability statistic, h^2 , or the proportion of total variance in the phenotype that is due to genetic influences. It is important to note that heritability, like the commensurate estimates for environmental influences, is a population-based statistic; thus, if we say that the heritability of a personality trait is 50%, we are saying that 50% of the variance in that trait in the population from which we sampled is due to genetic differences among people in that population; not that 50% of any one individual's personality is due to genes. If genetic influences completely explained all of the variation in a personality trait, we would expect that the correlation between MZ pairs would be 1.0, because MZ twins share all of their genes, while the correlation between DZ pairs would be 0.5 because DZ twins share ~50% of their genes.

The second source of influence is the shared or common environment, abbreviated c^2 . The shared environment indexes the extent to which growing up in the same household makes twins more similar to each other. Shared environment includes things like socioeconomic status, traditions, customs, habits, personality traits of rearing parents, and neighborhood characteristics. If the shared environment completely explained the variance in a personality trait, we would expect that both MZ and DZ twins reared together would correlate 1.0 because all twin pairs share the experience of having been reared together, regardless of their zygosity. The nonshared environment indexes the extent to which twins are different despite sharing the same household and genes. It is abbreviated e^2 and is also referred to as unique environment. Examples of nonshared environment include having friends, life experiences, and traumas that are different from one's siblings. The estimate of nonshared environment also contains any error or imprecision of measurement, and will thus be inflated to the extent that people are measured with less than perfect fidelity. Expectations resulting from nonshared environment completely explaining the variation in a personality trait would be MZ and DZ twin correlations of 0.0, consistent with the idea that the nonshared environment represents the uniqueness of a specific person.

Both shared and nonshared environmental effects are also commonly discussed as proportions of variance, like the heritability statistic. It is important to note that the distinction between nonshared and shared environmental influences can be subtle. Parenting practices could be conceived of as shared between all siblings in the family, to the extent that the same parenting style might make siblings more similar to each other (shared environment), but perceptions of parenting may be unique to each individual child and thus work to make children growing up with the same parent less similar to each other (nonshared environment).

Evidence from decades of work consistently shows that almost any psychologically interesting phenotype has a genetic

component, a finding so ubiquitous that it has been called the 'First Law' of behavior genetics. This includes almost every major personality trait or domain. Across varying samples, cultures, population cohorts, and personality measures, the heritability of any typical personality trait is around 50%, with the rest of the variance coming mostly from nonshared environmental influences. Very little personality variation can be accounted for by the effects of the rearing family environment, beyond the contribution of shared genetics. Much of this work has been conducted on traits from the Big Five personality domains (extraversion, openness, agreeableness, conscientiousness, and neuroticism). In their review of the literature on twin studies of the Big Five traits, Bouchard and Loehlin found that the heritability of all five domains was around 40–50%. The consistency of this finding across the traits, which differ widely in the aspects of human behavior that they capture, is compelling evidence of the ubiquity of genetic influences on human individual differences.

Several points related to these findings are worth considering. First, moderate to sizeable estimates of genetic influence have also been found for dimensional measures of pathological personality and categorical personality disorder diagnoses. Second, with only a few exceptions, (e.g., altruism), estimates of shared environment tend to hover close to 0, suggesting that influences from the family, beyond genetic inheritance, have little or no impact on personality. However, we cannot rule out the possibility that shared environmental influences act in an interactive manner on personality, as opposed to having a main effect. If interactional or transactional processes are at work, such that some family-level factors enhance and some suppress genetic effects on personality, the influence of such factors could appear in either heritability or nonshared environmental estimates.

Third, most heritability estimates are based on the assumption of additive genetic effects, the idea that individual genetic contributions are fungible and 'add up' in their influence on phenotypic variation. More complex genetic effects (such as genetic contributions interacting with each other, a phenomenon known as epistasis) are possible and may also be important in understanding the underlying molecular architecture of personality. Fourth, even though a substantial portion of the etiology of personality is estimated as nonshared environmental effects, research has been relatively unsuccessful in linking personality variation to specific environmental effects or risk factors, a topic we return to below.

Finally, much of the work to date on personality and behavior genetics has concentrated on adult twin samples using self-report methods. More recently, research has extended downward to child and adolescent samples, using both self- and observer report of personality. One study, using a sample of 9–10-year-old twins, found substantial heritability estimates for only two (Self-directedness and Harm Avoidance) of the scales from the Junior Character and Temperament Inventory. Notably, they found substantial shared environmental effects for Novelty Seeking and Cooperativeness. A different study used a sample of toddlers and found that the variation in inhibitory control (IC), a dimension of temperament, was 38% genetic and 62% nonshared environment using observer ratings, but 58% genetic, 26% shared environment, and 16%

nonshared environment using parent ratings, suggesting both developmental and rater effects may be important in understanding the etiology of personality.

Adoption Studies

Most behavior genetic research on personality has utilized the twin study design, but adoption studies also provide a genetically informative perspective on the etiology of personality. Families in which there is an adopted child, like the twin design, provide a natural experiment for understanding genetic and environmental influences on personality variation. Consider, for example, a family in which there are both biological children of the parents and adopted, nonbiologically related children (thus, not a kinship adoption). The adopted child or children will share 100% of their family environment with their adoptive parents and nonbiological adopted siblings, but 0% of their genes.

Adoption studies, like twin studies, find substantial nonshared environmental effects and little influence of the shared environment; however, they tend to produce smaller heritability estimates than do twin studies. There are two major possibilities for the discrepancy in findings between twin and adoption studies. One possibility is that identical twins reared together are highly correlated on phenotypes like personality because they are raised in environments that encourage imitation (e.g., being dressed alike by their parents). Twin studies operate under the equal environments assumption (EEA), which posits that the environments of MZ twins are no more alike than DZ twins; if this assumption were violated, MZ twin correlations could be inflated, thus increasing heritability estimates. A powerful research design, focusing on twins reared apart, has proved valuable in supporting the likelihood of the EEA. Any resemblance between twins who are reared apart cannot be traced to the shared environment. Studies of twins reared apart conducted in Minnesota and Sweden find estimates of heritability in line with what has been found in studies of twins reared together.

Another possibility for the discrepancy in heritability estimates between adoption studies and twin studies involves the role of nonadditive genetic effects on personality. As noted above, most twin studies assume that genetic effects are additive, and few find evidence of dominant or nonadditive genetic effects. It is possible that adoption studies are better at identifying nonadditive genetic effects, that is, effects due to interactions among specific genes. The Nonshared Environment in Adolescent Development (NEAD) study was important in furthering our understanding of the role of nonadditive effects in the variation in personality. This study combined information from MZ and DZ twins, full siblings, half siblings, and genetically unrelated children in the same family resulting from remarriage. Results indicated high heritability estimates, significant shared environmental estimates, and little effect of nonshared environment on broad domains of adjustment. In a follow-up study, the authors found slightly lower heritabilities than in the original study, and confirmed the presence of significant nonadditive genetic effects.

While, in general, adoption studies are commensurate with twin studies in showing little evidence of the shared environment, recent findings suggest that the adoption design may be

important in elucidating influences of the family environment on personality variation. A recent study used a large sample of both biologically related and adoptive families to examine genetic and environmental influences on a range of phenotypes, including personality traits of disinhibition and negative emotionality (NE). Both types of families consisted of parents and two adolescent siblings, either biologically related or, in the adoptive families, two adopted siblings or one adopted sibling and one biological sibling. While variation in NE was largely due to nonshared environment and genetic effects, there was evidence of significant shared environmental influences (20%) on disinhibition. The findings support the use of large samples of adoptive families to detect the presence of systematic family influences on the etiology of personality.

Multivariate Modeling of Personality

In the following sections, we argue that the approaches in behavior genetics, particularly advanced biometric models applied to data from twins, adoptions, or other informative behavior genetic designs (e.g., twin family), can help us in better understanding the etiology of personality. We begin by elucidating how biometric models can improve our understanding of the structure and development of personality, before turning to exploration of overlap with psychopathology.

Structure of Personality

Extending beyond the basic univariate twin modeling of personality, research has examined the overlap between genetic and environmental influences on several personality traits considered together. Multivariate biometric modeling of personality variables allows a researcher to decompose not only the variance within phenotypes, but also the covariance between phenotypes, into genetic and environmental influences. These multivariate biometric models have important implications for understanding the structure and organization of personality. For example, we know that at the phenotypic level, the facets of the five factor model (FFM) domain of neuroticism (e.g., angry hostility, anxiety) are correlated, thus supporting their use as indicators of a higher-order factor; biometric modeling can be used to determine if the genetic and environmental influences on these facets mirror the phenotypic factor structure. Biometric modeling of multiple phenotypes (i.e., two or more personality traits) works much like the analysis of single traits, estimating heritability and environmental proportions of variance unique to each, in addition to the amounts shared in common between the two phenotypes. Further, this type of model estimates the genetic and environmental correlations between different traits. A genetic correlation, for example, indexes the amount of overlap between the genetic influences on two different traits, ranging from 0 to 1.0. These genetic and environmental correlations can then be subject to factor analyses, much like phenotypic correlations between traits.

Findings from this work provide a complex picture of how genetic influences on specific domains of personality operate. For example, the genetic structure of personality traits from the FFM domains parallel the phenotypic structure; yet, in addition to genetic influences on the higher-order factors,

there are also genetic influences on more specific personality traits subsumed under the broad domains that are not accounted for by the higher-order genetic factors. Jang and colleagues examined the genetic and environmental structure of the FFM traits using data from a combined German and Canadian twin sample. They found that each of the five domains consisted of two genetic and two nonshared environmental factors, and concluded that the FFM higher-order personality traits may not represent coherent psychological entities. A subsequent study applied the same biometric multivariate models to data consisting of adjectives representing the FFM domains in a nationwide sample of American twins. One etiologically coherent common factor explained the variation in Extraversion and Neuroticism, suggesting that these domains came closest to being unitary personality constructs.

Personality over Time

Genetic and environmental influences can also be studied longitudinally. For example, one study examined the contribution of genetic and environmental influences to the stability and change in 'withdrawn' behavior from age 3 to 12. Substantial genetic influences were found at all ages, particularly at age 3 and 7, and high genetic correlations over time indicated that generally the same genetic influences were operating at all ages. Only modest shared environmental effects were found at any age, although they were slightly higher for girls than for boys and explained more of the stability of withdrawn behavior over time in girls (14% for girls vs. 4% for boys). Nonshared environmental effects increased over time, but smaller nonshared environmental correlations indicated that these effects were different at different ages. The general point is, given longitudinal data on twins, developmental processes can also be parsed into genetic and environmental aspects.

Links to Psychopathology

Approaches in behavior genetics have also been used to examine the shared etiology of personality and psychopathology. Considerable evidence points to the phenotypic associations between personality traits and different psychopathological syndromes. Behavior genetics provides useful tools for examining whether these associations are due to genetic overlap between personality and psychopathology. Extensions of the multivariate biometric model (described above) have also been used to estimate genetic and environmental influence shared in common between personality traits and symptoms of mental illness. Numerous studies have shown shared genetic influences between personality and different forms of psychopathology, including neuroticism and mood disorders and disinhibition and externalizing disorders.

Major theories of the links between personality and psychopathology have been reviewed extensively elsewhere. In brief, the model that has received perhaps the greatest support in both the child and adult literatures suggests that personality traits and different syndromes of psychopathology are lower-order components of a higher-order spectrum. For example, the internalizing–externalizing model of psychopathology indicates that mood and anxiety disorders are indicators of a higher-order spectrum of internalizing, while behavior

disorders of substance use and antisocial behavior and conduct disorders form indicators of a higher-order externalizing factor. The personality trait of neuroticism seems to fit well within the internalizing factor, while the personality trait of conscientiousness (reversed) fits well within the externalizing spectrum.

Two types of biometric models are particularly appropriate for examining the spectrum model of personality and psychopathology. The *common pathways* model posits that the covariation in a set of variables form a single latent phenotype (e.g., personality and psychopathology variables as in the internalizing factor), and this latent phenotype is influenced by one set of additive genetic, shared environmental, and nonshared environmental effects. In contrast, the *independent pathways* model specifies direct links to the personality and psychopathology variables from genetic, shared and nonshared environmental influences common to all the variables and unique to each individual variable. Researchers have recently begun to directly test these competing models. In a twin sample of more than 600 adolescents, Krueger and colleagues found that a common pathway model best explained the covariation between adolescent antisocial behavior, conduct disorder, alcohol dependence, drug dependence, and the personality trait of constraint (reverse scored). This finding is supported by parallel results finding a common factor model of externalizing behavior. More recently, Singh and Waldman compared the common pathway and independent pathway models to explain the covariation among NE and childhood externalizing disorders in a sample of 4–17-year-old twins. Unlike Krueger and colleagues, they found that the independent pathways model provided the best fit to the data, positing that the genetic influences common to both NE and externalizing disorders may support the role of NE as an endophenotype that lies between measured genes on the chromosome and syndromes of mental illness.

Biometric modeling has also been applied to the internalizing spectrum. Kendler and colleagues concluded that the genetic factor structure of the internalizing spectrum disorders, not including any personality traits, closely paralleled the phenotypic structure. A later analysis added neuroticism, and found two overlapping genetic factors; one factor was shared between neuroticism, major depression, generalized anxiety, panic disorder, and the phobias, while the other factor explained the covariation between major depression, generalized anxiety, and panic disorder, independent of neuroticism. Finally, South and Krueger found support for a one-factor model of internalizing with indicators of depression, generalized anxiety, panic attacks, and neuroticism; biometric modeling found estimates of moderate genetic influences and large nonshared environmental influences, with smaller estimates of the shared environment.

Environmental Influences

Having firmly established the importance of genetic influences on personality variation, the field of behavior genetics moved forward with the goal of identifying and explicating the role of environmental risk factors that impact the etiology of personality. One important line of research was initiated by David Rowe, showing genetic influences on putatively

'environmental' measures. Genetic influences have now been found across a variety of environmental measures and assessment approaches. This seminal finding was valuable in showing how people, to some extent, 'make' their own environments; thus, the quality of parent-child, sibling, and marital relationships, for instance, is due, in part, to the genetically influenced traits of the individuals in those relationships. This is known as *gene-environment correlation*, or the degree to which a genotype influences the likelihood of exposure to a specific environment. To directly examine this hypothesis, researchers have modeled the genetic and environmental overlap between personality and measures of the environment. As with the multivariate personality research described above, a Cholesky decomposition can be conducted with personality traits and environmental variables to estimate any shared genetic influences.

Research has shown that there are shared genetic influences between personality traits and aspects of the environment. In a sample of twins reared apart, Krueger and colleagues showed that there was genetic overlap between personality traits and aspects of the childhood rearing environment as recalled in adulthood; further, these genetic influences on personality accounted entirely for the genetic influences on the environment. Kandler and colleagues later replicated these results in a sample of twins reared together. Again, they found genetic overlap between aspects of the rearing environment (i.e., support) and personality traits, using both self- and peer-reports of a different personality measure than the prior study. South and colleagues, in a sample of adolescent twins, found genetic correlations between self-reported personality factors of positive emotionality, NE, and constraint from the Multidimensional Personality Questionnaire (MPQ) and aspects of the adolescent's relationship with his or her parent relationship. Together, these findings support the role of personality in shaping the nature of environment. Not only do genetically influenced personality traits impact the perception of the rearing environment, it appears that aspects of the environment (e.g., the quality of the parent-child relationship) are reactive to those same genetically influenced personality traits.

Another possible form of interplay between personality and the environment, beyond gene-environment correlation, is called gene-environment interaction, and refers to the fact that different environments might moderate the genetic and environmental influences on personality. In other words, whether or not genetic influences on personality traits are expressed may depend on the context or experience of certain environmental influences. Typically, when heritability is estimated in a biometric model using twin samples, it is estimated across the entire sample-specific population. Thus, the heritability estimate averages over any differences that might occur within certain subsamples in the population. Biometric moderation models have been developed that allow for different estimates of heritability depending on a person's standing on an identified environmental moderator variable. Consider that univariate and multivariate twin studies have, for many years, utilized biometric models that examine whether there are gender differences in heritability estimates. Biometric moderation models extend this idea, but instead of using gender they estimate whether heritability may differ depending on

environmental contexts like socioeconomic status, marital quality, or the parent-child relationship. A recent study used these biometric moderation models to examine gene X environment interactions between personality traits and the parent-child relationship in a sample of adolescent twins. They found that the heritability of broad personality factors (positive emotionality and NE) varied as a function of the quality of the parent-adolescent relationship, suggesting that how much genes influence the variation in personality may depend on the family context. This work is still in the early stages and much more still needs to be done before we can say with any great certainty whether gene-environment interplay will be a major step forward in understanding the developmental, causal pathways to personality.

Summary

In this article, we reviewed the decades of research in behavioral genetics that has consistently found moderately strong estimates of genetic and nonshared environmental influences on personality. Family influences, beyond genetic effects, have been more difficult to find, although recent studies using younger samples, different personality assessment methods, and adoption studies provide some tentative evidence that shared environment may be more important, particularly in childhood, than previously thought. While nonshared environmental effects have historically been substantial, researchers have struggled to identify the specific environmental contexts or risk factors involved in the etiology of personality. Biometric moderation models that estimate gene X environment interaction in the presence of gene-environment correlation may provide one way of finally elucidating important environmental contexts. This has particularly strong implications for finding measured genes (from a molecular genetic approach) involved in personality variation. As the field of behavior genetics of personality moves forward, there appears to be ripe opportunities for collaboration with molecular genetics, with methodologies from both fields helping to inform the other, linking more refined personality inventories with measured genes and the particular environmental contexts which modify their expression.

Glossary

Cardiothoracic impedance A noninvasive technique for the measurement of cardiothoracic blood flow by passing an electrical current through thorax and recording and analyzing changes in impedance (impediment to electric current flow). This information can be used to derive measures of cardiac contractility, which reflects alterations in sympathetic nervous system activity as well as cardiac output, which indexes cardiovascular status.

Cortisol A steroid hormone typically associated with the stress response that has broad effects on metabolic, cardiovascular, and immunological processes.

Galvanic skin response A method for measuring the electrical resistance of the skin which can serve as an index to sympathetic responses.

Heart rate variability The rhythmical fluctuation in heart rate that serves as a measure of autonomic cardiac control. Variations within particular band widths can then be used to parse out parasympathetic cardiac control through the quantification of the component of heart rate variability in the respiratory frequency band (respiratory sinus arrhythmia).

Oxytocin A hypothalamic neuropeptide that plays an important role in various social behaviors in animals and humans.

Introduction

Human behavior is an emergent phenomenon that results from complex neural and environmental determinants occurring across multiple levels of organization. Psychologists have long appreciated this fact, and the application of psychophysiological measures to psychological research has expanded in recent years. Multilevel analyses, such as those commonly used in psychophysiological research, represent a subset of interdisciplinary approaches where the measures, constructs, and theories cover multiple levels of organization. The growth of multilevel analysis has provided important insights into the reciprocal interactions between psychological and neurophysiological processes.

Multilevel analyses involve more than manipulating or measuring variables at different levels of organization. If multilevel analyses are to provide more extensive models of human behavior, they also require an explication of the mechanisms connecting these variables. This, in turn, requires an appreciation for the nature of the potential mappings between levels of organization. The unique scientific dialects used by the social and biological sciences can increase the prevalence of category errors, where seemingly parallel concepts from different levels of analysis reflect only partially overlapping domains, rather than representing a one-to-one isomorphism. Although the inherent complexity of psychophysical relations can present unique scientific challenges, multilevel analysis capitalizes on such complexity through a mutual calibration process whereby knowledge at one level of analysis can refine and inform another and reduce the incidence of category errors.

In this article, we highlight some features of contemporary neurobehavioral measurement within the context of multilevel analysis and provide a framework for applying such analyses to the study of human behavior.

Some Principles of Multilevel Measurement of Behavior

In this section we highlight some of the conceptual foundations of the multilevel measurement of phenomena relevant to human behavior and provide the rationale, and the potential limitations, for conducting such broad-based research.

The principle of *Multiple Determinism* postulates that processes occurring at one level of organization (e.g., psychological) will have multiple antecedents within and across levels of analysis. For example, individual differences in the psychological and behavioral manifestations of perceived stress are dependent on both genetic and environmental factors. Consequently, isolated analysis of behavioral output may provide information on psychological processes, but the precise determinants of such responses are not necessarily inherent in this behavior. Because of the multiple determinants across even proximal levels, the mappings across more divergent levels of analysis become increasingly complex. Although the ultimate goal of multilevel analysis is to bridge levels of analysis, the *Corollary of Proximity* suggests that this effort may be more straightforward for more closely related levels since the complexity of the mappings increases geometrically as one moves linearly across levels of organization. Skip levels, and the mappings can become impenetrably complex. This is not to suggest that bridging across broader levels of analysis is not possible or desirable; rather, it is a realization that the establishment of smaller bridges may be more efficient and can provide the foundation for more expansive bridge-building efforts.

The principle of *Nonadditive Determinism* reflects the fact that the properties of the whole cannot always be predicted by the properties of its parts. The sources of variance from higher-level processes are often broader than those for lower levels of organization; so, higher-level systems tend to be more complex. The increased complexity inherent in behavioral and

psychological processes can limit the utility of reductionistic approaches in the full explication of complex phenomena. For example, while understanding the contribution of isolated genes to psychiatric conditions can be quite useful, in order to understand pleiotropic effects of genetic networks one needs to understand how the gene products interact with each other and attempt to incorporate this emergent behavior into more comprehensive models. Thus, phenomena of interest should include observations at the highest level of organization at which it manifests, as it may not be understood by appeal exclusively to a priori understandings derived solely from lower levels of analysis, a concept termed the *Corollary of Asymmetry*. The corollary of asymmetry does not deny the utility of measurement at strictly lower-level analyses (e.g., cellular processes), but does assert that a single level of analysis may not universally provide the optimal description of scientific phenomena.

Lastly, the principle of *Reciprocal Determinism* asserts that there may be mutual, reciprocal influences among levels of organization where the direction of causation or explanation need not always flow from lower- to higher-level phenomena. One may be tempted to view causation as an entirely bottom-up process where lower-level operations (e.g., genes) strictly determine activity at higher levels (cellular, organ system, or behavior). While such bottom-up strategies have provided countless scientific breakthroughs, they do not provide a complete picture. For example, environmental influences can reprogram the expression of particular genes, which can then be passed on to subsequent generations through epigenetic inheritance. Therefore, because causal influences among levels can be bidirectional, the *Corollary of Interdependence* states

that a single level of analysis may not yield a comprehensive account of multilevel phenomena, and that no single level of analysis applies uniformly. Importantly, this is not to suggest that research conducted within individual levels is not important as multilevel research is necessarily dependent on the work done within single-level analysis. However, the corollary suggests that multilevel analysis may be necessary for a comprehensive understanding of phenomena as complex as human behavior.

Application of Psychophysiological Measurement

Psychophysiological measures of neurobehavioral processes provide a unique perspective on human behavior. Indeed, psychophysiological measures provide a global view of the emergent behavior of integrated neurophysiological systems that present a picture of neurobehavioral systems that may not be apparent through the isolated measurement of molecular or molar processes. Generally, neurophysiological measures are of interest primarily to the extent to which they allow one to index a psychological process (Figure 1). For example, the analysis of sympathetic and parasympathetic regulation of cardiac functioning is widely used to index the activity of neurobiological processes associated with psychological states including anxiety, attention, and arousal. In this regard, differential patterns of sympathetic and parasympathetic activation of the heart can provide valuable information on the neurobiological and psychological processes that control autonomic output. In the following section, we highlight some applications of psychophysiological measurement within the context of multilevel analysis.

Figure 1 Summary of commonly used measurement of psychophysiological measurement. Environmental stimuli modulate neurobiological processes, which subsequently modify psychobiological processing that can be indexed through imaging technologies (e.g., fMRI), cardiac autonomic control measurement, skin conductance alterations, and variations in stress hormone levels.

Measurement of Autonomic Nervous System Function in Neurobehavioral Processes

The theoretical underpinning of multilevel analysis to human behavior has existed for decades with contemporary views beginning to take shape at the turn of the nineteenth century. In his essay "Evolution and dissolution of the nervous system," Jackson (1884) laid the foundation for multilevel characterizations of neuroarchitectural developments. Jackson argued that the emergence of higher levels of neuronal organization does not involve a replacement of lower levels. Instead, higher-level brain structures (e.g., cerebral cortex) can be characterized by a hierarchical organizational pattern composed of simple reflex-like circuits at the lowest levels (brainstem and spinal cord) and distributed neural networks for more integrative computations at higher levels. Together these interacting hierarchical structures allow neural systems to respond to environmental and neurophysiological perturbations via rapid low-level processing (e.g., startle reflex) allowing more rostral neural substrates sufficient time to develop strategic responses.

Early hierarchical models of autonomic control were perhaps most visibly articulated by Walter Cannon in the early twentieth century. Cannon's work revolved around the concept of 'homeostasis' which proposed that a primary role of autonomic nervous system (ANS) was maintaining the constancy in vital neurophysiological processes (e.g., blood pressure). Cannon proposed that the sympathetic nervous system served as the primary modulator of homeostatic processes with activity in the parasympathetic branch serving to fine-tune end-organ responses. Based in part on Cannon's work, parasympathetic and sympathetic outputs, which generally have opposing actions, have been considered to be reciprocally regulated by central systems. Reciprocal activation patterns, where activity in one autonomic branch increases and the other decreases, are often observed in reflex responses where the reciprocal changes in the independent branches act in concert to expand dynamic control of end-organ responses.

In addition to hierarchical patterns of autonomic control, descending neural projections are capable of regulating

lower-level neural structures such as the brainstem and spinal cord through the activation of descending projections that bypass intermediate hierarchical structures. This *heterarchical* neuroarchitectural organization likely affords higher-level neural structures the ability to control autonomic and behavioral output patterns independent of intermediate processing levels. Importantly, heterarchical models have all the components of hierarchical systems but have the additional capacity to orchestrate complex behavioral responses through direct control over widely separated levels via direct connections.

Heterarchical control is apparent in central autonomic regulation. Although baroreflex responses typically entail reciprocal patterns of autonomic control, the autonomic branches are capable of independent activation. This has necessitated an expansion in the simple reciprocal bipolar model of autonomic control, in which autonomic states are considered to lie along a single continuum with maximal sympathetic (and minimal parasympathetic) activity at one end and maximal parasympathetic (and minimal sympathetic) activity at the other. Although this bipolar model may apply to reflexive brainstem circuits, the greater flexibility of more rostral neural systems, together with long heterarchical pathways, requires an expanded model of autonomic control that can account for the coactivation (or coinhibition) of the two autonomic branches. Additionally, there may be far greater individual differences in autonomic responses arising from the operations of neural systems controlling complex psychological and behavioral outputs. At a group level, the heart rate responses of human subjects to orthostatic stress and to standard psychological stressors (mental arithmetic, speech stress, reaction time task) are similar. Analysis of the separate contributions of the two autonomic branches by the use of pharmacological blockades revealed that activation of the baroreflex by orthostatic stress (transition from sitting to standing) yielded a rather consistent response across subjects, characterized by reciprocal autonomic output (sympathetic activation and parasympathetic withdrawal). However, psychological stress is capable of producing more varied autonomic responses across subjects, with no overall correlation between the responses of the autonomic branches (Figure 2).

Figure 2 Orthostatic versus psychological stress. Left panel: Group mean responses to orthostatic and psychological stressors depicted as response vectors on the autonomic plane, from baseline (intersection of horizontal and vertical dotted lines) to the stress conditions (arrowheads). Axes depict millisecond of heart period change related to sympathetic and parasympathetic control. Right panel: Individual response vectors to the psychological stressors revealing individual differences in the direction of response. Reprinted from Berntson GG, Cacioppo JT, Binkley PF, Uchino BN, Quigley KS, and Fieldstone A (1994) Autonomic cardiac control. III. Psychological stress and cardiac response in autonomic space as revealed by pharmacological blockades. *Psychophysiology* 31: 599–608, with permission from Blackwell.

The importance of the measurement model is illustrated by a study of a population-based sample in Chicago (Chicago Health and Social Relations Study, CHASRS). Based upon a bipolar model of autonomic control, a cardiac autonomic balance (CAB) metric was derived as a scale extending from maximal sympathetic activation on one end of a continuum to maximal parasympathetic activation at the other extreme (sympathetic minus parasympathetic control). While CAB was not associated with most aspects of health in a population-based sample (CHASRS), it was predictive of diabetes mellitus (Figure 3). In contrast to reciprocal models of autonomic activation, as noted earlier, contemporary models of psychophysiological processes emphasize the bivariate structure of autonomic regulation and the overall capacity for autonomic flexibility and variability. Accordingly, an index of cardiac autonomic regulatory capacity (CAR) was also derived as the sum of activities of the autonomic branches. In contrast to the reciprocal diagonal represented by CAB, CAR is a metric that captures the coactivation or independent activation of the autonomic branches. Analysis of the CHASRS sample revealed that CAR was a better predictor of overall health status and was a significant predictor of the occurrence of myocardial infarction (Figure 3). These results suggest that distinct patterns of autonomic control may be associated with distinct health dimensions.

Electrodermal Skin Response

In addition to the analysis of cardiac functioning described above, estimates of autonomic output can be determined through the measurement of electrodermal activity (EDA). The basis for such measurement derives from the innervation of the eccrine sweat glands by the sympathetic nervous system. Importantly, the eccrine sweat glands are outside the control of parasympathetic responses and this fact allows for relatively unbiased estimates of sympathetic output. EDA is widely used within psychological contexts as it is thought to reflect variations in emotional and neurophysiological arousal. Thus, EDA has been used as an objective index of affective processes, in controlled experimental contexts where extraneous variables are accounted for, and has been shown, for example, to be readily elicited by threatening stimuli.

Electrodermal and other psychophysiological measures are also influenced by higher subcortical and cortical brain areas associated with attention, anxiety, and decision making. These areas include the amygdala, anterior cingulate cortex, and prefrontal cortex among others, and EDA responses can be elicited by electrical stimulation of each of these structures. This neuroautonomic coupling confers utility on psychophysiological measures as markers of psychological processes. In fact, visceral/autonomic responses may not only reflect but also impact psychological processes. Since the writings of William James before the turn of the twentieth century, somatovisceral feedback has variously been speculated to be important in the evocation or regulation of emotion and behavioral guidance. Performance in decision-making tasks is associated with anticipatory EDA responses prior to risky or suboptimal choices, and this reactivity antedates conscious awareness of the outcome contingencies and has been suggested to guide learning and future adaptive choices. In this paradigm, damage to

Figure 3 Left panel: Bipolar versus bivariate representations of sympathetic and parasympathetic control. Right panel: CAR and CAB in disease states. Data points illustrate means and standard errors of CAR and CAB as a function of participant group, relative to the population. Compared to other participants, subjects with a prior myocardial infarction (MI) had lower CAR scores, indicating lower overall cardiac regulatory capacity, but were not highly deviant on CAB. In contrast, those with diabetes showed a lower CAB score, reflective of a predominant sympathetic balance, but were not highly deviant on CAR. Adapted from Berntson GG, Norman GJ, Hawkley LC, and Cacioppo JT (2008) Cardiac autonomic balance versus cardiac regulatory capacity. *Psychophysiology* 45(4): 643–652, with permission from Wiley.

ventromedial prefrontal cortex results in dysregulated emotional processes associated with abnormalities in strategic decision-making characterized by a failure to change disadvantageous behavioral patterns. While typical individuals alter their behavior to avoid punishment, patients with ventromedial prefrontal damage continue using the same pattern of behavior, even if this behavior is repeatedly associated with punishing outcomes. These patients also display abnormalities in the generation of EDA responses that manifest as a reduction

in normal anticipatory arousal in the decision-making task. The defect in anticipatory autonomic arousal may contribute to the behavioral deficit, as somatovisceral afference may normally serve to bias emotional behavior and sculpt strategic decision-making processes. Consistent with Jackson's view of evolutionary representation of function, the association between sympathetic output and decision making is likely the result of higher-level (e.g., prefrontal cortex) structures 'listening' to more primitive lower-level processes that reflect rapid changes in neurophysiological states in response to environmental stimuli. Measurement of EDA or other psychophysiological responses may thus provide a window into the psychological processes that reflect the activity of neurobiological structures important in integrating emotion and cognitive responses.

Serum Factors and Behavior

Hormones are in continuous reciprocal interaction with the operations of the central nervous system. The acute elevation of stress hormones represents an adaptive process that serves to coordinate metabolic, cardiovascular, and behavioral responses to environmental and neurophysiological perturbations. However, when stress and subsequent release of stress hormones becomes chronic, it can predispose individuals to a myriad of pathophysiological processes. The most well-studied stress hormone system is the hypothalamic–pituitary–adrenal (HPA) axis. The HPA consists of multiple peptide and hormonal signaling molecules that orchestrate broad alterations in metabolic functioning. The cascade is initiated by the detection of threat stimuli leading to an increase in corticotropin-releasing hormone (CRH) within the hypothalamus. The increased CRH then induces the systemic release of adrenocorticotropin-releasing hormone (ACTH) from the anterior pituitary, which subsequently increases the release of cortisol (or corticosterone in rats and mice) from the adrenal cortex. Cortisol levels are continuously monitored by nearly every cell of the body through activation of intracellular glucocorticoid receptors. Finally, the system is subject to servo control, as it is inhibited by high levels of cortisol binding at receptors in the hippocampus, which serve to inhibit further production and release of CRH.

Given the broad effects of HPA function on metabolic, immunological, and neurobiological functioning, psychophysiologicalists routinely quantify circulating levels of cortisol and ACTH as an index of psychological stress. While this research has provided numerous important empirical and theoretical insights into the interface between physiology and psychology, important interpretative caveats exist for the application of such measures to psychophysiological science. For example, circulating levels of ACTH and cortisol are released in a pulsatile manner, necessitating the measurement across multiple time points, or other approaches to provide an integrated metric. Furthermore, circulating levels of HPA hormones display large diurnal variations with highest levels typically observed in the early morning, requiring attention to the timing of measurements. In addition, alteration in diurnal variation in HPA axis output may itself be a relevant metric, as it has been found to be sensitive to various psychopathological conditions, such as depression and anxiety.

Another common method for analyzing HPA axis function is the dexamethasone suppression test (DST). Dexamethasone

is a synthetic glucocorticoid that, when given to healthy individuals, activates the negative feedback servo mechanisms described above, leading to significant reductions in circulating levels of endogenous glucocorticoids. In comparison to a single measure of glucocorticoid levels, the dexamethasone suppression possesses high construct validity and minimizes many of the measurement issues described earlier. Individuals suffering from any number of psychopathological conditions such as depression show diminished negative feedback indicative of glucocorticoid insensitivity. The inability to appropriately control HPA axis functioning can result in chronic elevations in circulating hormone levels, which have broad effects on structure and function in various brain regions associated with cognitive and affective processes. Furthermore, chronic levels of cortisol can result in the downregulation of glucocorticoid receptors in immune cells. Since cortisol has potent anti-inflammatory effects, the phenomena of glucocorticoid resistance can diminish the ability to regulate systemic inflammatory processes, which can have a negative influence on psychological and neurophysiological health outcomes.

An additional methodological consideration stems from the fact that the majority of circulating cortisol is bound to corticosteroid-binding globulin. Bound cortisol is unable to access intracellular glucocorticoid receptors, rendering it biologically inactive. Thus, measurements of circulating cortisol levels reflect both free and bound states making interpretation of such data more difficult. However, because binding proteins do not readily enter the salivary glands, salivary measures primarily reflect unbound cortisol. Furthermore, as compared to serum measures, measurement of salivary cortisol is easily collected and thus can be used across wide contexts and time points.

In addition to classical stress hormones, the neuropeptide oxytocin (OT) has recently become the focus of extensive research in the field of psychophysiology as a result of its potent and selective influence on social processes. OT is synthesized within the hypothalamus and released systemically and centrally. The release of OT within the brain is thought to prime neurobiological networks for social behavior. OT has been implicated in the social behavior of various species, including monkeys, rats, and humans. Indeed, functional OT signaling is necessary for social recognition within rodents. Central administration of OT can induce maternal behavior in virgin rats and increases social interaction between adults. Furthermore, the role of OT in human social behavior has recently become a topic of intense interest as it has been shown that the oxytocinergic system is remarkably sensitive to the neural processing of social information. The experience of early childhood neglect, for example, impairs the increase in peripheral OT levels typically triggered by mother–infant interaction and early parental separation has been proposed to alter central OT receptor sensitivity. In contrast, positive social interactions, such as social support, lead to increased levels of OT, and OT has been suggested to mediate the well-known beneficial effects of social support on stress responsivity and health, a topic discussed in further detail later. Intranasal administration of OT has been shown to attenuate amygdala activity and reduces amygdala–brainstem coupling in response to threatening social stimuli. Similarly, OT modulates the evaluation of socially relevant faces by influencing the activity of

Figure 4 Oxytocin effects on threat ratings. Mean (SEM). Prepost change scores in emotional arousal to threatening stimuli. Oxytocin selectively decreased emotional arousal to human but not nonhuman threatening stimuli. Reprinted with permission from Norman GJ, Cacioppo JT, Morris JS, Malarkey WB, DeVries AC, and Berntson GG (2010) Selective influences of oxytocin on the evaluative processing of social stimuli. *Psychopharmacology*, Epub ahead of print.

the amygdala. Recently, we have demonstrated that OT has potent and rather selective influences on affect as it decreases emotional arousal to threatening human but not animal stimuli (Figure 4). The effects of OT on neurobiological functioning translate into observable changes in behavior. Indeed, intranasal OT increases trust, independent of risk taking, and improves the ability to correctly infer the mental state of others and increases the duration of gazes toward the eye region of faces, an important behavior for the recognition of emotion in social interactions. Furthermore, OT receptor gene variants are associated with loneliness, empathy, and autism spectrum disorder. The recent expansion of research on the role of OT in human social behavior, with improvements in OT assays, may provide novel perspectives on psychophysiological relations.

Psychophysiological Relations

As discussed earlier, technological advances have allowed for ever more precise measurement of psychophysiological relations. However, even with the use of more sophisticated measures, the question arises as to how signals are to be interpreted and inferences drawn. Psychophysiological processes represent interactions between psychological (ψ) and neurophysiological (φ) domains. Psychophysiological processes entail multiple logical relationships between elements, and this fact has important implications in inferences derived from psychophysiological measures. Important to the measurement of psychophysiological processes, psychological relations can be characterized by five general categories of mappings between elements in the psychological and neurophysiological domains (Figure 5).

- I. No significant association between psychological and neurophysiological domains.
- II. One-to-one: psychological domain is associated with one, and only one, neurophysiological process.

Figure 5 Schematic of psychophysiological relations consisting of (I) No significant association between psychological and neurophysiological domains. (II) One-to-one: psychological domain is associated with one, and only one, neurophysiological process. (III) One-to-many: in which elements in psychological domain are related to more than one element in the neurophysiological domain. (IV) Many-to-one: in which two or more psychological elements are associated with a single element in the neurophysiological domain. (V) Many-to-many: where two or more psychological elements are associated with overlapping neurophysiological elements.

- III. One-to-many: in which elements in psychological domain are related to more than one element in the neurophysiological domain.
- IV. Many-to-one: in which two or more psychological elements are associated with a single element in the neurophysiological domain.
- V. Many-to-many: where two or more psychological elements are associated with overlapping neurophysiological elements.

As presented above, the first category includes relations that represent irrelevant sources of variance in psychophysiological associations and need to be accounted for in order to avoid spurious associations between psychological and neurophysiological domains. The second category includes one-to-one relationships where the psychological domain is associated with one, and only one, neurophysiological process. Next is the one-to-many relation where elements in the psychological domain are related to more than one element in the neurophysiological domain. The fourth domain is the many-to-one relationship where two or more psychological states are associated with a single neurophysiological process. The final category is the many-to-many relationship where two or more psychological elements are associated with overlapping neurophysiological elements.

Unfortunately, one-to-one relationships are not common in psychophysiology, whereas relationships involving one-to-many (category III) and many-to-many (category V) are common. The latter are far more problematic for interpreting psychophysiological relations. One approach to this problem is to reconceptualize the neurophysiological elements of a one-to-many relationship as composed of a combination of psychophysiological elements. Similarly, the consolidation of neurophysiological elements of many-to-many relationships into particular patterns of activation may serve to simplify relations into a many-to-one or even one-to-one relationship. However, caution should be applied in such instances as the inherent complexity of psychophysiological relations may not always be reducible to one-to-one or even one-to-many relationships. Appreciation of the distinct psychophysiological relations, along with their strengths and weaknesses, is vital for the appropriate interpretation of data involving broad levels of analysis, and maximizes the utility of such measures by limiting the occurrence of logical inconsistencies.

Inference in Psychophysiological Measurement

An overarching goal behind the measurement of psychophysiological relations is the elucidation of basic relationships between the mind and the body. With multilevel analysis come particular methodological and theoretical challenges associated with the complexity of interactions between levels ranging from the molecular to the psychological. However, advances in psychophysiology have provided important insights into human behavior that can serve as the basis for future multilevel analysis. Regardless of the precision of the particular methodology used, the interpretation of such broad-based data continues to be challenging and rife with pitfalls. Generally, the measurement of neurophysiological processes is useful to the extent to which they reflect psychological processes.

The table above details the classes of relations that may obtain between a psychological process (ψ) and neurophysiological measure (φ). In a hypothesis regarding the indexing of a psychological process (ψ) by a neurophysiological measure (φ) we seek the relation if (φ) then (ψ), but that only holds with a one-to-one relationship. However, as mentioned above, one-to-one relations are rare in psychophysiological science. Causal hypotheses regarding the involvement of a brain structure (φ) in a particular psychological processes (ψ) are of the form $\psi = f(\varphi)$. This logical relationship postulates that the occurrence of φ (e.g., amygdala activation) is a sufficient condition for ψ (fear), but it does not imply that ψ is necessarily preceded by φ . Furthermore, the activation of particular brain structures is often used as an index of a psychological state. Thus, in this instance the inference is of the form $\psi = f(\varphi)$ rather than not- $\psi = f(\text{not-}\varphi)$. Consequently, the goal of psychophysiology can be characterized by the conditional probability of ψ given φ : $P(\psi|\varphi) = 1$.

One common approach that attempts to address some of the logical issues discussed above is the subtractive method, where experimental and control conditions differ by one element with the particular outcome measure reflecting the impact of that single element. Through the application of this method, neurophysiological correlates of psychological

processes can be identified and concepts and theories can be refined and tested. The application of imaging technology (e.g., functional magnetic resonance imaging, fMRI) is one example of this methodology. Indeed, differences in neural activation patterns under experimental and control conditions are taken to reflect the activity specifically associated with the experimental condition. While this approach provides a unique perspective into psychophysiological relations, it does not allow for the determination of causal relationships, or the application of strong inference.

One potential issue with the interpretation of the data resulting from the subtractive method revolves around the fact that researchers sometimes treat their results as if neurobiological substrates were being manipulated directly (e.g., inhibition of prefrontal cortex) and psychological outcomes measured (e.g., elevations in depression). Indeed, causal hypotheses regarding the involvement of a brain structure (φ) in a particular psychological process (ψ) are of the form $\psi = f(\varphi)$. This logical relationship implies that the occurrence of φ (e.g., amygdala activation) is a sufficient condition for ψ (fear), but it does not imply that ψ is necessarily preceded by φ . Furthermore, the activation of particular brain structures is often used as an index of a psychological state. However, with the application of ever more powerful imaging technologies, many researchers succumb to the temptation to use the inverse logical argument generally in the form of $P(\varphi|\psi) = ?$ Psychophysiological measures provide information on φ as a function of ψ , but the conditional probabilities are equivalent [$P(\psi|\varphi) = P(\varphi|\psi)$] only if there is a one-to-one relationship between the neurophysiological element φ and the psychological element ψ .

In the interpretation of psychophysiological data, isomorphism between a psychological variable and neurophysiological variables (one-to-one relationship) must be directly tested, and deviations from isomorphism should be accounted for. In this regard, interdisciplinary, multilevel approaches to the measurement of psychophysiological variables are uniquely positioned such that they can provide complementary and converging evidence from direct manipulations of the neurophysiological variables (φ as independent variable). Using this methodology, one can bolster the confidence in the interpretation of the data by demonstrating that specific patterns of neural activation consistently covary across a broad range of conditions and contexts. However, while the covariation of neurophysiological and psychological realms may increase the confidence of inference of ψ from φ , causal inferences can only be determined through the application of converging evidence. For example, if a clinician observes an increase in amygdala activation in response to aversive stimuli across various contexts, and wants to determine whether or not a causal relationship exists, then the demonstration that manipulations of amygdala functioning (e.g., stimulation, ablation) modulate fear behavior in mice would allow for more valid inferences of causal mechanisms. Furthermore, with recent advances in transcranial magnetic stimulation technology as well as the application of deep brain stimulators to treat psychiatric disease has come the increased ability to apply more in-depth research into the causal mechanisms mediating psychophysiological relations. Thus, the application of converging lines of evidence can routinely deal with many of the weaknesses inherent in the subtractive method while still maintaining the strengths of this approach.

Conclusion

The use of measures spanning multiple levels of analysis has become increasingly common in contemporary psychological and neuroscientific research. Advancements in technology and conceptual understanding of human behavior will likely increase this trend. The expansion of knowledge and measurement of the molecular, systems, and psychological concomitants of human behavior will necessitate a similar increase in the application of methodologies that appropriately integrate facts across multiple levels of analysis. While such developments are important, it is imperative to couch these new measurements within a theoretical framework that appreciates multilevel analysis while simultaneously avoiding category errors through an understanding of particular limitations inherent in the measurement used. Thus, the future of psychophysiological research is promising, and as technological and theoretical constructs continue to advance across levels of analysis, so too will our understanding of psychophysiological processes.

Glossary

Behavioral game theory The application of limited rationality to strategic human interaction.

Discount factor A function of time that captures the degree to which current consumption is more important than future consumption.

Heuristics Rules of thumb used by individuals that substitute for fully optimizing behavior based on classical statistics.

Intrinsic reciprocity The desire to reciprocate based on the notion that one is hardwired to do so.

Liberalism versus paternalism The study of the policy response to less than perfect rationality.

Loss aversion The tendency of losses to bite more than gains of an equivalent magnitude.

Neuroeconomics The use of the methods of neuroscience in economics.

Probability weighting function A function that captures the subjective probability weight assigned by an individual to various events.

Reference point A level of outcome such that any outcome which is numerically greater is coded as a gain and any that is numerically lower is coded as a loss.

Social preferences The presence of bundles of goods of others, in addition to one's own, in one's utility function.

Utility function A function that assigns to bundles of goods and services, some level of human satisfaction that can be numerically measured.

Introduction

Traditional economics is based on the assumptions of fully rational and self-interested behavior. A very large body of evidence casts serious doubts on both these assumptions. A serious consideration of the psychological evidence for human motivation in economic phenomena and the construction of new theoretical models based on this evidence has given rise to behavioral economics. This new field is growing at a rapid pace and gaining increased acceptance in mainstream economics. In this essay, we provide a brief overview of behavioral economics and some of the insights that it offers.

Decision Theories

For simplicity, let x_1, x_2, \dots, x_n be real numbers, which we interpret as different levels of wealth (n can be any positive integer). We assume that we can rank the wealth levels in the following manner: $x_1 \leq x_2 \leq \dots \leq x_n$. Economists use the term lottery for the following entity

$$\mathcal{L} = (x_1, p_1; x_2, p_2; \dots; x_n, p_n) \quad [1]$$

where outcome, x_i , occurs with probability, p_i . So, in the lottery \mathcal{L} , outcome x_1 arises with probability p_1 , outcome x_2 arises with probability p_2 , and so on. We assume that the probabilities are nonnegative and sum up to one. Thus, a lottery is simply a description of all possible outcomes that could arise, along with their respective probabilities.

When the probabilities are verifiable independently of the decision maker, we have a situation of *risk*. On the other hand, if the probabilities can be inferred only from the actions of the decision maker, then we have a situation

of *uncertainty*. For instance, while objectively verifiable probabilities of the risk from the MMR (measles, mumps, and rubella) vaccine were shown to be low in almost all scientific studies, many individuals assigned high subjective probabilities, leading them to refuse the vaccination. Denote the set of all lotteries of the form in eqn [1] by \mathcal{L} . Which lottery in \mathcal{L} should be chosen?

Expected Utility Theory

The most widely used theory in economics under risk is the expected utility (EU) theory. Under axioms on individual preferences, known as the *axioms of rationality*, it can be shown that, for each decision maker, there exists a utility function u such that one may think of $u(x_i)$ as the utility or satisfaction arising from the outcome x_i . $u(x_i)$ is simply some real number. The utility function has the following main properties. (i) If the individual strictly prefers an outcome x_i to another outcome x_j then it must be the case that $u(x_i) > u(x_j)$, and (ii) if $x_i > x_j$ then $u(x_i) > u(x_j)$. Furthermore, for any lottery $\mathcal{L} = (x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, the expected utility to the decision maker, denoted by $EU(\mathcal{L})$, is defined as follows.

$$EU(\mathcal{L}) = \sum_{i=1}^n p_i u(x_i) \quad [2]$$

In eqn [2] we have used the shorthand notation $\sum_{i=1}^n p_i u(x_i) = p_1 u(x_1) + p_2 u(x_2) + \dots + p_n u(x_n)$. This is standard notation and we shall use it throughout this essay so it is best if the reader who has not encountered this before invests in understanding it at this point.

The decision maker is assumed to choose the lottery that gives the highest expected utility. EU allows for a rich pattern of attitudes to risk. However, EU incorporates risk preferences through the shape of the utility function (rather than through the probabilities).

Definition 1 Risk aversion

A decision maker is said to be risk averse if he/she prefers the expected value of the lottery to playing the lottery. The converse behavior is risk loving and indifference between the two is referred to as risk neutrality.

It can be shown that risk-neutrality/risk-aversion/risk-seeking are equivalent, respectively, to the utility function, u , being linear/concave/convex, respectively. Risk aversion, arising from a concave utility function, underpins important explanations of economic phenomena in most areas of economics. These include the study of insurance, the design of contract schemes in principal-agent problems, the optimal rates of taxes, determination of wage rates etc. A lottery L_p first-order stochastically dominates lottery L_q if the distribution function of L_p lies everywhere below that of L_q . Decision makers under EU do not choose stochastically dominated options.

The axioms of rationality that underpin EU appear intuitive and plausible. However, they are only assumptions about human behavior. In particular, they should not be confused with the notions of rationality as used in logic, psychology, or law. And, in fact, a large number of rigorous tests have rejected these axioms. This induced a major effort to propose auxiliary assumptions to EU in order to save it, but without much success.

Behavioral Decision Theories

Behavioral economics provides several alternative, axiomatically founded, theories that explain the evidence better than EU, yet are tractable. The EU formula in eqn [2] has two salient features. (1) It is linear in probabilities. (2) Utility is defined over final wealth levels. Behavioral alternatives have relaxed both these assumptions.

Rank-dependent utility (RDU) relaxes the linearity in probability assumption. The most satisfactory decision theory in economics, and the one with the strongest psychological foundation, is the Nobel Prize winning work on prospect theory (PT) due to the seminal paper in 1979 by Daniel Kahneman and Amos Tversky. However, PT allows for violations of first-order

stochastic dominance. Following the insights of RDU, PT was modified to cumulative prospect theory (CP). CP does not allow for the choice of stochastically dominated options. Since RDU is a special case of CP, it suffices to explain CP.

In CP (like PT but unlike EU and RDU) the carriers of utility are not final levels of wealth but deviations of these from a reference point; a well-established idea from psychology. For instance, dip your right hand in cold water and your left hand in warm water. After a few seconds put them both in lukewarm water. Your right hand then feels warm and your left hand feels cold, although they are both gauging the same temperature. The status quo turns out to be a useful reference point in many applications. But some other possible choices could be an expected level, a fair level or a legal entitlement. If the outcome turns out to be superior (respectively inferior) to the reference point, then the decision maker is in the domain of gains (respectively losses).

CP also incorporates experimental and field evidence, which suggests that utility is evaluated differently in the domain of gains and losses. First, losses bite more than equivalent gains (loss aversion). Second, the utility function is concave for gains and convex for losses. Thus, in each domain, there is diminished sensitivity to gains/losses. Tversky and Kahneman propose the following (axiomatically founded) utility function that captures all these facts.

$$v(x) = \begin{cases} x^\gamma & \text{if } x \geq 0 \\ -\lambda(-x)^\theta & \text{if } x < 0 \end{cases} \quad [3]$$

where x is the deviation of some outcome relative to the reference point. γ , θ , λ are constants; $0 < \gamma < 1$, $0 < \theta < 1$. $\lambda > 1$ is known as the *coefficient of loss aversion*. Experimental results initially suggested that γ and θ are approximately equal to 0.88 and λ is approximately equal to 2.25. However, subsequent research showed that the parameter of loss aversion is variable and depends on the context. The properties of the value function are illustrated in Figure 1. Notice that the reference point is at zero and the function is relatively steeper for negative values. It is also concave for positive values but convex for negative values.

Figure 1 The utility function under CCP.

The second main feature of CP (which it shares with PT and RDU but not EU) is that probabilities are transformed in a nonlinear manner, using the device of a probability weighting function (PWF), w . One may think of $w(p)$ as a real number, lying between zero and one, that captures the subjective weight assigned by the individual to the probability p . A PWF has the property that the individual assigns a higher subjective weight to higher probabilities, and

$$w(0) = 0, \quad w(1) = 1 \quad [4]$$

that is, a probability zero is assigned a subjective weight of zero and a probability one is assigned the maximum probability weight of one. Many PWF's have been proposed in the literature. The most satisfactory is the one by Drazen Prelec, which depends on two parameters and takes the following form

$$w(p) = \exp\{-\beta[-\ln p]^\alpha\}, \quad 0 < p \leq 1, \quad \alpha > 0, \quad \beta > 0 \quad [5]$$

A plot of the Prelec function is shown in Figure 2. For the particular parameter values chosen in the plot, it is consistent with the empirically verified inverse S-shape.

Let w^+ , w^- , respectively, be the PWF's for the domain of gains and losses. There is evidence that $w^+(p) = w^-(p) = w(p)$. Suppose that the reference income level is y_0 and the individual is presented with the following lottery (see our explanation of a lottery above):

$$L = (y_{-m}, p_{-m}; y_{-m+1}, p_{-m+1}; \dots; y_0, p_0; y_1, p_1; y_2, p_2; \dots; y_n, p_n) \quad [6]$$

where $y_{-m} < y_{-m+1} < \dots < y_0 < y_1 < y_2 < \dots < y_n$ are the $m+n$ outcomes such that there are m outcomes in the domain of loss (incomes lower than y_0) and n outcomes in the domain of gains (incomes higher than y_0).

Under PT or CP, individuals care about the level of income relative to the reference point. Define income relative to the reference point by

$$x_i = y_i - y_0; \quad i = -m, -m+1, \dots, 0, 1, 2, \dots, n. \quad [7]$$

Subtracting income relative to the reference income from each of the income levels in the lottery in eqn [6] and using eqn [7] we get the following lottery, which we denote by \bar{L}

$$\bar{L} = (x_{-m}, p_{-m}; x_{-m+1}, p_{-m+1}; \dots; x_0, p_0; x_1, p_1; x_2, p_2; \dots; x_n, p_n) \quad [8]$$

Figure 2 The Prelec function for $\beta=1$ and $\alpha=0.5$.

Define \mathcal{L}_p as the set of all possible lotteries of the form given in eqn [8]. Under PT and CP, decision makers wish to evaluate lotteries from the set \mathcal{L}_p . They do so by forming an appropriate value function. Definition 2 shows the value function for the lottery \bar{L} .

Definition 2 The value function under CP

The value of the lottery $L \in \mathcal{L}_p$ to the decision maker is given by

$$V(L) = \sum_{i=-m}^n \pi_i v(x_i) \quad [9]$$

Compare eqn [9] with eqn [2]. First we have used the summation notation in eqn [9] that we have explained above in the discussion following eqn [2]. Second, the utility function in eqn [9], $v(x_i)$, is defined so as to have the properties illustrated in eqn [3] above, while the utility function in eqn [2], $u(x_i)$, is not restricted to have these properties. Third, utilities are multiplied with probabilities in eqn [2] while in eqn [9] they are multiplied with decision weights, π_i , $i = -m, -m+1, \dots, 0, 1, 2, \dots, n$. The construction of decision weights is crucial in all versions of prospect theory (e.g., PT, CP, and CCP, which we describe below). We first formally describe the construction of decision weights in Definition 3, followed by some intuition. We shall use the summation notation, which we have described in the text following eqn [2] above.

Definition 3 For CP, the decision weights, π_i , are defined as follows:

$$\begin{aligned} \pi_n &= w^+(p_n) \\ \pi_i &= w^+(\sum_{j=i}^n p_j) - w^+(\sum_{j=i+1}^n p_j), \\ \pi_{-m} &= w^-(p_{-m}) \\ \pi_j &= w^-(\sum_{i=-m}^j p_i) - w^-(\sum_{i=-m}^{j-1} p_i). \end{aligned}$$

Recall that $v(0) = 0$. Hence it is immaterial what value is chosen for π_0 . This is why π_0 is undefined in Definition 3. The method of constructing decision weights in Definition 3 was originally suggested in a brilliant undergraduate thesis by John Quiggen. The idea is that the decision weights transform probabilities in a cumulative fashion using the probability weighting function. The decision weight in Definition 3, associated with some outcome is the marginal increase in the probability weight as one moves from that outcome to the next best outcome. Decision makers who form decision weights in this manner do not choose stochastically dominated options. This solved an important shortcoming associated with PT.

RDU is the special case of CP when all outcomes are in the domain of gains. EU is the special case of RDU when, in addition, $w(p) = p$ ($\alpha = \beta = 1$ in eqn [5]).

CP allows for a rich set of attitudes to risk, that depend not only on the curvature of the utility function but also on the shape of the PWF. A fourfold classification of risk is predicted by CP. In particular, decision makers are risk averse for moderate probability moderate gains (as in EU) but (unlike EU) they are risk seeking for low probability high gains. By contrast, decision makers are risk averse for low probability high losses (as in EU) but (unlike EU) are risk seeking for moderate probability moderate losses. This fourfold pattern of attitudes to risk is confirmed in laboratory experiments and explains a wide range of economic phenomena that EU is either unable to explain or finds it difficult to explain. See, for instance, the Asian disease example in the section on mental

accounting below for separate attitudes to risk in the domain of gains and losses.

One criticism made in the recent work by al-Nowaihi and Dhami is that all standard PWF's used in RDU and CP are extremely steep at the end points (in the sense that $\lim_{p \rightarrow 0} (w(p)/p) = \infty$, and $\lim_{p \rightarrow 1} ([1 - w(p)]/[1 - p]) = \infty$). This makes very low and very high probabilities extremely salient to decision makers and leads RDU and CP to make predictions inconsistent with a range of important observed phenomena. For example, CP (and RDU) predicts far too much demand for insurance (as compared to the evidence) against low probability natural hazards, such as earthquakes, floods, and hurricanes. Another example is that CP (and RDU and EU) predicts that the imposition of the severest possible punishments (e.g., capital punishment), even with vanishingly small probability of detection, would deter all crime. This is contrary to the evidence. Other similar violations come from a range of other phenomena such as red traffic light running, driving, and talking on mobile phones and not taking up adequate health checks.

In recent research, al-Nowaihi and Dhami account for these problems by proposing composite cumulative prospect theory (CCP). This differs from CP in that it uses a composite Prelec probability weighting function (CPF), illustrated in Figure 3. It is made up of segments from three Prelec functions over the respective ranges, $[0, \underline{p}]$, (\underline{p}, \bar{p}) , $(\bar{p}, 1]$. Very low probabilities are hugely underweighted in the sense that $\lim_{p \rightarrow 0} (w(p)/p) = 0$. This allows CCP to predict human behavior, for instance, toward insurance and law enforcement, that is in better conformity with the evidence. CCP is much more general than the account that we have given here; it can do everything that EU, RDU, and CP can do, but the converse is false.

Collectively, PT, CP, and CCP successfully explain a wide range of otherwise unexplained phenomena. These include why it is hard to find a taxi on a rainy day in New York, asymmetric price elasticities, tax evasion problems, demand for insurance, the Allais paradox, the St. Petersburg paradox, paradoxes in the economics of crime and punishment, the endowment effect, the disposition effect, the equity premium puzzle, asset pricing, incentive schemes, etc.

Figure 3 The composite prelec weighting function (CPF).

Heuristics and Biases

The heuristics and biases research program commenced with seminal papers by Tversky and Kahneman in the early 1970s. Its basic premise is that individuals are not fully rational, but they are not irrational either. Tversky and Kahneman took the middle ground that individuals solve problems by relying on some fast (in terms of time) and frugal (in terms of information acquisition and processing) heuristics. Because such heuristics do not optimize in the classical sense, the performance of the heuristics is not necessarily optimal.

For instance, individuals often judge distance of an object by the heuristic of how clear it is, sharper objects are thought to be closer. This heuristic is fast and frugal. While this heuristic often works well, it might also result in biased and misleading perceptions. For instance, when conditions are hazy, distances might be overestimated. Conversely, when conditions are very clear, distances might be underestimated.

The heuristics and biases approach demonstrates a systematic departure of actual behavior from that prescribed by the laws of classical statistics. Rather, individuals employ a range of judgement heuristics. The point or interval estimates arising from these judgement heuristics are often in conflict with classical inferences. Even statistically sophisticated researchers or experienced decision makers often rely on these judgment heuristics.

An important heuristic is the representativeness heuristic. When individuals use this heuristic they tend to assume that the properties of a small sample that they are familiar with is characteristic of the large population from which the sample was drawn. For example, an eminent colleague told us that up to quite late in his childhood he believed that most people in the world were Jewish members of the British Communist Party, because that was the circle of family and friends he grew up in. This is sometimes referred to as the law of small numbers. At other times, individuals exhibit the reverse bias, conservatism, that is, they underestimate the likelihood of a sample from a given distribution. For example, people typically underestimate the likelihood of getting a consecutive run of 3 heads in 10 random tosses of a fair coin. These heuristics explain many puzzles such as the gambler's fallacy (avoid betting on a number that has come up last time), hot hands and winning streaks (because a basketball player has scored the last few shots, he is even more likely to score this one).

The behavior of humans is inconsistent with Bayes' rule, especially when they are presented with probabilistic information (as opposed to frequency format information). In particular, individuals engage in base rate neglect. For example, consider the following question. "There is a rare condition whose probability is one in a million. There is a test whose success rate is 99%. You tested positive. What is the probability that you have this condition?" The typical answer is 99%. The true answer based on classical statistics is 0.01% (the reader can check this by applying Bayes' rule).

Anchoring is one of the most robust and important heuristics that people use. In situations where people do not know the answer to a question, they are unduly influenced by an initial suggestion or anchor. Interestingly, the anchor could be completely random and unrelated to the answer. For example, a roulette wheel is spun. The resulting number is, say, 50.

The subjects are then asked “how many countries are members of the UN?” The answers would then frequently be found to cluster around 50. Furthermore, once individuals fix an anchor in their minds, they adjust too slowly, and insufficiently, toward the target.

There is also a range of other judgement heuristics that the space constraint does not permit us to discuss further. These include hindsight-bias, false consensus, attribute substitution, conjunction fallacy, availability heuristic, affect heuristic, and taking a necessary condition to be sufficient.

Mental Accounting and Framing

The idea of mental accounts is a significant and important part of behavioral economics with wide ranging implications. Richard Thaler, whose name is most closely identified with this concept in economics, defines mental accounting as follows. “I wish to use the term mental accounting to describe the entire process of coding, categorizing, and evaluating events.” Elsewhere, he provides another definition that is useful in financial situations: “mental accounting is the set of cognitive operations used by individuals and households to organize, evaluate, and keep track of financial activities.”

Let us begin with two features of mental accounts.

1. Money is not fungible across the accounts. So, for instance, one might put aside money in a separate account for children’s education. This would be unnecessary if money were fully fungible across mental accounts.
2. The objective of the individual is not necessarily to maximize total financial wealth. An important objective that is highlighted in the mental accounts literature is to limit the size of loss in individual accounts.

Much of traditional theory makes the frame-invariance assumption. By contrast, individual decisions are sensitive to the framing of problems. In a famous experiment, Kahneman and Tversky use a representative sample of physicians and pose them the following question framed in two alternative, but classically equivalent, ways that, respectively, stress the positive and the negative aspects. The question posed was the following.

Example 1 Imagine that the United States is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

Positive Framing: If program A is adopted, 200 people will be saved. If program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved. Which of the two programs would you favor?

Under positive framing, the solution is framed in terms of ‘lives saved.’ The result was that 72% of physicians chose A, the safe strategy and 28% chose program B, the risky strategy.

Negative Framing: If program C is adopted, 400 people will die. If program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die. Which of the two programs would you favor?

For negative framing, only 28% of the physicians voted for the safe strategy C while 72% of them opted for D, the risky strategy.

The problem in each of the two frames (positive and negative) is identical. Thus, if A is preferred to B then C must be preferred to D (or vice versa). While the aim of Kahneman and Tversky was to show that individuals are risk averse for gains and risk loving for losses (see the discussion of prospect theory, above), the reframing of the same question leads to completely different choices. Framing matters, and it can determine which mental account an item of expenditure or income is put into.

The evidence from models of consumption suggests that the marginal propensity to consume out of distinct mental accounts could be different. Thus, the effect of salary composition, for instance, between wage and bonus could have an effect on the employee’s saving decision. Different pension plans that have otherwise identical effects in standard economics on account of perfect fungibility of money have distinct effects in the presence of nonfungibility and different marginal propensities to consume from different mental accounts. Hence, in the mental accounting framework, the effects of pension plans depend on which mental account is used to pay for the pension contributions.

Why does the ticking of the taxi meter reduce one’s pleasure from the taxi ride? Why do we normally prefer to prepay for a vacation? Why do we often prefer to pay for consumer durables in instalments? These simple facts fall outside the ambit of the workhorse life cycle model in macroeconomics. Prelec and Loewenstein argue that consumption that has already been paid for can be enjoyed as if it were free in the current period, which potentially increases its current enjoyment, hence, explaining prepayment of vacations. Similarly, the thought of future payments reduces current utility from the consumption of a good/service (hence, the unpleasantness arising from a ticking taxi meter). Consumer durables on the other hand lead to a stream of future benefits, often for several years, after the date of purchase. Hence, paying in instalments for them is not aversive as compared to a vacation, which is enjoyed for a small duration of time. The framework suggested by Prelec and Loewenstein can also explain the growing use of debit cards, use of tokens at casinos, dependence of mortgage payments on property values, popularity of fixed fee payment schemes, Club Med vacations and gift giving among couples, etc.

Individuals tend to break down complex problems into simpler ones that require less cognitive ability. Read, Loewenstein and Rabin term this as choice bracketing. An army General who focuses only on the battle at hand (narrow bracketing) might lose sight of winning the war (broad bracketing). Recall the problem of finding a taxi on a rainy day in New York. One possibility is that taxi drivers set a daily target for earnings (narrow bracketing) rather than an income target over a longer period (broad bracketing). The target is more quickly achieved on a busy rainy day leading to too many quits, too soon. The optimum for a taxi driver is, however, to work longer during rainy days because customers are more plentiful and the effective wage, higher.

Choice bracketing also takes the form of deciding on the horizon over which one would evaluate one’s portfolio. So, for

instance, if one holds stocks and evaluates one's portfolio too often then one would observe too many upward and downward movements in the return to equities relative to bonds, creating feelings of anxiety. Equities might then require a higher premium, relative to the predictions of standard theory, if they are to be held in a portfolio. This explains an important puzzle, the equity premium puzzle, namely, an excess of return on equities over bonds that cannot be justified on the grounds of risk alone. Choice bracketing can also explain strategies used at alcoholics anonymous and the desire for risk aggregation. Alcoholics under treatment are usually asked to take one day at a time (narrow bracketing) because the possibility of lifetime abstinence (broad bracketing) is too daunting. Similarly, when a range of risks are aggregated (broad bracketing) they might well seem less onerous because a low outcome under one form of risk could be mitigated by a high outcome under another form of risk.

In standard economic theory, actual choice is the result of well-defined initial preferences and well-defined subjective probability distributions over uncertain events. By contrast, Ariely, Loewenstein, and Prelec show that the initial framing of problems or situations can have an inordinate effect on ones initial preferences. In turn, this determines the individual's subsequent choices. One is then led to question the very notion of humans having well-defined initial preferences and subjective probability distributions over events. This helps to explain a range of phenomena, such as the initial hype before mega sporting events, or the advertisement blitz before the introduction of a new product.

An assortment of other mental accounting phenomena exists. An important category of such problems arises when individuals take actions to (mentally) justify sunk costs that have been incurred in the past. Hence, there is a tendency to hold on to loss making stocks for too long and sell winners too early. The reason is that individuals create a mental account for a particular category of expenditure. Sunk costs push this mental account into the red, which causes anxiety. Individuals then take wasteful actions to avoid closing accounts that are in red.

Recent research has also highlighted the mental accounting of goals. Individuals often form goals and targets, for example, completing term papers, referee reports, quitting an addiction, losing a prespecified amount of weight by a certain date and so on. While goals can be motivational, they can also be counter-productive. On account of loss aversion, missed goals impose large losses, and the individual might also engage in emotional repair following a missed goal, etc.

Mental accounting has also been applied to retirement savings. Of particular importance is the role of status-quo options. It has been found that if the default is that the individual is signed-into a pension plan (as opposed to the converse) then the take-up of pension plans increases. The number of options offered in an investment plan is also important. Too many options can make choice more difficult. Individuals also use the diversification heuristic to choose among alternative pension vehicles, which motivates individuals to spread their money evenly among the available options even when the prediction of standard economics is to engage in an uneven spread.

Emotions

In economics, it has become standard to focus on emotionless deliberation. However, much recent research shows that this view is not supported by the evidence. Emotions are central to humans and affect much of human deliberation.

We often worry about an uncertain future. Will my pension contributions be sufficient for my retired life? Will early retirement turn out to be a good decision? Should I buy or sell my stocks in the current economic environment? These and other temporal economic decisions produce a feeling of apprehension and unease: We shall simply refer to these feelings as anxiety. Anticipation of a (stressful) future event can create anxiety that in some cases is worse than the event itself. Think, for instance, of an impending visit to a dentist for treatment. Such feelings of anxiety have two features: (1) they are caused by anticipation of future events, and (2) they are aversive in the sense that we dread such future events. As a result, one might delay a visit to the dentist, with detrimental consequences for health.

Future events need not, however, always be unpleasant. We might savor a pleasurable experience such as waiting for a dessert at the end of a meal. Or, we might delay a pleasurable vacation. Pleasant events provide examples where an individual seems to exhibit a negative discount rate; a preference for the future rather than the present. Insofar as feelings of anxiety and savoring impact on intertemporal choice in important ways, we need to amend the standard model.

In one model by Caplin and Leahy, uncertainty is introduced into a model of anticipatory utility. In an interesting application they derived equilibrium prices of assets whose returns are ex-ante random. The randomness in the returns creates a current feeling of anxiety. Hence, the ownership of a risky stock reduces its price and increases its return relative to the no-anxiety case and relative to assets whose returns are not too random, such as bonds. This provides one possible explanation for the equity premium puzzle.

Most dynamic models assume that future tastes are known. However, tastes can change over time due to a variety of reasons, for example, habit formation, moods, social environment, maturity etc. Projection bias arises when individuals make predictions of their future tastes that are not realized in equilibrium. Evidence shows that people are disproportionately influenced by their current tastes in making predictions of their future tastes. For instance, when ordering food at the beginning of a meal we must predict how hungry we will be at the end of the meal. We often overestimate our future hunger and order more than we can eat. One can also make forecasting errors in mainstream economics but, in the dominant rational expectations view, there are no such errors in the absence of random shocks and, on average, such errors are zero. Both features are violated under projection bias.

Individuals who have projection bias make time inconsistent choices, without being aware of it. Under the influence of projection bias, individuals might end up buying goods in a hot state that they might regret later. In a hot state they might end up marrying or proposing a marriage/divorce without sufficient deliberation. Public policy in some cases provides a cooling-off period before which applications for marriage and

divorce cannot be filed. Projection bias also provides an alternative explanation for why individuals get addicted. First, people underestimate the (negative) effect of current consumption on future utility. Second, individuals might under-appreciate the formation of habit, for example, addiction to a harmful product. By contrast, in mainstream economics, individuals know the entire time path of costs and benefits of addiction and if they choose to be addicts, they do so rationally. This view is not in accord with the evidence.

Fairness and Reciprocity

Traditional economic theory relies on the assumption of self-interested behavior (or selfish preferences). This is contradicted by the evidence. A substantial fraction of individuals exhibit social preferences, that is, care about the consumption and well being of others. These preferences are more general than simply altruism (unconditional kindness) and spite (unconditional unkindness). In practice, however, altruism is unable to explain a very wide range of behaviors. For instance, it does not explain why many individuals are conditional cooperators, that is, cooperate only when others cooperate. Intrinsic reciprocity, on the other hand, takes the form of responding to kindness (unkindness) with kindness (unkindness) even in the absence of obvious longer term gains.

Purely selfish preferences are unable to explain a range of phenomena from many diverse areas such as collective action, contract theory, the structure of incentives, political economy and the results of several experimental games. Many of these phenomena can be accounted for by a model which recognizes that individuals have social preferences.

1. Wages are usually not lowered in a recession by firms for fear that this action could be construed by workers as unfair and can affect their morale and effort levels.
2. Voters voluntarily vote, when pure self interest might dictate them not to take the trouble of voting (almost all single votes are not pivotal, except in small committees, and voting is costly).
3. In an experiment, most respondents thought that a hardware store's actions to increase the price of shovels following a snowstorm was unfair. However, they did not perceive an increase in price following an increase in the cost of inputs as unfair.
4. Why does bargaining stall, with adverse consequences in a range of situations, such as civil litigation, labor unrest, domestic strife, and clashes among religious and ethnic groups? Individuals confuse what serves their self interest with what is fair. This self-serving bias can lead to a bargaining impasse.

Social preferences have been found in a range of experimental games that allow for small group or bilateral interaction. These experiments include the gift exchange game, the ultimatum game, the dictator game, the trust game, the public good game, among others. The most commonly replicated of these experiments is the ultimatum game.

The ultimatum game is a game played between two players who could share a cake (or prize) of some fixed size, say 100, that is finitely divisible into 100 equal parts. The first player,

the proposer, proposes to give a share of the cake s between 1 and 100 to the second player, the responder. If the responder accepts the offer, the cake is split according to the proposed split. If the responder rejects the offer, the cake is lost to both players. Under selfish preferences the subgame perfect outcome (which is the appropriate notion of the game theoretic equilibrium here) is $s = 1$, $1 - s = 99$. The basic idea being that if the responder does not engage in this game then he gets nothing, so he would accept the smallest indivisible unit of the cake. The experimental results reject the prediction $s = 1$, $1 - s = 99$. The gist of the results is as follows. (1) The mean offer is $s = 30 - 40$. (2) The median offer is $s = 40 - 50$. (3) There are rarely any unfair offers, $s = 0 - 10$ or over-fair offers $s > 50$. (4) Low offers are often rejected. These results continue to hold for high stake games. The outcome is easily explained by assuming that individuals have social preferences.

In public good games, the purpose is to explain human cooperation in undertaking a task for the common good. All individuals simultaneously make a voluntary contribution to a common pool. The experimenter then returns a fraction of the total sum of money to each participant; this captures the essence of a public good. The prediction of the standard model with selfish preferences is that everyone should free ride, that is, depend on others to make the contribution and make zero contributions themselves. The experimental results are that individuals start with a reasonably high level of contribution. However, in successive rounds the level of contributions drops off to a level that is consistent with the model of selfish preferences. Does the standard model stand vindicated then? Not necessarily. It does not explain why subjects start off with initially high levels of contribution. Furthermore, if these subjects start afresh then they again start with high levels of contributions. Negative reciprocity is a leading explanation. Most individuals start off by contributing reasonably high amounts but some do not. In subsequent rounds, negative reciprocity kicks in and everyone lowers their contribution amounts.

An important variant of the public good game is the public good game with punishment. What if contributors are allowed to punish the noncontributors at the end of the experiment. The prediction of standard theory is that individuals should treat by-gones as by-gones and not engage in any punishment. Anticipating this, noncooperators will not be deterred. The results of experiments do not support this prediction. Allowing for the possibility of punishment, contribution levels reach almost the first-best level and noncontributors are heavily punished. The public good experiments indicate that subjects are conditional cooperators. They cooperate when they think that others will cooperate. Furthermore, their preferences allow for the material payoffs of others (social preferences), thus giving them an incentive to punish even in games with a finite horizon. The implications of this result are deeper than just the current context.

Humans take account of the role of intentions. Humans do not punish unkind behavior if it was unintentional. However, intentionally unkind behavior can get severely punished. These issues are formally modeled in psychological game theory.

Some experimental evidence in certain contexts indicates that the split between individuals with selfish and social preferences is 40–60. An important and interesting issue for

theoretical and empirical research is to examine the implications of heterogeneity of preferences in the population. A range of theoretical and experimental work indicates that even a minority of individuals with social preferences can significantly alter the standard predictions.

Conditional reciprocity, inequity aversion, and the role of intentions explain several phenomena in contract theory such as the following. Why don't incentives always work? Why do we often observe cooperation in finitely repeated relationships? Why do we observe bonus contracts? Why are contracts often incomplete? Too great a use of the carrot and stick policy is likely to be perceived as hostile intent by workers, who could conditionally reciprocate by reducing effort. The standard model with purely selfish preferences is unable to provide a convincing explanation.

Time Discounting

Decisions that have a time dimension are central to many economic problems. The basic idea in most modern theories of time preference is the tension between immediate gratification and delayed, but greater, gratification. For example, if an individual or nation desires greater consumption in the future, then current consumption has to be reduced to increase saving and investment. This trade-off determines the consumption profile of individuals and nations. Models which are separable in time and outcome are sometimes called discounted utility models (DU).

Given two dates, t and $t + T$, let, $c_t = (c_t, c_{t+1}, \dots, c_{t+T})$, be a stream of dated consumption levels, or a consumption profile. A consumption profile could either be a historical record of the actual consumption levels, or a plan for future consumption formulated at a time, $t_0 \leq t$. The DU model states that the utility from this consumption profile is,

$$U(c_t) = \sum_{\tau=0}^T D(t+\tau)u(c_{t+\tau}) \quad [10]$$

where D is the discount function and u is the single-period utility function also known as felicity. Note that D is a function of time only and u depends on time only through the dependence of c on time.

An important question is the following. Suppose that the consumption profile, c_t , is optimal, in the sense that it maximizes eqn [10] subject to the constraints facing the consumer. Is the consumption profile $c_{t+s} = (c_{t+s}, c_{t+s+1}, \dots, c_{t+s+T})$ also optimal in the sense that it maximizes $U(c_{t+s}) = \sum_{\tau=0}^T D(t+s+\tau)u(c_{t+s+\tau})$? If this is the case then, c_t is said to be *time-consistent* otherwise it is said to be *time-inconsistent*.

Generally, optimal consumption plans are time-inconsistent. For example, as Richard Thaler argued in an influential example, a consumer may, now, prefer to have two apples in 51 days time to one apple in 50 days time but, come day 50, the consumer may prefer one apple that day to two apples the following day.

A special case of the DU model is the exponential discounted utility model (EDU) of Paul Samuelson, 1937. In this case the discount function takes the form

$$D(t) = e^{-\theta t}, \quad \theta > 0, \quad [11]$$

where θ is a constant parameter known as the discount rate and $\delta = e^{-\theta}$ is known as the discount factor. Thus, we also have $D(t) = \delta^t$, $0 < \delta < 1$. This model has proved extremely tractable and useful for many purposes. In particular, optimal consumption plans are always time-consistent if, and only if, the discount function is given by eqn [11]. However, EDU is rejected by the evidence.

Anomalies of EDU include the following. Under EDU, the discount rate between a time period of a given length remains the same irrespective of when the time period begins. However, the supposition of a constant discount rate is violated in many experiments; a finding that is known as the common difference effect. The most famous illustration of the common difference effect is Thaler's apples example, mentioned above. This led George Loewenstein and Drazen Prelec, in 1992, to propose the following hyperbolic discount function that can address the common difference effect:

$$D(t) = (1 + \alpha t)^{-\beta/\alpha}, \quad \alpha > 0, \quad \beta > 0. \quad [12]$$

Other anomalies of EDU include the following. Gains are more salient than losses (the sign effect), greater magnitudes are more salient than smaller ones (the magnitude effect), discounting over an interval depends on how that interval is subdivided (subadditive discounting), choices may appear to be cyclical (apparent intransitivity of preferences), choices may depend on the spread or monotonicity of the consumption sequence despite different sequences having the same discounted utility, and so on.

Loewenstein and Prelec explained the sign effect by proposing a per-period utility function or felicity (u in eqn [10]) with greater elasticity for losses as compared to gains. They explained gain-loss asymmetry by proposing that the elasticity of the felicity for losses exceeds that for gains. They explained the magnitude effect by assuming that the elasticity of the felicity is increasing. A functional form for the felicity that incorporates all these features was given by Ali al-Nowaihi and Sanjit Dhami. The combination of such a value function with the discount function [12] may be called the hyperbolically discounted utility model (HDU). This can explain the important violations of the EDU model.

Why do human and nonhuman subjects exhibit hyperbolic discounting? The work of Partha Dasgupta and Eric Maskin examines the evolutionary basis for this phenomenon. A wide range of puzzles that are largely unresolved with EDU can be explained by HDU. These include the following. Why does consumption track income so closely? Why do individuals under-save for retirement? Why is there a sharp drop in consumption at retirement? Why do individuals hold illiquid assets and credit card debt simultaneously? Why have national savings rates been declining? Why is marginal propensity to consume asset specific?

Unlike the EDU model, where the discount rate is constant across any two time periods of equal length, in the HDU model, the discount depends on the distance from the present, say, time t . In particular, under HDU, the discount rate over the interval $[t, s]$, $s > t$ is higher than the discount rate over the equal sized interval $[s, s + (s - t)]$. A higher discount rate implies a lower discount factor and, so, a lower weight on the

future. In this sense, the decision maker is said to be present-biased relative to the EDU model.

A second class of models that allows for a departure of the present from the future (relative to the EDU model) is the model of multiple selves. In this approach, the same individual, over time, can be viewed as a collection of different selves, one for each time period. Furthermore, the current self cannot perfectly control future selves by command. However, the current self can potentially take actions that can alter the constraints faced by future selves.

An important issue in the present-bias models is the degree of awareness that a current self has about the degree of present bias of one's own future selves. Experimental evidence is, at the moment, not conclusive about the degree of self awareness of the individual. It seems, however, that completely sophisticated behavior, that is, full awareness of one's future self-control problems and completely naive behavior, that is, no awareness of future self-control problems are both unreasonable relative to the intermediate case of partial awareness.

There are several applications of present biased preferences. Applied to the life cycle model it turns out that the present-bias of individuals leads to greater current consumption and lower savings relative to the time consistent behavior found in the EDU model. The current selves can, however, take certain actions to bind the future selves.

One possibility is for the current self to invest in illiquid assets, such as housing, that constrains the ability of the future selves to engage in excessive consumption. This can explain, for instance, why individuals simultaneously hold illiquid assets, such as housing (certainly illiquid as compared to financial assets), and credit card debt, a phenomenon that EDU cannot explain. The current self buys an illiquid asset to discipline the self-indulgent behavior of the future selves. The future self is now faced with mortgage payments (or a lack of cash due to the purchase of the house) and, so, this alters his/her budget constraint. However, the easy availability of credit cards could induce the future self to borrow and, so, successfully, relax the budget constraint. In so doing, the future self might believe that his/her future selves will be more responsible, which might well turn out to be a naive assumption.

Neuroeconomics

Neuroeconomics studies the neural activity in the human brain when one makes economic choices. One of the leading neuroeconomists, Colin Camerer, defines the subject matter in the following manner: neuroeconomics is a specialization of behavioral economics that plans to use neural data to create a mathematical and neurally disciplined approach to the micro-foundation of economics.

There is a wide variety of techniques used in neuroeconomics to measure brain activity. Some of these techniques are so invasive, for example, single neuron recordings, that they can only be used on animals. However, this is of value, as humans share a primitive mammalian brain with other mammals and so the lessons learnt from animal neuroeconomic experiments can provide valuable information. Other techniques, for example, functional magnetic resonance

imaging, FMRI, are less invasive and are able to measure the hemodynamic response, that is, the changes in blood flows to different parts of the brain while pinpointing, with varying accuracy, to relatively small and specific areas. Establishing causality is an issue with many of these techniques. Such is the speed of progress in neuroscience that it is now possible to be more sure of direct causality using very new techniques such as transcranial magnetic stimulation, TMS, whose method can be described as follows. Suppose that we suspect that some region, R , of the brain is responsible for some behavior, B , that is relevant to economics. Then TMS can temporarily curtail/stimulate area R . If this curtails/enhances behavior B then there is indeed a possibility that region R is responsible for behavior, B .

It is also possible to fruitfully apply older techniques that rely on psychophysical measurements, such as pupil dilation, heart rate, skin conductance etc. For instance, pupil dilation is enhanced when one sends false or misleading information. This has obvious implications for economics, for example, in predicting the truthfulness of messages in an asymmetric information game. When contributors punish noncontributors activation in the dorsal striatum (which is the brain's reward circuit) informs why the outcomes in the public good game with and without punishment are so different. Existing neoclassical models are unable to offer a convincing explanation.

Clearly, neuroeconomic variables have a direct role to play in economic models. But they can also be useful indirectly. Economic models are generally estimated by hypothesizing that some endogenous variable, y , is determined by a set of exogenous variables x_1, x_2, \dots, x_N and some noise term, ε . Typically, data is available on only a subset of the variables, x_1, x_2, \dots, x_s , $s < N$. The omitted variables are then, necessarily, subsumed within the noise term, ε . It is possible, however, that some neuroeconomic variables, z_1, z_2, \dots, z_m , influence y and are correlated with the omitted variables and, hence, can be used as instruments for them.

Usually, there are competing economic explanations for the same phenomenon. One can then ask which explanation is more neurally plausible, in the sense of being consistent with known findings from neuroeconomics. Thus, potentially, neuroeconomics could deliver an additional criterion for selecting among competing explanations.

We regard behavioral economics as an extension of mainstream (neoclassical) economics, using insights from psychology and sociology, into areas (and there are many) where mainstream economics has empirically failed. The neuroeconomic findings are suggestive of a dual-system functioning of the brain in which system 2 (the neocortex) determines cognition and system 1 (the limbic system) determines emotion. Thus, one may hypothesize that decisions made by system 2 would be in accord with rational choice theories while the interaction between the two systems would be in accord with alternative behavioral theories. Of course, the two systems need not be in conflict. Thus, both systems would, for example, urge us to breathe, eat and drink, seek shelter, and avoid hazardous situations. And, indeed, neuroeconomic findings have supported a range of rational choice models. Support for the rational choice models, however, seems to arise largely in environments that are stationary

and where evolution has had enough time to make an impact. Support for behavioral alternatives is more widespread; and include, for example, models of fairness and reciprocity, prospect theory, models of limited iterative thinking and hyperbolic time discounting.

Behavioral Game Theory

Game theory deals with situations in which a set of individuals (called players) take actions or play strategies that affect not only their own payoffs (or utilities) but also those of others. The fundamental concept in game theory is that of a noncooperative equilibrium, proposed by John Nash in 1950, hence, also known as a Nash equilibrium. In such an equilibrium, each player plays a strategy that is best for himself in terms of maximizing payoffs or utility (i.e., a best reply), given the equilibrium strategies of the other players. Nash proved that every finite game (finite number of players and finite number of actions) has a Nash equilibrium.

It is permitted for players to have a probability distribution over the play of their actions. To emphasize this point, sometimes strategies are referred to as mixed strategies. If each action is played with strictly positive probability, then the strategy is strictly mixed. By contrast, in a pure strategy, each action is played with probability 0 or 1. A strategy x dominates a strategy y , for player i , if x gives higher payoffs for i than y , irrespective of the strategies of the other players. One very simple method of searching for a Nash equilibrium is that of iterated elimination of dominated strategies.

A dynamic game is a game played over time in which players have the opportunity of observing and learning from the previous actions of other players. A simple way to find a Nash equilibrium of a dynamic game is by backward induction: find a Nash equilibrium for the subgame played in the final period. Then find a Nash equilibrium in the penultimate game, assuming that players, come the final period subgame, will play the Nash equilibrium already found for that subgame. Carry on till the initial subgame. Backward induction has the added attraction that it does not allow threats that are not credible (i.e., those that would never be used). Such an equilibrium is called a subgame perfect equilibrium.

Behavioral game theory has developed as a response to the violations of the predictions of (mainstream) game theory. Contrary to the prediction of game theory, players do not engage in iterated deletion of dominated strategies if this involves more than 2–3 steps of iteration. Within the context of two steps of iterated eliminations of dominated strategies, the outcome has also been shown to be sensitive to framing effects.

A test of the iterated deletion of dominated strategies is in the context of the Abreu–Matsushima mechanism design solution. This is a mechanism that is implementable by using very few steps of iterated elimination of dominated strategies. The results of Martin Sefton and Abdullah Yavas show empirically that the predictions of this mechanism fail. In conjunction with similar evidence from elsewhere, this casts doubt on the implementability of other mechanisms (most of which are even more complex).

The backward induction argument usually fails in experiments.

Multiple Nash equilibria arise in almost all areas of economics. An important question is whether players can coordinate (agree) on one of the equilibria (preferably the best for all, if such an equilibrium exists). Widespread failure to coordinate on any equilibrium (particularly the one that maximizes joint payoffs) is observed in experimental results. Preplay communication does not necessarily enhance coordination. History plays a powerful role in influencing the degree of coordination. Only under some conditions, for example, gradual growth of group sizes, successful coordination in small groups, knowledge of the history of such coordination, etc., does coordination emerge successfully. In experiments, if generations give public advice to their successors then coordination can be enhanced.

While players often seem to play mixed strategies they do not do so in the proportions predicted by a mixed strategy Nash equilibrium (MNE). Furthermore, while the aggregate proportions (across players) are sometimes found to be consistent with MNE, individual proportions of play are typically inconsistent with a MNE. Tennis and football professionals seem to play mixed strategies that are consistent with the evidence. However, the serial dependence of serves, in tennis for example, is inconsistent with the predictions of a MNE.

There is also a fascinating new literature that tests the predictions of standard game theory by directly attempting to infer the cognitive process when subjects play experimental games. Game theory does not make any assumptions on the cognitive process when subjects play games. Some traditionalists argue that a study of the cognitive process cannot confirm or reject anything in game theory. Consider, for instance, the work of Eric Johnson et al. They consider Rubinstein's alternative offers bargaining game played by two players over three rounds. The game is easily solved by backward induction. One would, therefore, expect that subjects will look to see the last round data such as payoffs, actions etc., then look at the penultimate round data and finally, the first round data. The authors use MOUSELAB software to observe if the pattern of searches made by experimental subjects is backward, beginning with the third period data. It turns out that subjects search forward rather than backward, that is, looking first at the first round data, then the second round data, and finally, the third round data.

The Nash equilibrium concept and its refinements have helped to shed light on many interesting questions in economics. Furthermore, the machinery of game theory has forced economists to be completely explicit about who the players are, what moves are open to them, the sequence of their moves, what objectives they have, what information they acquire and when, etc. This level of rigor gives modern economics a tremendous advantage over pre-game-theoretic economics. However, the empirical evidence on the Nash equilibrium and its refinements is not very encouraging, especially when individuals interact in bilateral or small group settings. More positive evidence is found at the level of market outcomes and in large groups.

There are now several alternative models of behavioral game theory that perform better than a MNE. These include the concept of a quantal response equilibrium (QRE). QRE has been able to explain a range of findings from experimental/field data that the classical equilibrium concepts have found

troubling to explain. In a QRE, players play strictly mixed strategies. In contrast to notions in classical game theory, such as trembling hand perfection, the trembles do not, in the limit, tend to zero in a QRE. Trembles are fundamental and remain significantly large in a QRE. This avoids a range of problems that arise in classical theory regarding assigning beliefs about actions that are not played in equilibrium. The reason is that, in a QRE, all paths of play are ex-ante possible. The main requirement of a QRE is that players form beliefs that are correct in equilibrium. However, because players randomize over all their actions in a QRE, they do not necessarily play best replies.

Forming beliefs that are correct in equilibrium, as in QRE, is cognitively challenging. This requirement is relaxed in a second class of behavioral game theory models, the level- k models. In these disequilibrium models, players' beliefs need not be correct. However, players play best responses, conditional on these, possibly incorrect, beliefs.

Game theorists steeped in classical theory might well react indignantly and ask how players could possibly hold on to beliefs that turn out to be incorrect? There are two responses. (1) Level- k models are motivated by actual experimental evidence which indicates disequilibrium beliefs. (2) Even when a process of learning might correct the beliefs of players over time, there are still good reasons to pay attention to level- k models. First, many important decisions that economic agents make in real life are of the nature of one-off decisions or decisions that are not repeated often enough. Second, in many experiments where long-term learning has a positive impact, the economic environment is held fixed. In real life, however, the economic environment is often too variable to permit the clean learning results of experiments.

Level- k models introduce heterogeneity among players by distinguishing between types of players, $L0$, $L1$, $L2$, ... The generic type is denoted by Lk . Type $L0$, the only nonstrategic type, typically chooses to simply randomize among the various available actions. In general, any type Lk , $k \geq 1$ assumes that all other players are of type $Lk - 1$ only. In its cognitive hierarchy version, type Lk , $k \geq 1$ assumes that there is a distribution of all the lower types of players. Fixing beliefs in this manner, each type of player then chooses a best response over its available actions. Type $L0$, sometimes known as the anchoring type, need not be physically present in the population. It can exist purely as a model of other players in the minds of type $L1$ players.

Consider the p -beauty contest. In the simplest such game, subjects are asked to guess numbers between 0 and 100. The subject whose guess is closest to $2/3$ times the average wins a prize. The Nash equilibrium prediction is for each player to choose 0 (the reader should check this).

However, the level- k model predicts that people will play the p -beauty contest as follows. A type $L0$ player simply randomizes and so chooses the number 50. A type $L1$ player thinks that all others are type $L0$ so chooses the number $\frac{2}{3}(50) \approx 33$. A type $L2$ player thinks that all others are type $L1$ and so chooses the number $50(\frac{2}{3})^2 \approx 22$, and so on. Thus, if players were indeed of types $L0$, $L1$, $L2$, ... then we would expect to see spikes in the data at the numbers $50(\frac{2}{3})^0$, $50(\frac{2}{3})^1$, $50(\frac{2}{3})^2$, ... This is a remarkably precise and unambiguous prediction. Moreover, this prediction has been verified in several empirical works even when played with very high ability subjects.

Level- k models can explain a range of phenomena that are difficult to explain with other models. These include results from auctions and market entry games, among many others. The evidence from MOUSELAB experiments indicates that types $L1$ and $L2$, in the level- k models, make up 67–89% of the population. This data is hard to reconcile with QRE models suggesting that the level- k models have better psychological foundations.

There is a range of other behavioral game theory models. These include the noisy introspection model, models that consider the role of memory explicitly, models of coarse thinking and mental categorization, analogy based equilibrium models, cursed equilibrium and so on. Some are more speculative than others.

We have not touched on behavioral models of learning because of space constraints and the fact that the technical requirements for understanding even the basics are beyond the scope of the current contribution.

Liberalism and Paternalism

A fundamental principle of classical liberalism is that people are the best judges of their own welfare. This lies, explicitly or implicitly, at the heart of traditional public economics. Thus, the role of government is limited to upholding the law, enforcing contracts and correcting for market failures, when practicable. Of course, it has always been recognized that some well-defined groups, children for example, are not fully able to judge their own interests. The opposite view that, in the main, people are not the best judges of their own welfare, is known as paternalism. Under paternalism, an institution is needed to judge people's welfare for them, for example a government, political party or religious establishment.

Paternalism has not often had a beneficial impact in human history. However, there is strong empirical evidence from behavioral economics that people are, by and large, not rational optimizers, unlike the assumption under liberalism. A small selected sample of the violation of the rationality assumption is as follows. Many individuals do not utilize the full limits of their 401k pension plans despite the fact that the company will match the extra contributions. There is also inadequate diversification of portfolios. People often use a range of judgement heuristics to make decisions. The evidence is largely (but not always) inconsistent with the use of Bayes' rule, rational expectations, and even strict optimization. People become obese without any apparent liking for the condition of obesity or addicts who then often need to be helped by others to get rid of the habit. There is also an overutilization of payday loans. These are loans that are repaid when the next paycheck arrives; the short-term interest rates on these loans are much higher than loans available elsewhere.

In some cases, the textbook rational behavior might not be observed on account of lack of information, or limited cognitive abilities. In other cases, it could be due to a current-bias in preferences, which lead to self-control problems and dynamic inconsistency. Examples are various forms of addictive behavior, the desire to quit, and the subsequent relapses that are often difficult to reconcile by using the traditional rationality framework. People exhibit preference reversals. Preferences are often not well-defined, are often incomplete, and dependent on the framing of information.

Shlomo Benartzi and Richard Thaler show that only 20% of the people in their sample prefer their own portfolio to the median portfolio. In other important contexts such as pensions, individuals sometimes use the $1/n$ heuristic to allocate their portfolio where n is the number of options available, hence, making outcomes very sensitive to what assets are available.

This evidence has disturbing implications for the debate between liberalism and paternalism. Aware of this, behavioral economists sometimes refer to paternalism in the traditional sense as heavy-handed paternalism. By contrast, the form of paternalism suggested by behavioral economists is sometimes called soft paternalism or light paternalism. It is this form of paternalism that we now briefly review.

Some view the relaxation of rationality in welfare economics as a natural progression of the relaxation of other restrictive assumptions in economics, such as perfect competition, perfect information, certainty etc.

At the heart of most proposals under the ambit of light paternalism is the need to distort individual decisions/choices as little as possible and use as little coercion as possible. The idea is that the mistakes (or misperceptions) of the bounded rational types will be nudged in the direction of a correction while the minimal intrusion associated with light paternalism should have little effect on the actions of the fully rational types. To operationalize light paternalism, one needs to specify what a mistake/misperception is. Furthermore, in the light of these mistakes/misperceptions, how should we judge the outcomes of light-paternalistic policies? The latter question requires us to have some behavioral welfare criteria. The reason that a traditional welfare criteria would not be suitable is that actual choices might not be indicative of an individual's best interests. Thus, unlike the classical analysis we cannot use preference based measures of welfare such as equivalent variation and/or compensating variation to seek the direction in which individual welfare is improving. As Loewenstein and Haisley put it: "Clearly, it doesn't make sense to assess whether someone is committing an error using a measure that is premised on the assumption that people don't commit errors."

Botond Koszegi and Matthew Rabin argue that unless one imposes ancillary assumptions, it is impossible to infer preferences from choice even with unlimited data and under the assumption that people are 100% rational. Consider, for instance, the possibility that people have social preferences. Suppose that we observe a set of choices in which an individual shares with others when there is an option to do so. From this, should we conclude that the individual is happy to share with others? Or that she would feel guilty if she did not? Or that she would prefer not to have an option to share? These distinctions cannot be made based on the choice data.

Although additional evidence is already accumulating at a rapid rate, behavioral economics is a relatively new field and many important effects and channels are not fully understood yet. For that reason one needs to be cautious and careful in testing the implications of various paternalistic policies. Some have advocated careful small-scale pilot studies as well as field studies before the actual implementation of paternalistic policies. The evidence suggests that not all people are subject to the relevant behavioral biases. Clearly regulation that is too stringent might have a negative effect on these rational types.

Many notions of behavioral paternalism have been advocated in the literature that the reader might wish to follow up on. These include libertarian paternalism attributable to Richard Thaler and Cass Sunstein, asymmetric paternalism attributable to Colin Camerer et al. and a pragmatic approach attributable to George Loewenstein and Emily Haisley.

Brief Conclusions

Behavioral economics is one of the most rapidly growing fields in economics and is gradually becoming mainstream. It relies on a strong respect for the evidence, falsifiability, and a recognition that experiments in the lab, and neuroeconomic evidence, can usefully complement field data. It draws its principles from several decades of research in psychology (and sociology). Behavioral economics has seriously questioned the rationality assumption in economics as well as the assumption of selfish preferences. While traditional economics did recognize the possibility of less than perfect rationality, it assumed that these errors would cancel out in the aggregate. Behavioral economics has, instead, shown that these errors might cumulate and snowball in one direction and lead to outcomes that are very different from those predicted by traditional economics. Behavioral economics has also stressed the importance of emotions in making decisions, role of framing in influencing outcomes, provided richer theories of decision-making under risk and over time and provided new solution concepts in strategic interactions. In this sense it has provided new theory to explain the emerging evidence that is both refutable, and based on empirically robust psychological principles.

Glossary

Allele An alternate form of a gene at a particular place (locus) on a chromosome.

Association Correlation between phenotypic variation and a marker (genetic, allelic, or DNA) of variation on a chromosome.

Dominance The ability of one allele (the dominant) to override the phenotypic expression of another allele (the recessive).

Epistasis Nonadditive effects of the combined actions of two or more genes, that is, gene–gene interaction.

Gene A segment of a chromosome (deoxyribonucleic acid or DNA) that codes for some aspect of protein synthesis.

Genotype The genetic composition of an individual.

Heritability The proportion of phenotypic variability that can be accounted for by genetic differences.

Inbreeding Matings between closely genetically related individuals.

Linkage The extent to which two genes near each other on the same chromosome are transmitted together instead of segregating and independently assorting.

Phenotype The variant of a measurable characteristic or trait.

Pleiotropy Multiple phenotypic effects of the same gene.

Behavioral genetics, as the name indicates, is the interdisciplinary research area concerned with determining if and how genetic factors influence any of the phenomena studied in the behavioral sciences, especially psychology. Behavioral geneticists apply the concepts and methodologies of molecular, population, and quantitative genetics to behavior as the trait of interest.

Introduction

Two readily apparent, related aspects of human behavior make a compelling case for the need to study genetic influences on behavior. These are stability and variability.

If a behavior, for example, scoring high on tests of intelligence, is consistently manifested by an individual across time and across many different situations, then the stability of this behavior must be due to some consistent set of physical determinants. Through consistent reinforcement and/or punishment of certain behaviors, plus generalization, a stable behavior could have been established by environmental influences on the individual. On the other hand, the behavior could be a manifestation of some consistent ‘hard-wired’ physiological process, for example, greater efficiency of the connections in the brain’s neural network. Since all physiological/biological processes ultimately begin from some genetic code, it could be inferred that the stable behavior is the result of the individual having inherited some gene or genes for the behavior.

In turn, both the lack of variability and the presence of variability in stable behaviors also require the influence of some set of consistent physical determinants. For example, all physiologically normal humans raised among other humans acquire the ability to use language. The lack of variability in this behavior among humans, plus the absence of this behavior in this form in other animal species, is consistent with the supposition that all normal humans inherit a set of genes that code for the physiological structures that are required for

language. Other stable behaviors, such as performance on intelligence tests, are characterized by great variability among humans, and this variability is maintained in spite of historical and social changes in the environmental factors thought to influence the behaviors. Since each individual is genetically unique, stable individual differences in behavior are also consistent with the supposition that genetic determinants may be involved.

Although behavioral genetics is concerned with establishing the genetic correlates of behavior, the discussion above makes clear that genes, in fact, do not directly cause behavior. **Figure 1** reiterates the idea that genes are basically a biochemical process for coding the synthesis of proteins which, in turn, are assembled into the physiological structures and processes of the organism. These physiological structures then become one of the determinants of behavior, and the study of this process is the realm of physiological psychology. Thus, any finding from behavioral genetics of significant genetic contributions to behavior automatically implies that some physiological mechanism is the more proximal determinant.

Behavior can also be influenced by the environment through learning, and one dotted line shows the presumption in physiological psychology that ultimately learning operates by modifying the physiology of the organism. It should also be noted that genetic influences always operate on physiology within the context of some set of environmental influences. The other dotted line presents the possibility (discussed below) that genetic processes can affect environmental influences.

In **Figure 1**, the understanding of how genetic processes are translated into physiology is noted to be the realm of molecular genetics/genomics. Molecular genetics is concerned with the sequence and operation of biochemically defined genetic material (the DNA base pairs described below) in transcribing, transmitting, and implementing the code for the synthesis of physiological structures and processes. Genomics focuses on gene expression, much of which has evolved to be responsive to intracellular and extracellular environmental effects.

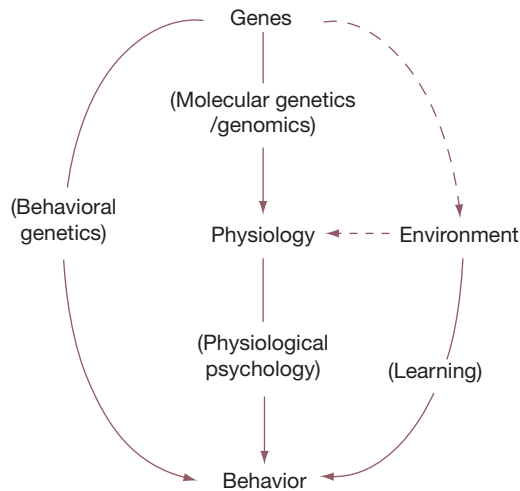

Figure 1 Relationship of genes to behavior.

Quantitative genetics estimates the relative contribution of genetic versus environmental influences to variation in a trait by comparing differential resemblances or patterns of differential variability among individuals with different degrees of genetic relatedness. Population genetics bridges molecular and quantitative genetic approaches, as well as evolutionary processes, by seeking to relate gene frequencies and degree of genetic influence with particular traits for populations of organisms operating within particular environmental contexts.

Since behavioral genetics is basically the application of genetics to a special set of traits, behavior, much of this article will be an overview of genetic concepts and methodologies. We begin with a discussion of Darwin's theory of evolution by natural selection and of Mendel's work on the logic of genetic transmission.

Evolution and Mendelian Genetics

The evolutionary theory of Charles Darwin (1809–1882) had a profound impact on Western thought. Even though it provides a basis for a unified understanding of all biological phenomena, the theory was and remains controversial. In psychology, it was integrated into the concepts of the nineteenth century physiological psychologists, became a major inspiration for William James' school of functionalism (the school which, somewhat ironically in this context, led to John B. Watson's behaviorism) and Sigmund Freud's school of psychoanalysis, and the work of Darwin's cousin Francis Galton, was also the starting point for the scientific study of individual differences and genetic influences on human behavior.

Darwin's theory, first published as *On the Origin of Species by Means of Natural Selection* in 1858, has three major components, each of which has important implications for the understanding of human behavior:

1. *Induction of variation* proposes that members of a species differ from each other at birth and through maturation along a multitude of different trait dimensions and that biological processes continually create these individual

differences. Not only are such differences ubiquitous for any species, they are absolutely essential for the survival of the species in the face of relentless changes in environmental conditions. One obvious implication of this for psychology is that, in contrast to the ideas of several early behaviorists, individual members of a species, including humans, are biologically unique and should not be expected to respond to the same environmental influences on behavior in exactly the same way.

2. *Maintenance of variation* proposes that individual differences in the traits that vary within a species are biologically transmissible from one generation to the next. Again, this is absolutely essential for the survival of the species. This idea leads to the immediate inference that behavior must also be biologically transmissible, since stable patterns of behavior are undoubtedly essential aspects of species survival. Thousands of years of humans breeding animals for behavioral traits supported the idea of genetic bases for behavior, even for humans.
3. *Natural selection* assumes that there are always more members of a species born at any one time than will ever survive to reproduce. Darwin proposed that environmental conditions at a particular time, for example, availability of food, nature of predators and parasites, climate, etc., tend to give some individuals born with one set of traits, an advantage in being able to survive, reproduce, and rear offsprings to maturity over other individuals with different levels of these traits. Over several generations of this natural selection, more individuals with the advantageous characteristics are born with and transmit these characteristics, while there is a decreased incidence and transmission of the disadvantageous characteristics. Darwin argued that over a sufficient number of generations, particularly in response to some major change in the environment, the members of a species may now possess such different traits from the starting population that they constitute a new species.

As noted above, Darwin's theory clearly reinforces the importance of genetic transmission and biologically based individual differences as determinants of the characteristics of organisms, including behavioral characteristics. The theory also implies that all species, including humans, are biologically related on some level to every other species. The similarities and differences between and within species could be understood solely in terms of the interactions between the genetic endowments of a species and the selection pressures in the environment. Research into the determinants of behavior in other animal species in order to understand human behavior is justified, because other animals and humans have some of the same or similar physiological structures and processes that determine behavior. Other implications include the expectation that humans retain physiological structures that were once adaptive or neutral in reproductive fitness value in natural environments, but which may be maladaptive in rapidly changing modern societies (e.g., the 'fight or flight' response). Another implication is that even those 'higher' aspects of human behavior and mental processes that supposedly differentiate us from other animals can be related to genetically transmitted physiological functions that resulted from natural selection.

Although natural selection was the most parsimonious and successful proposed mechanism for accounting for species change, at the time Darwin published his theory the way that traits were biologically transmitted was poorly understood. Darwin himself realized that the then current concept that parents gave off biological particles ('gemmules') that merged and blended in the offspring would, in fact, invalidate his principles of induction and maintenance of variation. Due to regression toward the mean, generations of blending traits would result in all individuals having the same averaged trait, that is, no variation. It was only after the work of Mendel and the beginning of modern genetics that a mechanism for the maintenance of variation was established.

Gregor Mendel (1822–1884) studied the types and frequencies of plant characteristics that resulted when members of a species possessing one kind of characteristic were crossed with members having a different characteristic. For his most famous work on pea plants, such characteristics included green versus yellow pea color, smooth versus wrinkled pea form, long versus short plant stem, etc. His cross-breeding studies led him to infer two principles for genetic transmission.

The *law of segregation* stated that every character (the phenotype) is determined by the combination of two elements (genes), one from each parent. These elements split off cleanly (segregate) from each other in the production of the sex cells and are transmitted intact to the offspring. Since it is possible for one form of the gene (a dominant allele) to prevent the expression of the other form (the recessive allele), a process called dominance, the same phenotype could result from different combinations of genetic elements (the genotype). For example, a green pea would result whether the genotype consisted of both alleles coding for green color (homozygous dominant) or a genotype with both green and yellow coding alleles (heterozygous), since the green allele was dominant. This was apparent when Mendel crossed 'pure' green and 'pure' yellow pea plants and found that the next generation all had green peas. When this second generation was crossed with each other, however, Mendel found that one-fourth of the succeeding generation again manifested yellow peas (both alleles coding for yellow; homozygous recessive). Thus, the yellow alleles were not blended, the frequency of the recessive phenotype could be predicted from the random combination of the dominant and recessive alleles, and the variability of the genes determining green versus yellow pea color was maintained.

The *law of independent assortment* stated that different genes determined different characteristics. These genes were randomly combined in the sex cells and, hence, independently transmitted to the offspring. Mendel found that when he looked at the results of crossing plants for two different traits, for example, green pea color/long stem with yellow pea color/short stem plants, the odds of a plant possessing green versus yellow peas were completely independent of the odds of the plant having a long versus a short stem. This was also important for Darwin's theory, since it meant that one trait could be selected for without affecting some other trait.

As it turned out, modern genetic findings have turned up several exceptions to Mendel's laws. Many genetic/physiological and/or environmental factors can result in a genotype not being completely manifested in the phenotype (*incomplete*

expression/penetrance). Many traits determined by single genes (one pair of alleles) do not show dominance, such that heterozygous genotypes may result in phenotypes intermediate between phenotypes resulting from the two homozygous genotypes. Heterozygous genotypes may produce more extreme phenotypes (*overdominance*). Genes on the X-chromosome (discussed below) are differentially transmitted to male versus female offspring. Recent findings suggest that parents in a few genetic systems may be able to determine the expression of both alleles of an offspring (*genomic imprinting* and *uniparental disomy*). An important recent discovery concerns *simple sequence repeats* or *gene amplification*, where three-nucleotide base-pair sequences within genes increase in number over generations, leading to disruptions in normal gene functioning. With regard to independent assortment, it is now known that genes that are close to each other on the same chromosome are often transmitted together (*linkage*) and that single genes can have multiple phenotypic effects (*pleiotropy*). Nevertheless, Mendel's laws more than adequately accounted for observations of genetic transmission at the phenotypic level long before the biochemical nature of genes was understood.

Although Mendel presented his findings at a scientific meeting in 1865, they were 'lost' until 1900, when several biologists (Erich Tschermak von Seysenegg, Hugo, de Vries, and Carl Correns) rediscovered and started widely applying the laws. In the meantime, Darwin's cousin Francis Galton (1822–1911) was using the theory of evolution to establish the science of behavioral genetics.

Galton immediately inferred from Darwin's theory that all human behaviors had a biological/genetic basis and were the result of natural selection. With his book *Hereditary Genius: An Inquiry Into It's Laws and Consequences* (1869), he asserted that social eminence (reflective of intelligence) was genetically determined. He demonstrated this by showing how the incidence of eminence in the male relatives (fathers, sons, uncles, cousins, etc.) of eminent men was a strict function of the degree of biological relatedness between the probands (the index cases from whom other family members are identified) and the relatives. He developed the idea of the twin research design, when he studied more physically similar twins versus less similar twins and asserted that the former's greater similarity on psychological traits also indicated a genetic basis for psychological as well as physical characteristics. He established laboratories for the systematic measurement of thousands of individuals on physical (height, weight, etc.) and psychological (acuity of eyesight, acuity of hearing, reaction time, etc.) traits in hopes of establishing the large data bases he knew were required to delineate genetically based distributional characteristics, social class differences, developmental trends, and familial resemblances.

Besides his enormous contributions to psychology in establishing ways of measuring psychological phenomena of all sorts, Galton's quest for ways to demonstrate genetic transmission in relatives led to the development of new statistical techniques. His student, Karl Pearson, developed the correlation coefficient to quantify familial resemblances in some standardized fashion, and genetic questions spurred the development of statistical procedures commonly used in the social sciences (e.g., Fisher's chi-square and *F*-tests).

Thus, much of the logic and methodologies of modern behavioral genetics had been laid down by Galton and his

students by the time Mendel's ideas were rediscovered. Ironically, it took some time and controversy to reconcile Galton's ideas, that accumulations of genetic elements of some sort produce continuous, typically normal distributions of traits, such as intelligence, with Mendel's ideas about discrete traits under the control of only a few combinations of alleles. The reconciliation involved the recognition that the random combination (consistent with independent assortment) of several discrete genetic elements, all of which have some influence on the trait, would produce the continuous, normal distributions Galton saw. It is still important, though, to distinguish between traits thought to be under the control of a single gene versus those under the control of several genes.

Although Darwin's ideas were important for the school of functionalism established in the United States by William James and others at the end of the nineteenth century, and Galton's ideas were the starting point for trait theories of intelligence and personality, genetic explanations for behavior were largely eclipsed by behaviorism throughout most of the twentieth century. There was also a great amount of philosophical resistance in the general public to the idea of biological/genetic determinants of human behavior. For instance, there was considerable public controversy following the publication of Arthur Jensen's 1969 paper asserting that, due to the high heritability of intelligence, educational programs would have only minimal effects in ameliorating race differences in I.Q. Ironically, this same controversy was resuscitated by the 1994 publication of Richard Herrnstein and Charles Murray's *The Bell Curve*.

Several historical developments have led to the much greater acceptance today of behavioral genetics in both mainstream psychology and the general public. The discovery of the structure of deoxyribonucleic acid (DNA), the fundamental molecule of heredity, by Watson and Crick in 1953 spurred the vast expansion of knowledge in recent years on the biochemical characteristics and processes of what had up to then been only a hypothetical genetic mechanism. Discoveries about the biochemical workings of genes and gene products continue and will continue to be among the most exciting findings in science. The findings from physiological psychology and neuroscience have greatly expanded our understanding of the biological processes that determine behavior, while the idea of learning as the sole basis for behavior no longer has ascendancy. Meanwhile, the accumulation of findings from pedigree, twin, and adoption studies has provided compelling evidence for the significant heritability of intelligence, personality, schizophrenia, alcoholism, etc.

Population Genetics

Prior to the development of the techniques discussed below under Molecular Genetics for identifying markers of DNA variation, genetics research involved inferring underlying genetic mechanisms from observed phenotypic variations. Both population and quantitative genetics primarily analyze such informative phenotypic variation, and both fields are moving toward the greater incorporation of DNA markers into research designs for more precise analyses of genetic processes.

As noted above, population genetics seeks to understand the frequencies and relative contributions of genes on

particular variations in traits for a group of organisms operating within a particular environmental context. An important starting point for population genetics was the statistical derivation of the Hardy-Weinberg-Castle equilibrium, which showed that, in the absence of influences that produce disequilibrium (discussed below), the relative frequencies of alleles (dominant vs. recessive, etc.) and genotypes (homozygous dominant, heterozygous, etc.) for a phenotype remain at a constant ratio over generations. This was basically just a restatement of Darwin's idea of maintenance of genetic variation, but in this case it was derived through mathematically following the logic of genetic transmission defined by Mendel.

There are four major forces that can change allelic frequencies, that is, the relative frequencies of one form of a gene versus another, in a population:

Migration can change allelic frequencies if individuals who move into or out of a population differ from the original population in their allelic frequencies. For example, it can be argued that the waves of immigrants who came to the United States throughout its history were more likely to carry genes for such phenotypes as adventurousness, hardiness, rebelliousness, etc., compared to the populations left behind.

Random genetic drift can affect small populations, when chance causes some alleles and not others to accumulate over several generations.

Mutation is the ultimate source of inducing genetic variations, as alleles are altered by errors in genetic replication and transmission and by environmental influences. The spontaneous mutation rate, however, is thought to be quite low, and the effect of mutation on allelic frequencies in most cases is minor compared to natural selection.

Natural selection is the prime basis for genetic change described by Darwin. Natural selection operates on the basis of the phenotypes that give an organism some advantage or disadvantage (relative fitness) in surviving to reproduce offspring who, in turn, will pass on the genes that determine the phenotype. If a phenotype, such as schizophrenia, is selected against by the environment, that is, the phenotype reduces the reproductive success of the individual, and is determined by a dominant allele, then both homozygous dominant and heterozygous genotypes will be selected against. In this case, natural selection will rapidly decrease the frequency of the dominant allele. If, however, the maladaptive phenotype is coded for by a recessive allele, as is the case for phenylketonuria (discussed below), then only homozygous recessive genotypes will be selected against, and large numbers of heterozygotes (*carriers*) will continue to transmit the 'bad' allele to some of their offspring. This process tends to ensure that adaptive phenotypes are coded for by dominant alleles, while maladaptive phenotypes are carried and maintained on recessives in populations. This picture becomes more complicated when there is not complete dominance for a gene. In the extreme case, selection may eliminate all but one form of a gene for an adaptive trait in a population or species, and this trait then becomes a species characteristic (i.e., there is no variability for the trait).

Natural selection may also act to maintain or even increase the variability of a trait in the population, creating a so-called balanced polymorphism. For example, sickle-cell anemia is a typically fatal medical condition in individuals of African

ancestry. The disease is caused by an autosomal recessive gene, thus homozygous recessive genotypes are selected against. Heterozygotes, however, manifest a greater resistance to malaria in malarial environments than homozygous dominants, and both alleles are maintained in the population, in spite of the deleterious effects of the recessive gene by itself. Predator–prey and parasite–host relationships also often manifest balanced polymorphisms, as natural selection for adaptations in one organism are constantly being compensated for by corresponding natural selection for adaptations in the other organism.

Since characteristics that increase the probability of being chosen as a mate also directly affect reproductive success, sexual selection is a special form of natural selection and can produce many of the same effects described above. On the other hand, the phenotypes chosen by mates may not be consistent with those resulting from natural selection, that is, as a result of sexual selection, species may come to manifest traits that appear to be maladaptive.

Besides forces that change allelic frequencies, population geneticists also consider two forces, inbreeding, and assortative mating, that change genotypic (but not allelic) frequencies by increasing the similarity of the genes that both parents transmit to their offspring. This is important, because such parental similarities in the genes they transmit would increase the relative frequencies of homozygous dominant and recessive genotypes, while decreasing the proportion of heterozygotes. This, in turn, typically has the effect of increasing the variability of the trait in the offspring generation, since there would be higher frequencies of the extreme genotypes. This increased variability might counter the reduction in trait variability resulting from unidirectional natural selection.

Inbreeding is the mating of closely genetically related individuals and, as described above, causes parents to be more similar in the genes they transmit to offspring. Since recessive alleles often code for deleterious phenotypes but are not expressed, due to their being paired with a dominant, the increased incidence of homozygous recessive genotypes resulting from inbreeding often results in decreased fitness for the offspring of such matings (*inbreeding depression*). The counterpart to this is the increased fitness (*hybrid vigor*) found when more genetically unrelated individuals are mated. Some evidence for both inbreeding depression and hybrid vigor effects on intelligence have been found in studies of offspring from first cousin versus those from cross-ethnic group marriages.

Assortative mating (which is ubiquitous for human behavioral traits) is where mates are similar in their phenotypes, whether due to mate choice or environmental factors. There are three different ways in which assortative mating may occur:

In *genetic similarity*, mates select each other or are selected for each other on the basis on having similar genes, and the effects of this on offspring genotypic frequencies are similar to inbreeding. This phenomenon has been demonstrated in some animal species, but is controversial in humans.

In *phenotypic assortment*, mates select each other on the basis of similarities in observable characteristics. Phenotypic assortment can only produce greater genetic similarity between the parents if there is a significant relationship between the genotype and the phenotype, that is, if the characteristic is heritable. In fact, many human behaviors, such as intelligence, personality, attitudes, some psychopathology, etc., have been shown

to produce moderate to high spouse correlations indicative of phenotypic assortment.

In *social homogamy*, mates are similar in their phenotypes simply because the environments in which they meet and mate only have individuals possessing certain characteristics. In a highly stratified society, social class differences can cause human mates to be highly similar in several behaviors relative to mates from other classes, even when there is no active phenotypic assortment. Social homogamy can only produce greater parental genetic similarity if the phenotypes of interest are heritable and there's a significant gene–environment correlation (discussed below).

Phenotypes may also be found to be similar in mates due to mates influencing each other after getting together, a phenomenon sometimes called *contagion*.

One important offshoot of population genetics is *sociobiology*, which seeks to determine the evolutionary significance (i.e., fitness value) of behavioral systems. For example, sociobiologists are interested in the environmental conditions, physiological characteristics of the organism, and available genetically transmissible behaviors that cause one animal species to be characterized by altruistic behaviors, while other otherwise similar species are not altruistic. While behavioral geneticists generally attempt to determine the relative contribution of genetic factors on variations in behavior within a species, sociobiologists tend to look at the influence of such factors on variations in behavior across species. In turn, sociobiological ideas spurred the development of *evolutionary psychology*, which seeks to relate variations in contemporary human behavior to a history of natural selection.

Quantitative Genetics

Quantitative genetics assesses the relative contribution of genetic versus environmental factors (nature vs. nurture) in determining individual variations in traits within a species or population. If only the phenotypes are measured, and the genetic bases for the familial resemblances discussed below only assumed, quantitative genetics must rely heavily on statistical techniques to arrive at its conclusions. It should also be noted that, as with population genetics, quantitative genetic findings are descriptive of relative genetic and environmental influences averaged across a particular population operating in a particular environmental context and subject to all of the forces discussed above that change allelic and genotypic frequencies.

The starting point for quantitative genetics is variability. As discussed at the beginning of this article, stable individual differences in behavior or any other trait must be the result of genetic and/or environmental processes that are both unique for each individual and consistent in their effects across time. Heritability is defined as that proportion of the variability of a phenotype that can be accounted for by genetic factors or $h^2 = V_G/V_P$, where V_G and V_P are the genetic and phenotypic variabilities, respectively. Traits without any variability, such as the ability to use language in humans, may be entirely under genetic control, but the lack of variability for the trait precludes any statistical tests to determine the relative influence of genes and environment.

The counterpart to the assumptions about variability is that, if relatives resemble each other (i.e., do not vary) for some trait, it must be because they share the same genetic and/or environmental determinants of the variability of the trait. By comparing the relative degrees of resemblance (correlations) for the phenotype of interest across relationship types that theoretically differ in their underlying shared genetic and environmental determinants, the quantitative geneticist can infer the extent to which genetic versus environmental variability accounted for the variability of the phenotype.

For the commonly used study of twins reared together, identical (monozygotic or MZ) twins are known to share all of their genetic variability (they literally have the same genes), as well as sharing the same family environment. Fraternal (dizygotic or DZ) twins are like nontwin siblings in only sharing half of their additive (additive vs. nonadditive genetic effects are discussed below) genetic variance, but they are like MZ twins in sharing the same family environment. Hence, if MZ twins are more alike than DZ twins, it is assumed that this is because the former share twice as much genetic variability as the latter. Thus, doubling the difference between the MZ and DZ correlations should estimate the heritability. For example, adult MZ twins reared together typically correlate around 0.75 on tests of intelligence, while DZ twins reared together correlate around 0.50. Thus the heritability would be $h^2 = 2(r_{MZ} - r_{DZ}) = 2(0.75 - 0.50) = 0.50$, or 50% of the variability in intelligence is accounted for by genetic factors. Fifty percent heritability means that part of the MZ resemblance of 0.75 is still unaccounted for. This part, 0.25 or 25%, is presumably due to the effects of shared family environment.

Genetic influences can be classified as additive or nonadditive. Additive effects are analogous to the idea of 'gene dosage,' in that for polygenically determined traits familial resemblances are predicted from the extent of the linear accumulation of shared genes. For example, each parent shares on average 50% of the additive genetic variability for a phenotype with his/her offspring by transmitting half of the offspring's genome. Siblings share with each other on average 50% of the additive genetic variability, because for each of the two parents the probability is 25% that the same genes were transmitted to both siblings (50% to one sibling \times 50% to the other). Additive genetic variability is important in that it determines the extent to which a trait can be changed in a population through natural or artificial selection.

The two types of nonadditive genetic effects, *dominance* and *epistasis*, can be thought of as being analogous to statistical interactions. The dominance effects described above for single genes are interallele interactions, where the effect of one allele cannot be predicted without knowing the effect of the other allele. Thus, parents and offspring do not share any dominance genetic variability, since dominance effects require particular combinations of alleles from both parents. Siblings, on the other hand, do share 25% of dominance genetic variability, since that is the probability of both siblings receiving exactly the same combination of alleles (at least for a two-allele gene) from both parents.

Epistasis is an intergene interaction, where the effect of one gene cannot be predicted without knowing the effect of some other gene or genes. Only identical twins share epistatic genetic variability, since they inherit not only the same genes, but also the exact same combination and ordering of the genes.

Environmental effects can be classified as shared (common), special twin, and unshared (specific). Shared environmental variability represents the assumption that individuals growing up in the same family may resemble each other, because they are influenced by the same environmental determinants of the phenotype. Adoptive siblings and adoptive parents and their offspring provide strong tests of shared environmental effects, since presumably this is the only factor that would create any familial resemblances. Special twin environmental variability is a special form of shared environmental effects that assumes that twins may share more similar environmental influences, perhaps due to being of the same age, than nontwin siblings.

Unshared environmental effects make family members different from each other. This may be due to idiosyncratic events in a person's life and differential treatment of siblings by parents, as well as measurement unreliability. Differences between identical twins reared together must be due to unshared environmental variability, since that is the only factor MZs don't have in common.

Genetic effects may also be correlated with environmental effects. *Gene-environment correlations* can be *passive*, where the child is born into a family environment in which environmental conditions created by the parents are consistent with the parents' and the offspring's genotype. They can be *evocative*, where the environment changes in response to the offspring's genotype, or *active*, where the offspring's genotype causes him/her to change the environment to make it more consistent with his/her genotype. Positive gene-environment correlations can presumably magnify genetic effects, while negative gene-environment correlations can diminish them. Gene-environment correlations also create the possibility that measures of the family environment used by psychologists, such as parents' socioeconomic status, may in fact be confounded by genetic factors.

Finally, there is the possibility of *gene-environment interactions*, where genetic effects cannot be predicted unless the environmental conditions are known. For example, genes determining high intelligence appear to be better expressed if a child is raised in an enriched environment.

Table 1 presents the theoretical extents to which the factors presented above can cause relatives to resemble each other across various relationship types. Quantitative genetic studies typically compare phenotypic resemblances across two and occasionally more relationship types, and some of the most commonly used designs will be described below. For several of these factors, the differences across relationship types are too small to reliably detect their effects. For instance, it can be seen that dominance and epistatic genetic effects are basically indistinguishable, and gene-environment correlations and interactions are barely distinguishable from pure genetic effects.

Before describing quantitative genetic designs used to estimate heritabilities for human behavior, animal behavioral genetic studies should be mentioned. To the extent that, due to evolutionary reasons, other animal species, such as *Drosophila* (fruit flies), nematodes, mice, and rats, share with humans the same genes and resultant physiological structures and processes that determine behavior, animal genetic studies have a number of advantages in providing information about the genetic determinants of human behavior. Unlike human

Table 1 Components of shared variance for different familial relationships

	<i>Genetic</i>			<i>Environmental</i>			<i>Gene–environment</i>	
	Additive	Dominance	Epistatic	Shared	Twin	Specific	Correlation	Interaction
Identical (MZ) twins	1.0	1.0	1.0	1.0	1.0	0	1.0	1.0
Fraternal (DZ) twins	0.5	0.25	0	1.0	1.0	0	< 0.5?	< 0.5?
Nontwin siblings	0.5	0.25	0	1.0	0	0	< 0.5?	< 0.5?
Parents/offspring	0.5	0	0	1.0	0	0	< 0.5?	< 0.5?
Half-siblings	0.25	0	0	1.0	0	0	< 0.25?	< 0.25?
Uncles-aunts/nephew-nieces	0.25	0	0	0?	0	0	< 0.25?	< 0.25?
First cousins	0.125	0	0	0?	0	0	< 0.125?	< 0.125?
Adoptees	0	0	0	1.0	0	0	0	0

adoption studies, in research with animals prenatal environments can be controlled by transplanting fetuses across animals with different genotypes. Rearing environments can be controlled to eliminate the effects of such environmental differences or manipulated to test for gene–environment interactions. Inbred strains of genetically identical animals can be used to control for genetic variability. Heritabilities can be estimated by assessing the phenotypic response to selective breeding for extremes on the trait.

Family studies with humans involve obtaining parent–offspring and/or sibling correlations. As can be seen in [Table 1](#), such studies cannot disentangle the effects of genetic influences from shared environmental influences, although they can provide an ‘upper limit’ for heritability. The extension of a family design to the examination of large pedigrees can provide evidence for the Mendelian transmission of a trait under the control of a single gene.

Comparisons of reared-together identical versus fraternal twin resemblances can provide an estimate of heritability, but cannot easily disentangle additive versus nonadditive genetic effects. As can be seen in [Table 1](#), MZs may resemble each other more than DZs also due to greater shared gene–environment correlations and interactions. In addition, these comparisons assume that greater MZ than DZ resemblances for a trait are not the result of MZs being treated more alike than DZs causing more phenotypic similarity in MZs. Studies have validated this ‘equal environments’ assumption for intelligence and personality, but it remains untested for many other phenotypes.

Adoption studies involve some combination of comparing resemblances of biological parents with their adopted-away offspring versus the resemblances of the adoptive parents with the offspring or comparing adoptive versus nonadoptive sibling resemblances. Such designs have the advantage of theoretically separating additive genetic and shared environmental influences, although pre- and neonatal environmental effects cannot be controlled for. Attempts by adoption agencies to match adoptive parents with the biological parents (*selective placement*) could confound the analyzes, but this effect has been found to be negligible in studies of intelligence and personality. The typically narrower range of rearing environments for samples of adoptive parents compared to biological parents may also attenuate shared environment effects.

In order to illustrate two other important aspects of quantitative genetic analysis, [Figure 2](#) presents a path model for the genetic transmission of two different phenotypes (subscripts x and y) from fathers (subscript F) and mothers (subscript M) to

their biological offspring (subscript O). In the model, each phenotype P is determined by a genetic factor G and an environmental factor E. The Gs of the parents are linked to the Gs of the offspring by 1/2, reflecting the 50% of shared additive genetic variability of parents and offspring, which in this case is confounded by shared environment.

The first additional aspect of note is the arrows connecting the Ps at the top of the figure. These represent phenotypic assortative mating between fathers and mothers and, as can be seen, these arrows allow for greater similarity of the genetic variability transmitted by both parents to the offspring. For instance, mother’s transmission of G_{Mx} to G_{Ox} is augmented by an additional path from father’s G_{Fx} through the assortative mating path to G_{Mx} . This must be accounted for in estimating the heritability h^2 .

The other aspect of note is the r_G arrows connecting the G_x s and G_y s. These represent the *genetic correlations* discussed above in terms of linkage and pleiotropy. As can be seen in [Figure 1](#), these genetic correlations are shared genetic effects, and they may be indicative of functional genetic relationships. For example, a significant genetic correlation between performance on tests of verbal ability and performance on tests of spatial ability would indicate some common physiological/genetic process for these abilities.

Several important caveats should be reiterated. As was the case for population genetics, heritabilities reflect the relative contribution of genetic factors on the variability of a trait for just the particular sample of individuals studied and the particular environmental conditions in which they are living. Heritability estimates may not generalize to other populations, and they may greatly change if environmental conditions change. Similarly, high heritabilities do not preclude a trait from being influenced by the environment. Another caveat refers back to the idea that high heritability is dependent on high phenotypic variability, but high phenotypic variability is associated with traits that have not been highly selected for, that is, are not important for biological fitness, unless there is a balanced polymorphism.

Molecular Genetics

The DNA molecules in every living cell consist of two strands of phosphate and deoxyribose sugar groups held at a fixed distance from each other by pairs of nitrogenous compounds called bases. Each of the four bases is attached to one strand

Figure 2 Path model of bivariate parent-offspring genetic transmission.

and can only pair with the corresponding base on the other strand in a particular combination: adenine with thymine and guanine with cytosine. The molecule itself is held together by its double helix structure, as discovered by Watson and Crick. When the molecule is 'unzipped,' each strand thus is a mirror-image of the other strand and can be used as a template for the construction of proteins and enzymes, when three-base ribonucleic acid (RNA) units carrying amino acids link up with the DNA strand in the order dictated by the exposed base pairs.

Through this transcription and replication mechanism, each cell programs the synthesis of the structures and chemicals needed to maintain itself, and the DNA in the cell's nucleus carries the program to create new cells. Also through this mechanism multicellular organisms transmit the program for the creation of new organisms. These strands of nuclear DNA are called chromosomes, and a gene is simply a segment (*locus*) of the chromosome that codes for some protein or enzyme. In sexually reproducing organisms, the 'blueprint' for the organism resides in one or more pairs of chromosomes (26 pairs in humans), and each parent transmits one half of each pair of chromosomes in the sex cells to the offspring. This is the biochemical basis for Mendel's hypothetical genes and alleles.

Autosomal genes are those that are on the 'normal' chromosomes not involved in determining gender. When the gene (allele) from one parent pairs up with the gene from the other parent at a locus, one gene may biochemically 'turn off' the transcription mechanism of the other gene. This is what Mendel observed as dominance.

Chromosomes that determine gender are often different from the other chromosomes in that both members of the pair may not be equivalent in size and, hence, amount of genetic material. In humans, females carry one pair of so-called X-chromosomes, while males carry an X-chromosome paired up with a much smaller Y-chromosome, which carries almost no genetic information other than to turn on the process for altering the developmental course of the embryo to become a male. Traits coded for by genes on the X-chromosome in males (which is transmitted by the mother) will thus be expressed, including traits on recessive genes that might otherwise have been inactivated by a dominant gene on the other X-chromosome that females receive from the father. The results of so-called X-linkage are seen, for example, in the higher incidence in males of the relatively common form of congenital mental retardation called the fragile-X syndrome, where a

piece of the X-chromosome is 'loose' or broken off and the genes on that piece are disrupted.

One theme that emerges from an understanding of the mechanisms of genetic transmission is the Darwinian idea of the importance of maintaining variability in a species. Sexual reproduction itself, although costly to the organism in terms of energy use, lost opportunities for food gathering, and vulnerability to predation, is clearly meant to create new genetic combinations in the offspring by combining genes from both parents. The process of splitting the chromosome pairs for the sex cells also involves recombination of genetic material, as the members of the pair cross over each other and exchange genes. Mutations that spontaneously occur as a result of DNA replication errors or environmental insults can alter the transmitted genes.

Another theme that emerged early on from molecular genetics was that some human behaviors, particularly mental retardation, were clearly the result of simple genetic mechanisms. Errors in chromosomal replication and division at times result in missing or duplicated chromosomes in the sex cells transmitted to the offspring. The offspring then end up with a missing member or piece of a member of a chromosome pair or with an extra chromosome (*trisomy*). These chromosomal defects are usually fatal for the fetus, when they occur on the larger chromosomes, and usually result in some degree of mental retardation, when they occur on the smaller chromosomes of a viable offspring. Besides the fragile-X syndrome noted above, another common form of mental retardation is Down's syndrome, which is a product of a trisomy on chromosome 21.

Another good example of a simple genetic mechanism responsible for mental retardation is phenylketonuria, which is caused by a recessive autosomal gene that fails to code for the synthesis of an active enzyme responsible for the breakdown of the amino acid phenylalanine. The build-up of phenylalanine in the infant depresses the transport of amino acids to the brain and hinders normal nervous system development. The pleiotropic effects of this genetic defect include hyperactivity, irritability, and moderate to severe mental retardation. This syndrome is also interesting in demonstrating that genetically determined traits can be modified by the environment. Infants who are detected early with the double recessive genotype can be put on a low phenylalanine diet, and this diet has been shown to be effective in virtually eliminating the deleterious effects of the gene.

A technique called linkage analysis is used to confirm the relationship of the transmission of genes or genetic markers with the transmission of specific traits in families. This involves identifying several large family pedigrees (two or more generations, with large numbers of siblings in each generation) or large numbers of sibling pairs with a high incidence of the trait of interest (e.g., some form of mental retardation). Each individual in a pedigree is assessed for the occurrence or absence of the trait, and the pattern of transmission of the trait through the pedigree can be tested against the pattern expected by different kinds of Mendelian single-gene transmission modes, for example, autosomal dominant, X-linked recessive, etc. In addition, each individual is also tested for the co-occurrence of some other trait (a genetic marker), for example, a blood group type, known to be controlled by a single gene at an

approximate locus on a particular chromosome. If the trait of interest consistently co-occurs with the linkage marker, that is, there is a genetic correlation, then the traits are not independently assorting and must be close to each other on the same now-identified chromosome. The deviation from expected Mendelian ratios for independent assortment, indicative of linkage, is expressed as a so-called LOD (logarithmic odds) score.

Linkage analysis is a special case of an *association study*, where the aim is to correlate markers of DNA variation (particularly allelic variation) with phenotypic variation across individuals. The simplest association study design is a two-group comparison (*case control*) of individuals differing in some phenotype of interest. While this design is most advantageous in terms of ease of recruiting subjects and consequent generalizability, its internal validity is compromised by numerous factors, including the problem of population stratification, where DNA differences between groups may result from irrelevant DNA differences in different genetic lineages within the groups. *Sibling pair* designs that compare siblings who are similar versus different in the phenotype of interest eliminate the problem of population stratification but cannot delineate the mode of genetic transmission. Family data, such as parents + child trios, are a special case of an association study, which allows combining linkage and allelic association information. The *full pedigree* design described above is the most sensitive for finding genetic associations, but recruiting such pedigrees is difficult, which often limits generalizability.

Today markers of DNA differences typically involve *microsatellite markers*, involving many alleles, or more commonly *single nucleotide polymorphisms (SNPs)* based on a nucleotide base difference across individuals on a short strand of DNA. SNPs are detected through *microarrays* of DNA probes that fluoresce when they find their match (*hybridize*) in a sample of DNA (typically amplified through a replication process called *polymerase chain reaction*). With the mapping of the entire human genome in 2001 and the concomitant and subsequent developments in biochemical and computing technologies for high-throughput genotyping, research is moving away from *candidate gene* studies that look at a few promising genes to *genome-wide association* studies that use tens of thousands of SNPs to detect associations across all the known genes.

By now, however, molecular genetic studies have confirmed that for nearly all behavioral traits of interest, whether for normal behavioral variation or psychopathology, multiple genes are associated with their etiology. Furthermore, the Human Genome Project determined that, instead of the 100 000–140 000 genes formerly thought to be in the human genome, there are only 25 000 genes, and research has shown that the same genes are often involved in diverse phenotypes, for example, in schizophrenia and bipolar disorder. These findings have emphasized the importance of searching for *quantitative trait loci (QTLs)*, small genetic effects for polygenically determined, continuously distributed phenotypes, but to be able to detect such small effects requires massive sample sizes. Genetic effects must clearly be looked at from a developmental perspective that not only considers what genes are involved, but also when they are turned on and off in development, how they interact with other genes, and how they interact with environmental factors over the lifespan of the individual.

Behavioral Genetics and Psychology

After a contentious start, behavioral genetics has become an accepted part of mainstream psychology. By now significant heritability has been well-established for most stable individual differences in behavioral domains of interest to psychologists, and association studies are rapidly linking these phenotypes to particular genes. However, the early hope of finding simple genetic mechanisms for these behaviors, mechanisms which could be easily targeted for physiological interventions to eliminate psychopathology or enhance normal behavioral attainments, was clearly overly optimistic. Perhaps this should not have been surprising, given the iterative, dynamic, and systemic nature of Darwinian evolution. Ironically, behavioral genetics has confirmed the importance of

the environment as a determinant of behavior, but has led to a more nuanced understanding of how that environment works in conjunction with the genes and physiology of the individual.

Glossary

Behavioral intervention Theory-based strategies and activities aimed at promoting healthy behaviors.

Behavioral medicine An interdisciplinary field concerned with the development and integration of behavioral and biomedical science, knowledge and techniques relevant to health and illness, and application of this knowledge, and techniques relevant to prevention, diagnosis, treatment, and rehabilitation.

Ecological models Models proposing that behaviors are influenced by the interactions between multiple levels of the social environment: intrapersonal, sociocultural, policy, and physical environmental factors.

Health behavior Psychological processes, such as values, perceptions, beliefs, personality traits, and mood, as well as overt behavioral patterns, actions, and habits that relate to health.

Health promotion Any planned combination of educational, political, environmental, regulatory, or organizational mechanisms that support actions and conditions of living conducive to individuals, group, or communities.

Health psychology The study of psychological processes related to health and health care.

Primary prevention Efforts to forestall the onset of illness or injury during the prepathogenesis period.

Psychoneuroimmunology The study of interactions among the behavioral, neural, endocrine, and immune systems on maintenance of healthy functioning, and development and progression of illness.

Secondary prevention Efforts that occur after individuals are experiencing symptoms or who have been diagnosed with a disease.

Tertiary prevention Efforts aimed at individuals who are already severely affected by a disease (e.g., impairment or disability).

Introduction

Much progress was made in the twentieth century to improve health and prolong life. At the turn of the century, the leading causes of death were mostly communicable in nature, however, advances in science produced improvements in sanitation and hygiene, medication therapies, and vaccines to control – and in some cases eradicate – infectious diseases. As a result, in many industrialized and some developing nations there has been a shift in disease patterns. Currently cardiovascular diseases, which have complex etiologies and are associated with numerous lifestyle behaviors, are the leading cause of death worldwide. Modifiable behaviors such as exposure to tobacco products, consumption of high-fat diets, and physical inactivity are responsible for approximately one-third of all deaths within the United States.

Understanding how lifestyle behaviors work in concert with genetic, biological, and psychosocial factors to protect against or exacerbate disease requires a multifaceted approach. Behavioral medicine is an interdisciplinary field that studies the interplay among psychosocial, biological, and behavioral pathways on the natural progression of disease. Perhaps what sets behavioral medicine apart from other related fields is that in addition to studying the mechanisms of disease, it focuses on transferring this knowledge to behavioral interventions that can be delivered in medical and community settings. Behavioral medicine brings together theoretical knowledge and methodological innovations from the social sciences (psychology, sociology, anthropology, epidemiology, and health promotion) as well as the biomedical sciences (psychiatry, physiology, endocrinology, immunology, pharmacology, nutrition, biology, and chemistry). Moreover, the field of behavioral

medicine unites academic researchers as well as health professionals, such as physicians, nurses, dentists, and health educators.

Brief Historical Context

The concept of behavioral medicine predates the formal discipline of psychology, and can be traced to Hippocrates. Its evolution is a result of innovations in related disciplines, such as medicine, psychology, psychiatry, and psychosomatic medicine. There were several landmark events that helped shape the field as we know it today. A few of these are mentioned herein. In 1800s, Wilhelm Wundt, the founder of experimental psychology, and Emil Kraepelin began to integrate psychology within a medical setting. By 1869, all symptoms that were derived from the mind were classified as psychogenetic; thus, there was a formal delineation between symptoms of physical origin versus those of psychological origin. Claude Bernard introduced the concept of *homeostasis*, which refers to the body's ability to self-regulate its internal milieu in order to maintain healthy functioning. Bernard's work focused on the role of the nervous system in maintaining homeostasis. Building on Bernard's research, in 1932 Walter Cannon produced a detailed account of the relationship between the body's reactivity to stress and negative emotions, such as anger and fear. He later coined the term *fight or flight* response to describe the body's physiological reactions when confronted with stressful stimuli. Based on this seminal work, Hans Selye and Harold Wolf in the 1950s would go on to study the physiological responses to prolonged stress, and find that chronic stress weakened the body, making it vulnerable

to infection. This work would not only contribute to the field of behavioral medicine, but also to other related fields such as biopsychology and psychoneuroimmunology (PNI).

By the 1930s, the field of psychiatry had emerged as an important medical specialty. In 1936, the Menningers, a well-known family of psychiatrists, noted that aggressive men were more prone to cardiovascular conditions. Physicians interested in mind–body interactions were compelled by the psychoanalytical approaches of Sigmund Freud. There was an interest in understanding how conscious and unconscious emotional states contributed to the development of pathologies. The assumption was that if the psychological conflict could be resolved then its associated physiological manifestations would also diminish, and eventually disappear. In 1938, the psychiatrist Helen Flanders Dunbar was appointed as the first editor of a new journal – *Psychosomatic Medicine* – which later became the official publication of the American Psychosomatic Society, founded in 1942. Dunbar and her contemporaries contributed valuable knowledge about the interplay between external stress, psychological conflict, and organic disease; however, the field of psychosomatic medicine was initially criticized for its lack of scientific rigor and failure to provide efficacious treatments. As a result, psychosomatic medicine began to adopt more rigorous research methods, and integrated the sociobehavioral and biological sciences. Behavioral medicine was developed, in part, as a response to the initial shortcomings and narrower focus of psychosomatic medicine.

Prior to the 1970s, the reigning paradigm on disease and health was focused on biological explanations; however, increasing awareness about lifestyle behaviors and environmental factors ushered in a new paradigm on health and disease. George Engel called for a medical model that accounted for the interactive process between biological, psychological, and social factors on health and disease progression. Engel asserted that in situations of loss the ‘giving up’ response may precede the development of illness among individuals who already had a genetic predisposition for a given illness. This new model was referred to as biopsychology, an integrative approach that demonstrated the interdependence between contextual factors, coping, and biological pathways. Concurrently, Skinnerian psychology fell out of favor, and Albert Bandura’s social learning theory gained popularity. Social learning theory and other cognitive behavioral models that followed focused on the role of individual choice, and how these choices were influenced by perceptions, emotions, and social norms. Thus, the changing paradigm highlighted the role of personal responsibility, cognitions, behavior, and the social environment in which the behavior took place.

The Emergence of Behavioral Medicine

While there is no one event that marked the creation of behavioral medicine, the 1970s gave way to a culmination of events that defined and formalized the field. In 1974, Canada produced a national report on the role of lifestyle behaviors, and environmental influences on health. In the same year, the United States passed the Health Information and Health Promotion Act, which created what is now known as Office of Disease Prevention and Health Promotion. In 1979, the United States produced the first Healthy People

report, which was a summation of the literature to-date on the relationship between personal behavior and health status. Healthy People gave policymakers and the general public a user friendly guide to lifestyle behaviors that may reduce disease risk. It was also in the late 1970s that the US government recognized the field of behavioral medicine and initiated mechanisms for the funding of behavioral medical research. In 1979, the National Institutes for Health (NIH) established a study section on behavioral medicine, and soon after other government agencies followed suit. In 1984, the Centers for Disease Control and Prevention (CDC) established the Behavioral Risk Factor Surveillance System (BRFSS), which is a state-based telephone survey that collects information on health risk behaviors, preventive health practices, and health care access primarily related to chronic disease and injury. At first only 15 states administered the BRFSS, but by 1994 the system was nationwide. In 1995, the NIH established the Office of Behavioral and Social Sciences Research (OBSSR) in recognition of the dynamic relationship between behavior and social factors on morbidity and mortality. The purpose of OBSSR is to stimulate behavioral and social sciences research throughout NIH and to integrate these areas of research into other NIH centers.

Formalization of the Field

Behavioral medicine was formally recognized as a new field in 1977 at the Yale Conference for Behavioral Medicine. In 1978, the United States National Academy of Science’s Institute for Medicine developed the definition that remains today, which centers on the integration of behavioral and biomedical sciences, and application of this knowledge to prevent, diagnosis, and treat illness. In 1979, Ovide Pomerleau and Paul Brady established one of the earliest behavioral medicine research centers at the University of Pittsburgh, and in the same year they established the *Society of Behavioral Medicine* (SBM). At first the society’s main emphasis was on medication habits associated with stress, obesity, and smoking; however, they received criticism for this narrow focus and widened their focus to include a larger breadth of health problems. Today SBM entertains a wide range of topics, including: adolescent health, aging, anxiety, cardiovascular disease, chronic pain, depression, diabetes, eating disorders, environmental health, headaches, HIV/AIDS, insomnia, minority health, quality of life, sexually transmitted diseases, social support, and substance abuse. The SBM sponsors an annual meeting to bring together researchers and clinical practitioners. The society’s official journal is the *Annals of Behavioral Medicine*, which publishes original empirical articles – including reports of randomized controlled trials, observational studies, or other basic and clinical investigations – and integrative reviews of the evidence for the application of behavioral interventions in health care. Since the establishment of SBM, an international federation of over 20 behavioral medicine societies across the globe formed the *International Society Behavioral Medicine* (ISBM). The first ISBM meeting was held in Sweden in 1990, and the first issue of their journal *International Journal of Behavioral Medicine* was published in 1994. The goals of ISBM are to stimulate research and practice as well as disseminate behavioral medicine research via the society’s journal, and international teaching seminars.

Understanding Interactive Pathways of Disease

During the latter half of the twentieth century, many lifestyle behaviors and psychosocial variables were found to be associated with the development and progression of chronic diseases. This stimulated further scientific investigation into the mechanisms or pathways of disease. Without understanding the underlying catalysts of disease it is difficult, if not impossible, to prevent, diagnose, and treat the condition. There are many pathways of disease; herein we note some of the most widely researched behavioral, psychosocial, and biological mechanisms associated with chronic disease, as well as highlight current and future research directions.

Behavioral Pathways

As disease patterns have shifted, so has the emphasis on understanding the influence of lifestyle and behaviors on health outcomes. Currently, tobacco, high-fat diets, and physical inactivity are the leading actual causes of death in the United States. Actual causes of death are defined as lifestyle and behavioral factors that contribute to mortality. While it will not be discussed in detail here, it is fair to note that lifestyle behaviors also interact with each other, which in turn can have additive or multipliable effects on risk of disease development or exacerbate already existing conditions. That is to say that many times risky behaviors cluster together, and their compounded effects can diminish health and well-being.

Tobacco exposure

The World Health Organization (WHO) reports that it is the second leading cause of death worldwide. Exposure to tobacco products is associated with the development of cardiovascular disease, cancers of the mouth, lung, and esophagus, as well as respiratory conditions including emphysema, bronchitis, and chronic obstructive lung disease. In 2006, the US Surgeon General reported that there is no risk-free level of tobacco exposure. While the effects of first- and second-hand smoke have been well documented and are associated with multiple negative health outcomes, there is a growing body of literature that suggests that third-hand smoke may also be of concern. Third-hand smoke is currently defined as residual tobacco smoke contamination that remains after the cigarette has been extinguished.

The WHO reports that while global tobacco consumption is leveling off and even decreasing in some countries; more people are smoking, and smokers are consuming more cigarettes. It is projected that by the year 2030 industrialized nations will have approximately 3 million smoking related deaths, and it is projected that developing nations will have approximately 7 million deaths. The WHO estimates that smoking prevalence will continue to increase as a function of population growth; however, while prevalence rates may go down, the actual number of smokers worldwide may increase.

Physical inactivity and diet

There has been a dramatic increase in prevalence rates of obesity and type 2 diabetes mellitus. In the United States in particular, many researchers claim that obesity has reached epidemic proportions. This is disconcerting because obesity

and diabetes are major risk factors for many chronic conditions, including cardiovascular diseases. Concurrent with the increase in obesity, there has been a rise in the prevalence of type 2 diabetes mellitus. Unlike type 1 diabetes mellitus, which is an autoimmune disease that develops in childhood, type 2 diabetes often develops in adulthood as a result of obesity and poor lifestyle behaviors. Type 2 diabetes usually begins as an insulin resistance disorder in which the cells do not use insulin properly, and the pancreas gradually loses its ability to produce insulin. If not treated, patients can suffer innumerable adverse consequences, including impaired circulation to the lower limbs (which may result in chronic unhealing wounds and/or amputation), glaucoma, and cardiovascular diseases.

Obesity and diabetes are associated with poor diet and physical inactivity. The WHO estimates that physical inactivity causes 2 million deaths per year. With regard to diet, there has been a push to increase fruit and vegetable consumption, however, many individuals partake in high-fat diets, and this coupled with physical inactivity contributes to the rising rates of obesity.

Psychosocial Pathways

Psychosocial factors have been associated with lifestyle behaviors as well as biological outcomes. In particular, the field of health psychology, which is encompassed within the field of behavioral medicine, has made significant contributions to understanding the role of core psychological processes on health, including social support, stress and coping, personality disorders, and adaption to chronic illness. The field of Health Psychology seeks to advance contributions of psychology to the understanding of health and illness and encourages the integration of biomedical information with current psychological knowledge. Psychosocial factors can be grouped into three categories: intrapersonal, interpersonal, and societal. The constructs within these groupings are interrelated and interdependent in ways that may affect health outcomes. While many psychosocial factors have been studied, we will only attend to the most widely studied constructs related to health and disease processes in this article.

Intrapersonal factors

Intrapersonal characteristics refer to self-attributes, and these can include personality traits and mood disorders. The construct of self-esteem has been related to many health-protective behaviors and favorable clinical outcomes. It refers to evaluations of self-worth and the extent to which people value or approve of themselves. Self-efficacy, a personal belief in one's ability to perform a behavior or set of behaviors in a way that will produce a desired outcome, has also been related to increased frequency of health-protective behaviors. For example, one's ability to use condoms correctly has been associated with increased intentions to use condoms as well as frequency of use. Personal control can be defined as personal expectancies related to the extent to which individuals believe an outcome is within their control. Personal control has also been associated with increased conduct of health-protective behaviors, including weight loss and exercise. However, while theoretically higher levels of self-esteem and personal control are generally considered to be favorable, the literature presents

inconclusive results, that is, these constructs are not always associated with health, and in some cases they have been associated with negative health outcomes.

Negative emotions have been widely associated with health-damaging behaviors and poor clinical outcomes. Depression is a mental disorder that presents with low mood, loss of interest or pleasure, feelings of guilt or low self-worth, disturbed sleep or appetite, low energy, and/or poor concentration. The WHO reports that depression is the leading cause of disability worldwide and that its prevalence is quickly rising. In particular, depression is comorbidity for many chronic diseases. Some researchers argue that the prevalence of comorbid depression is a result of limitations on physical and, many times, cognitive functioning associated with living with a chronic disease. However, there is a body of evidence to suggest that depression shares many biological pathways with chronic diseases such as heart failure and other cardiovascular conditions. Thus, in some cases comorbid depression is not merely an emotional reaction to the challenges of living with a chronic disease, but also the result of biological mechanism that explains mood change. Increased depression symptomatology has been associated with increased risk of smoking, physical inactivity, and nonadherence to medication as prescribed by a physician.

Hostility has also been associated with negative health outcomes. Hostility is composed of cognitive, affective, and behavioral components: (1) cognitive aspects include negative beliefs about and attitudes toward others; (2) affective components include the frequency, and intensity of unpleasant emotions ranging from irritation to rage; and (3) behavioral aspects of hostility include actions or intentions to either verbally or physically harm others. Cognitive aspects of hostility have been associated with coronary heart disease, and affective aspects associated with hypertension. Hostility is also associated with a variety of health behaviors, including smoking, alcohol consumption, and obesity.

Interpersonal factors

Interpersonal factors refer to the influence of social interactions on health and well-being. This can include formal and informal exchanges with family members, friends, neighbors, and coworkers. Perceived social support has been widely discussed in behavioral medicine literature. Social support refers to the social resources that individuals perceive are available to them. They are usually classified into one of three main categories: emotional, instrumental, and informational support. Emotional support refers to the availability of one or more persons who can listen sympathetically, as well as provide signs of caring and acceptance. Theoretically this type of support should enhance self-worth, reduce negative affect, and motivate coping behaviors. Instrumental support refers to tangible aid and practical help, such as help with childcare and provisions of transportation or money. Theoretically, this type of support should help individuals solve practical problems, which allows for increased rest and relaxation and a reduction of psychological stress. Finally, informational support refers to receiving information about resources. An example of this type of support might be helping a friend develop an effective course of action to resolve a problem or suggesting a resource (shelter, counselor, community organization, etc.). In general,

social support is thought to have positive effects on health because it 'buffers' stress. Thus, those who report higher levels of social support hypothetically should have better health outcomes. Studies indicate that higher levels of social support, particularly emotional support, is widely associated with psychological well-being, including lower levels of depression. Higher levels of social support have also been linked to lower physiological (e.g., blood pressure and/or heart rate) responses to stress.

Social conflict is another interpersonal dimension that may affect health; however, it has received much less attention than social support. Social conflict refers to negative social interactions that may occur within social relationships including arguments, criticism, and unwanted demands. Social conflict has been related to elevated cardiovascular and neuroendocrine biomarkers.

Societal factors

Societal factors refer to education, income, occupation, race, and ethnicity as well as neighborhood and community context. In the 1980s, there was a growing consciousness that lifestyle factors and disease were unevenly distributed across the US population. Moreover, some populations were experiencing greater prevalence and incidence, as well as morbidity and mortality associated with particular diseases. Many epidemiological studies, such as the Whitehall Study conducted by Michael Marmot, have demonstrated that lower socioeconomic status (SES) or position is associated with higher prevalence of health-damaging behaviors, and poorer health outcomes. Traditionally, SES has been defined by education, income, and occupation. These variables have been assessed individually, and have also been combined to form composite scores. While the pathways between SES and health are complex, and still not well-defined, increased funding opportunities and the subsequent research in this area have provided some important findings. Lower SES has been associated with higher smoking prevalence, lower consumption of fiber and fresh fruits, physical inactivity, and heavy drinking. Moreover, those living in lower SES environments may experience more chronic stress associated with financial strain, crowding, noise exposure, and unsafe neighborhoods. There are vast differences in health and quality of life across different racial and ethnic groups. In particular, there is a growing body of research showing that minority populations have less access to quality healthcare, and many groups have a higher prevalence of risk behaviors associated with chronic disease. Within the United States, there has been an interest in chronic psychological stress associated with the perception of being treated unfairly based on race or ethnicity. This construct has been linked to hypertension, self-reported poor health, breast cancer, and mood disorders, as well as obesity, smoking, infrequent condom use, and substance use. Prolonged exposure to discrimination may prepare the body to be more physically reactive to stressful situations. Increased reactivity and engagement in unhealthy behaviors may moderate the relationship between perceived discrimination and health. With regard to environmental factors geomapping software, and census data have helped researchers to look more closely at neighborhood and community characteristics, including the availability of fruit and vegetables and the number of fast food restaurants. The integration

of biodemography, a field concerned with the synergistic effects of demographic and biological determinants on disease and aging patterns, into behavioral medicine has helped to reveal how environmental context interplays with behaviors, psychological, and biological factors.

Health throughout the life course

In order to better understand these factors, many researchers have adopted a lifespan approach. From this perspective, health is viewed as a product of risk behaviors, protective factors, and environmental agents that are encountered throughout the lifespan. The lifespan approach provides a framework for interpreting how experiences during early years of life can later affect health and functioning in adulthood. Moreover, this approach allows for us to calculate cumulative, additive, and even multiplicative impacts of risk behaviors and protective factors on health outcomes. Improvements in longitudinal study design and statistical methodologies have allowed behavioral medicine research to study multiple risk and protective factors on the natural progression of disease over time.

Biological Pathways

An important aspect of behavioral medicine is that it links behavioral and psychosocial factors to physiological activity and biological outcomes. Since its inception, the field of behavioral medicine has been keenly interested in the sympathetic nervous system (SNS). This is because the SNS has far ranging relevance to almost all areas of health, including acute and chronic stress, mood, psychiatric disorders, neuroimmune regulation, cancer, and cardiovascular diseases. However, further examination of mind-body interactions indicates that there are many reciprocal relationships among the central nervous system, the autonomic and neuroendocrine system, and the immune system that affect health.

Psychoneuroimmunology

The field of PNI provides an integrative framework to study complex interactions amongst neural, endocrine, and immune systems, as well as behavioral and psychosocial factors on maintenance of healthy functioning, and development and progression of illness. PNI has helped advance behavioral medicine investigation of the pathophysiology of many chronic diseases, especially cardiovascular disorders. The PsychoNeuro-Immunology Research Society is an international organization that supports all aspects of PNI research. Its international journal, *Brain, Behavior, and Immunity*, was founded in 1987 and publishes peer-reviewed basic, experimental, and clinical studies dealing with behavioral, neural, endocrine, and immune system interactions in humans and animals.

The three main biological systems examined in PNI include: (1) the central nervous system, which recognizes and records experiences; (2) the autonomic and neuroendocrine systems, which govern bodily functions; and (3) the immune system, which organizes responses to infections and eliminates tumor cells. Normal functioning of the multiple interconnected regulatory pathways across these systems is necessary to maintain health; when pathways are compromised through loss of regulation, disease can ensue. While each of these systems has been studied separately, the innovation of PNI is that it aims to

understand how these systems work together in concert. It is important to recognize that although the function of a single hormone, cytokine, or neurotransmitter can be studied in isolation, when taken out of the context of the broader physiological milieu, the ability to fully understand its role is severely limited.

PNI and behavioral medicine: acute stress and vaccination response

Behavioral medicine researchers often use findings from the field of PNI to inform intervention design. One way that PNI research has been applied to behavioral medicine is through research on acute stress and vaccination response. We focus here on some of the acute stress and vaccination response findings because it is one of the most clinically relevant and promising applications of PNI that has been applied to behavioral medicine. Understanding SNS and endocrine effects on immune functioning has been of considerable interest. Some researchers have found that the acute stress response enhances subsequent immune responses if the stress is experienced shortly before the immune system is presented with certain types of challenges. From an evolutionary perspective, it would enhance survival, and subsequently fitness of the species to have robust immune responses during times of stress, considering that stress can also suppress immune functioning, which in turn makes the body more vulnerable to illness. Researchers tested this hypothesis in rodent models, and found that rats that were exposed to an acute stressor in close temporal proximity to receiving a vaccination had higher levels of antibody response than rats that experienced chronic stressors or those who were not exposed to any kind of stressor. Additional research on acute stress and vaccination suggests that rodents with compromised immune systems experience higher levels of antibodies compared to healthy rats; findings recently replicated in humans. Studies in young healthy adults find that concentric cycling, acute psychological stress, and weight training exercise enhance responses to influenza and meningococcal vaccination. Studies also suggest that immunocompromised individuals have greater increases in levels of antibodies produced as compared to healthy adults; thus, those with impaired immune systems may experience greater benefits from being acutely stressed before receiving a vaccination. The exact mechanism of the relationship between acute stress and the vaccination-induced immune response is still under investigation. However, it is believed that stress-induced redistribution of certain subclasses of lymphocytes is responsible for the enhanced antibody response.

Behavioral Interventions

By understanding the mechanisms of disease, scientists are better able to intervene in causal pathways to prevent or slow disease progression. Empirical evidence gained from studying interactions between behavioral, psychosocial, and biological factors has helped to shape and develop prevention and treatment efforts. Traditionally, behavioral medicine focused on biofeedback models for pain disorders, mood disorders, etc. Biofeedback is a modality of treatment that monitors physiological characteristics, and relays this information back to the patient in real time. Patients learn to control and modify

the physiological responses being measured. A current example of biofeedback is a pedometer. A pedometer indicates the number of steps taken, and patients can monitor and use this information to increase their physical activity. In particular, the field of health promotion, which is encompassed within behavioral medicine, has pioneered the design, operationalization, and integration of many behavioral interventions into medical and community settings. A behavioral intervention usually refers to one or a series of activities that focus on reducing risk behaviors (e.g., smoking), and increasing and strengthening protective factors (e.g., spending time with non-smokers). The time points at which these activities occur are based upon the knowledge of disease etiology as well as the theories of behavior change. In essence, behavioral interventions are concerned with achieving behavioral changes that maximize health and improve quality of life. Behavioral interventions have been classified using two distinct approaches. The first approach classifies interventions based on the point at which they occur along the health continuum: prepathogenesis, early stages of pathogenesis, or severe pathogenesis. The second classifies interventions based on the level of the social ecology that they target: interpersonal, community, organizational, or societal.

Primary, Secondary, and Tertiary Prevention Efforts

This intervention approach conceptualizes the progression of disease on a continuum where at one end is good health and other is death. Interventions can be conducted at any point along this continuum. Primary prevention refers to interventions that forestall the onset of illness or injury during the prepathogenesis period. These interventions are focused on reducing risk behaviors among individuals who do not have the specified disease or disorder. For example, primary prevention efforts include interventions to promote safe and frequent condom use among HIV-negative individuals. Secondary prevention refers to efforts that occur after the individual has been diagnosed with a condition. In this case, secondary prevention might include efforts to promote condom use among partners who are both HIV positive, but have different strains of the virus. Condom use would then reduce the chances of coinfection by another strain of HIV. Tertiary prevention efforts are aimed at individuals who are already severely affected by a disease (e.g., impairment or disability). In the case of HIV, tertiary prevention efforts target people with progressive AIDS or HIV infection, and caretakers and health care professionals involved with the ill person. These efforts are concerned with preventing as many of the disabling aspects of AIDS as possible.

Levels of Intervention

Historically, behavioral interventions have been designed based on individual-level theories, with little regard for the influence of contextual factors on behavior change. As our understanding of pathways of health and illness has evolved, it has become evident that individual behaviors cannot be treated without considering the context in which they occur. Thus, there has been a movement to integrate individual-level

theories into the larger social ecology. It is important to note that there are over 65 theories of behavior change (which will not be discussed here); however, we reference ecological models because behavioral interventions are often classified according to the particular stratum of the social ecology that they target.

Levels of intervention can be defined as individual, community, organizational, and societal. However, some sources further divide these levels into sublevels. The societal level is the broadest, and it usually refers to nation-wide prevention efforts. For example, the United States has produced several social media campaigns to increase awareness and change social norms about many behaviors, including smoking and seatbelt use. Intervention strategies included billboards, television advertisements, as well as policies that increase taxes on tobacco products and financial penalties for not wearing a seat belt. Interventions conducted at a societal level often have simple messages that are relevant to the majority of the target audience. Behavioral interventions conducted at the organizational and community levels are targeted at a specific subset of the population who hold membership to a particular organization or community. These interventions might target members of schools, neighborhoods, or even a particular racial or ethnic group. With regard to the latter, within the past three decades there have been increased efforts to reduce health disparities. One way that public health and behavioral medicine has responded has been to create and deliver culturally relevant behavioral interventions targeted toward members of a specific racial and ethnic community. Finally, interventions focused on the individual are characterized by high levels of interpersonal interactions between the targets of the interventions and the health providers. Psychotherapy or HIV case management programs are examples of individual-level interventions.

Challenges in Behavioral Medicine

In spite of great developments, the field of behavioral medicine has also encountered challenges. Behavior change can be slow and difficult to sustain. Many times individual-level interventions are not successful because there are social or environmental influences that impede the adoption of new behaviors. For example, there are inconsistent research findings on the effects of psychological therapies (e.g., cognitive behavioral therapy, mediation and relaxation therapies) to modify immune pathways and disease outcomes. The WHO and leading national health authorities estimate that the prevalence of depression is rapidly increasing worldwide. Depression has also been strongly associated with many chronic diseases. While there are several behavioral therapies to reduce depressive symptoms, the prevalence continues to rise. Newer theoretical models of behavioral medicine are guided by socioecological frameworks, which intervene at multiple levels of the patient's social ecology (e.g., intrapersonal, interpersonal, community, national laws). For example, environmental interventions such as increased parks, sidewalks, and bike lanes are promising, and have been associated with increased physical activity and reductions in weight.

Innovations in Behavioral Medicine

Evidence-Based Practice

Within the past decade there has been a movement to integrate individual care with the best available practices, which are determined by a systematic review of the literature. Historically, it has been challenging to compare across behavioral interventions due to differences in measurement, sampling, and theoretical fidelity. Thus, an evidence-based approach calls for standardized study methods and evaluation in order to compare findings across studies. Proponents of an evidence-based approach believe it helps clinicians and health practitioners maximize effective intervention strategies as well as reduce less effective strategies, and ultimately, improve clinical outcomes. Those against evidence-based approaches believe that researchers are uninformed and out of touch with the realities of clinical practice, and that stringent evaluation protocols adversely influence the ability of physicians to make unimpeded clinical decisions.

Nevertheless, the movement for evidence-based practices continues to grow. For example, the CDC developed a compendium of best-evidence HIV behavioral interventions. The CDC states that these interventions have been 'rigorously' evaluated and have shown significant effects in eliminating or reducing HIV risk behaviors. Some US government funding agencies and programs have started to only fund clinics and community organizations that implement interventions that have been evaluated and shown consistently, in literature, to reduce risk behaviors and increase positive health outcomes.

Measurement Technology

Behavioral medicine has always been interested in obtaining physiological and biochemical measurements. Such measurements typically include cardiovascular measures such as blood pressure, heart rate, stroke volume, and peripheral resistance, as well as biochemical measures of the autonomic nervous system, hormones, and immune system peptides that are found in blood and/or urine. More recently, the validated use of saliva for the assessment of certain neurohormones and inflammatory products has greatly expanded the ability of behavioral researchers to obtain biochemical measurements in field research. Ambulatory measures (e.g., 24 h ambulatory blood pressure monitoring and sleep actigraphy monitors) have enabled researchers to look outside their laboratories and monitor research participants for extended time periods in their home environments. Newer technological advances include the use of dried bloodspot (DBS) samples for the collection of biochemical markers. This latter relatively noninvasive methodology, which involves collecting drops of whole blood on filter paper (typically from a finger prick), supports the ability to assay a wide range of circulating biomarkers. This methodology is still being refined, and protocols and assays for many biomarkers are not as yet as reliable as what can be determined from larger blood volumes obtained from venipuncture.

Within behavioral interventions, there has been increased integration of objective measures in addition to traditional self-report instruments. For example, studies of children's

physical activity have collected self-report measures as well as research assistant's observed playground activity or counted number of toys that a child uses to be physically active (e.g., bike, trampoline, etc.). Moreover, there has been an increased use of accelerometers, a device that participants can wear that continuously records time and intensity of physical activity. With regard to delivery of behavioral interventions, there continues to be increased use of web-based interventions as well as text messaging. For example, some programs remind and encourage participants to be physically active or take their medication via text message. More recently researchers are working on behavioral interventions that promote physical activity using interactive video games, such as Nintendo's Wii.

Conclusions

As disease patterns have shifted, so has the emphasis on understanding the influence of lifestyle behaviors on health outcomes. Currently, cardiovascular conditions and cancers are the leading causes of death in many countries. Modifiable behaviors such as exposure to tobacco products, high-fat diets, and physical inactivity are responsible for high rates of morbidity and mortality associated with many chronic conditions. Chronic diseases have complex etiologies and are interdependent upon lifestyle behaviors. Understanding how these behaviors work in concert with biological and psychosocial factors to protect against, or exacerbate, disease requires a multifaceted approach. Behavioral medicine is an interdisciplinary field that studies the interplay among psychosocial, biological, and behavior pathways on the natural progression of disease. Perhaps what sets behavioral medicine apart from other related fields is that in addition to studying the mechanisms of disease, it focuses on transferring this knowledge to behavioral interventions that can be delivered in medical and community settings. Recent advancements in the field center on studying mechanisms of health disparities, developing behavioral interventions to address these gaps, refinement of measurement techniques, use of web-based and video games to deliver behavioral interventions as well as systematic and standardized evaluation to determine best practices. Overall, the field of behavioral medicine is concerned with advancements that promote improvements in clinical outcomes, and quality of life.

Glossary

Classical conditioning A phenomenon first studied by Pavlov in which a previously neutral stimulus is paired with a stimulus that elicits a reflexive response. Eventually the neutral stimulus will elicit the reflexive behavior.

Discriminative stimulus A stimulus that signals that a response will be followed by the presentation of a reinforcer.

Operant behavior Behavior that is maintained by its past consequences rather than elicited or evoked by a stimulus or antecedent condition.

Physical dependence The state in which a withdrawal symptom is observed upon the abrupt discontinuation of chronic drug administration.

Reinforcing stimulus A stimulus that increases the frequency of a response upon which its presentation is contingent.

Schedule of reinforcement This term describes the relationship between the delivery of a reinforcing stimulus and operant response or responses it follows. The most common ones are ratio schedules where the reinforcer is delivered when a number of responses have been emitted, and interval schedules where the reinforcer is delivered after a response on the basis of the passage of time.

Skinner box A chamber of a type invented by B. F. Skinner used to study operant behavior in laboratory animals. The chamber is isolated from external stimulation and contains devices activated by responses of the animal which permit delivery and recording of reinforcements.

Tolerance A lessening of the effect of a drug when the same dose is repeatedly administered, or conversely, the necessity of giving a higher dose with repeated administrations in order to achieve the same effect.

Behavioral pharmacology may be defined in one of two ways. The term was initially used by Peter Dews of Harvard Medical School to refer to the analysis of drug effects using operant analysis of behavior as developed by B. F. Skinner. More recently the term is being used in a broader sense to refer to the study of the effects of drugs on behavior using any of the experimental techniques of modern behaviorally oriented psychology. The key word here is 'behavior,' since this expansion in definition does not extend to include mentalistic concepts such as emotion, motivation, or cognition unless they are defined in terms of observable behavior. Before Dews suggested the term 'behavioral pharmacology' in the 1950s, research in this area was commonly referred to as 'psychopharmacology' – a combination of the fields of psychology and pharmacology. 'Psychopharmacology' is still used, but is generally taken to include research involving any aspect of psychology, including the mentalistic, and is used particularly to refer to the study of drugs in the treatment of mental illness or psychological disorders.

It is important to note that there may be several aims of research in behavioral pharmacology. As Travis Thompson and Charles Schuster, the authors of the first text in the field, put it, 'The behavioral pharmacologist is not only interested in observing behavioral changes produced by drugs, but analyzing the mechanisms of the drug's effect.' In addition, Peter Dews has pointed out that not only are behavioral techniques useful in helping analyze the behavioral mechanisms through which drugs alter behavior, but just as often, drugs may be used as tools to help untangle complex problems in the analysis of behavior.

History of Behavioral Pharmacology

Humans have always been curious about substances that alter the mind. Alcohol, cannabis, and opium have been used for

millennia. Aristotle commented on the effects of alcohol, and the analgesic effects of opium were noted by the very earliest Greek and Egyptian physicians. Up until the beginning of the twentieth century, however, investigations of these substances involved only verbal descriptions of the effects of the drug on the subjective experience, more often with literary rather than scientific intent. Such descriptions as DeQuincey's *Confessions of an English Opium Eater* and Gautier's *La Club des Hachichins* were fascinating descriptions of the drug experience, but were of limited value to science.

Systematic studies of the effects of these substances had to await two developments. First, there was the development of modern chemical techniques in the nineteenth century that permitted the isolation of drugs from natural substances, and the synthesis of substances that do not occur naturally.

The second important development was a precise, systematic and replicable means of describing, recording, and analyzing behavior. Three such systems were developed. In Russia, the Nobel Prize-winning physiologist Ivan P. Pavlov discovered and did extensive research on the conditioning of reflexes, what we now call *respondent behavior*. The conditioning of respondent behaviors is often referred to as *classical conditioning*. In his laboratory in St. Petersburg, caffeine and other drugs were administered to dogs and their effects on acquisition and extinction of conditioned reflexes were observed. In addition, Pavlov also successfully conditioned the effects of drugs to previously neutral stimuli. His work produced interesting results, but Pavlov did not pursue this line of research further.

In North America, Thorndike and his followers pioneered the study of learning in laboratory animals using repeated single discrete trials in an apparatus such as a maze or a runway etc. This method became known as *instrumental learning*. In the 1920s, Macht acquired a maze from Thorndike and in a series

of studies investigated the effects of a number of different drugs on rat behavior. Once again, this work did not immediately stimulate much further investigation until later when people started looking for methods to screen newly discovered, behaviorally active drugs such as chlorpromazine.

Also in North America, B. F. Skinner and his coworkers developed the technique known as the *operant analysis of behavior*. Skinner and his students developed a technology whereby the behavior of an animal in an isolated environment (Skinner box) could be manipulated by altering the schedule of reinforcement, that is, by precisely controlling the contingency between performance of a specific action such as pressing a lever, and the delivery of a reinforcer such as food. Using these techniques, the rate and pattern of responding of experimental animals, usually rats and pigeons, could be controlled with a precision not previously possible, and remained stable throughout lengthy experimental sessions and over repeated sessions. Skinner and Heron recognized early that this technique could be particularly useful in studying the effects of drugs and in 1937 they published a paper describing the effects of DL-amphetamine and caffeine on the behavior of rats. Their study was published in the psychological literature rather than in a pharmacology journal and it appears not to have been noticed by pharmacologists.

After Skinner and Heron, there were other attempts to investigate the effects of various drugs using operant techniques, but up until the mid-1950s such studies were sporadic and uncoordinated.

At this time there was a growing interest among pharmacologists in drugs that affected the central nervous system; however, most pharmacologists were unaware of the techniques developed by psychologists. Consequently, behavioral research carried out by pharmacologists mostly involved observing laboratory animals after they had been given a drug, and quantifying the total amount of activity in an unstructured situation. If the drug increased locomotor activity it was taken to indicate that the drug was a central nervous system 'stimulant'; if activity decreased, the drug was a 'depressant.'

Even though both psychologists and pharmacologists were doing behavioral research with drugs, up until the 1950s there could not be considered to be a separate discipline of behavioral pharmacology. The impetus to develop such a field came in the early 1950s and arose largely from two events. The first was the tremendous therapeutic and commercial success of chlorpromazine and other antipsychotic drugs, and the resulting need to find tests in laboratory animals that were useful in screening drugs for potential therapeutic effects on behavior of humans. The second was the compelling demonstration by Peter B. Dews of the usefulness of Skinner's operant techniques to study drug effects.

Chlorpromazine

Chlorpromazine was marketed by the French pharmaceutical company Rhône-Poulenc as an antipsychotic drug in 1952. Initially it was used to prevent surgical shock, but it was soon discovered that it was also effective in treating the specific symptoms of schizophrenia and other psychoses. The success of chlorpromazine demonstrated the tremendous economic potential of behaviorally active drugs, and an intensive

search for new drugs and new medical applications of older drugs began.

In the development of chlorpromazine, behavioral techniques had been used to confirm that chlorpromazine and other phenothiazines had antipsychotic properties. In fact, one of the techniques used to identify the important behavioral properties of the phenothiazine antipsychotics was a rope-climbing task developed by Macht in the tradition of instrumental learning. It became obvious that there was a need for better understanding of how drugs altered behavior, and that the synthesis of pharmacology and behavioral techniques would be useful, not only to pharmaceutical companies wanting to develop and test new compounds, but as a separate field of investigation that could lead to a better understanding of the interaction of drugs and behavioral processes.

Operant Analysis of Behavior

In 1955, Peter Dews began publishing a series of papers in pharmacology journals in which he reported using Skinner's operant technology to demonstrate some remarkable and surprising drug effects. Dews was trained as a physician in England and came to the United States where he worked for Burroughs Wellcome Co. and later earned a Ph.D. in physiology from the University of Minnesota. In 1952, he took a position at Harvard Medical School. Earlier in his career he had attempted to study the effects of THC on behavior (THC is one of the active ingredients in cannabis), but had given up in frustration because '... there were no promising techniques in pharmacology for studying behavioral effects.' He went on to do experiments on the effects of histamines and antihistamines on isolated smooth muscles of guinea pigs and blood pressure of cats. These techniques involved the continuous recording of physiological responses in real time on a polygraph.

When he arrived at Harvard, Dews went across the river to Cambridge "... to see B. F. Skinner who introduced me to C. B. Ferster who in turn took me into their laboratory. And there they were recording something they called operant behavior as ups and downs of a continuous line in real time. I was at home at once and was determined to follow the lead of Skinner and Heron 15 years before and to apply the techniques to behavioral pharmacology."

Of particular appeal to Dews was the fact that operant techniques recorded a steady-state behavior for an extended period of time during which the effects of a pharmacological treatment could be continuously monitored and recorded. Initially comparisons between drug and control conditions during a single session were made for each individual animal. As the techniques developed, comparisons were made between drug and control conditions between different sessions in individual animals.
