Passive aggression: When the intern, while inserting an IV, missed her vein, she smiled at him, told him not to worry, and said, "When you're just a medical student, it must be hard to get things right." Unable to sleep, she watched her IV run dry. Later, at 4 a.m., the night nurse had to call the intern to restart the IV. She cheerfully told him that she had not rung for the nurse because she knew how busy everyone in the hospital was. Diagnosis: Passive Aggressive Personality

Acting out: Shortly after leaving the hospital, she was unfaithful to her husband with four different men in a month, twice picking up men in cocktail lounges and once seducing an 18-year-old delivery boy. Prior to that time, she had no sexual interest in any man but her husband. Diagnosis: Sociopath

A. 'Psychotic' defenses

Distortion: On the third postoperative day, she announced that she was a Christian Scientist and was signing out immediately. Besides, she had to go home because she and her husband were planning a trip to Bermuda that weekend. (In reality, their total income was \$200 a week and their Blue Cross had lapsed.) She added with a naughty laugh that they needed a vacation to do a little 'spring planting.' Diagnosis: Mania

Delusional projection: She felt that the hospital was being run by racists who were trying to sterilize her. She tried to telephone the FBI to report the hospital for genocide. She refused her pain medication, claiming it was an experimental drug for thought control. Diagnosis: Paranoid Schizophrenia

Psychotic denial: She started ordering the nurses to move her upstairs to the maternity ward. She wandered about the hospital looking for her baby. By phone, she ordered an expensive bassinet and baby clothes to be delivered to her house. She experienced no postoperative pain. Diagnosis: Mania

woman wins community praise for founding a shelter for battered women (altruism), but she dismisses her behavior as 'a need to rent my house.' Another woman is imprisoned for breaking her toddler daughter's arm in a tantrum (acting out),

but she dismisses her behavior as an accident. In fact, social agency records from 30 years before reveal that both women had been taken at age two from the care of physically abusive alcoholic mothers.

The Q-sort method (described in *Ego Mechanisms of Defence*) appears the most reliable method for assessing defenses from a clinical narrative.

Prospective Validation of the Hierarchy

The Study of Adult Development at Harvard consisted of three cohorts followed for a lifetime: the COLLEGE sample (Harvard sophomores selected for mental health in 1940), the CORE CITY sample (socioeconomically deprived, but nondelinquent, inner city adolescents selected in 1940), and the TERMAN sample (California 4th grade girls with high IQs selected for longitudinal study in 1922).

For all three samples, the adaptiveness of each subject's defenses was assessed along a 9-point scale; point 1 equaled using only mature defenses, and point 9 equaled using only immature defenses. Table 3 illustrates, that, analogous to clotting mechanisms, choice of defense mechanisms is relatively unaffected by parental social class, IQ, and education. However, Table 4 illustrates that prospectively choice of defense mechanism predicts successful aging and income.

In order to cut through the unreliability of projective tests and the subjectivity of pencil and paper tests, Menninger psychologist, Lester Luborsky, devised a behavioral guide (Health-Sickness Rating Scale or HSRS) to assess psychological functioning on a scale of 0–100. Two of the architects of DSM-III developed a revision of the HSRS called the Global Assessment Scale (GAS). A modified version of the GAS was introduced in DSM-III-R as the Global Assessment of Functioning (GAF or Axis V). Table 5 illustrates how much psychopathology and/or mental health is associated with choice of selected defense mechanisms.

Treatment

Psychiatry needs to understand how best to facilitate the transmutation of less adaptive defenses into more adaptive defenses. The modification of immature defenses occupies the attention of high school teachers, criminal justice personnel, and psychotherapists everywhere. At present, little evidence-based treatment is available; nevertheless, there is literature information on change in defenses over treatment and time, which indicates (mostly noncontrolled studies) that immature defenses decrease and mature defenses increase significantly. (Perry et al., 2008)

Perhaps, the best way to alter a person's choice of defensive style under stress is to make his/her social milieu more predictable and supportive. We are all a little schizoid and paranoid when among strangers whom we fear may treat us harshly. We are all more adept at altruism, suppression, and playful sublimation when among friends and others empathic toward our pain. The second strategy is to facilitate the intactness of the central nervous system (e.g., sleep, nutrition, sobriety, and removal of sources of toxicity and infection).

Toxic brain syndrome is often associated with paranoia; intoxication leads to fantasy; both grief and anger can lead to rage turned upon the self. We are all more mature when not hungry, tired, and lonely.

Finally, if we breach patients' defenses, we must be sure that we have their permission. If in the course of examination we

Table 3 Correlation of social antecedents with adaptiveness of defenses

Antecedent	Adaptiveness of defenses		
	College N = 154 ^a	Core city N = 189 ^a	Terman N = 40
Years of education	0.13	0.10	0.33*
IQ	0.04	0.14	0.07
Parental social class	0.11	0.00	0.13

* $p < 0.05$, *** $p < 0.001$ Spearman correlation coefficient.

^aSample size is reduced. In order to control confounders, men with IQ < 86, depression, alcohol dependence, and schizophrenia have been excluded.

Table 4 Late life consequences of adaptive defenses at age 20–47

	Core city N = 137 ^a	College N = 154 ^a
I. <i>Objective evidence</i>	Adaptiveness of defenses	Adaptiveness of defenses
Income (Midlife)	0.25**	0.28***
Psychosocial adjustment (50–65)	0.16	0.34***
Social supports ^b	0.12	0.34***
II. <i>Subjective evidence</i>		
Joy in living ^b	0.14	0.35***

Spearman correlation coefficient (ρ) was the statistic used.

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.

^aSample size is reduced because men who died before age 65 are excluded.

^bMeasured at age 65 for the core city men and measured at age 75 for the College men.

Table 5 Percent of core city men at different levels of global mental health using selected defenses

Major defense	HSRS			
	Impaired 0–65 n = 53	66–70 n = 36	Healthy 71–84 n = 143	85–99 n = 74
Projection (%)	30	17	7	0
Fantasy (%)	19	11	1	0
Hypochondriasis (%)	21	11	1	0
Passive aggression (%)	32	36	15	1
Dissociation (%)	55	36	15	1
Altruism (%)	0	3	6	35
Suppression (%)	2	14	27	59

ask patients to remove their protective covering, we must protect them with something else. Either we must offer ourselves – a luxury rarely available to busy clinicians – or we must offer and facilitate a substitute defense. It is only sometimes that psychopharmacology is specific enough to do the job.

Delusions

P R Corlett, Yale University, New Haven, CT, USA

Glossary

Habit Habitual behavior is rigid, inflexible, and insensitive to the current value of the ends that it achieves. Delusions may be habits of thought.

Heuristic A 'rule of thumb' or educated guess; used to come to an optimal solution as rapidly as possible.

Inference The process of interpolating the next logical step in an intuited pattern. The conclusion drawn is also called an inference.

Judgment The evaluation of evidence in the making of a decision.

Perception The process of understanding sensory information; distinguished from sensation by the observation that it is substantially constructive, that is,

what we have previously perceived influences subsequent processing of inputs.

Prediction error The mismatch between what is expected in a given situation and what is subsequently experienced. Prediction errors relate to the very essence of learning; by minimizing prediction errors, organisms learn to better predict their environment.

Salience The capacity for stimuli, thoughts, and percepts to grab attention and drive action.

Uncertainty Related to prediction error – this quantity is minimized through learning. It drives the allocation of attention toward explanatory cues. In formal models, it is related to free energy or entropy. Motivational factors like need for closure are engaged when uncertainty is high.

Introduction

Delusions occur in the context of numerous pathological states, ranging from head injuries to schizophrenia, Alzheimer's, and Parkinson's diseases, to rare autoimmune encephalopathies. This biological heterogeneity is mirrored in the psychological and philosophical realms; a menagerie of state- and trait-related processes have been invoked to explain delusions. Worse still, delusions have myriad contents, ranging from the mundane ('my partner is cheating on me') to the exotic ('I am the right foot of God'). Hence, delusional beliefs represent a challenge: Can they be understood? Are they aberrations of belief? Are they the rational products of aberrant perception or empty speech acts? To meet this challenge, perhaps a definition is a good place to start. As we shall see, this may be easier said than done.

Delusions Defined?

We all know what delusions are, but can we define them? Clinicians adopt a normative approach to diagnosing delusions, and, since delusions are judged against societal norms, such an approach allows scientists and laypeople to recognize delusions without necessarily understanding or being able to define them.

According to the Diagnostic and Statistical Manual (IV, Text Revision), delusions are

false beliefs based on incorrect inference about external reality that persist despite the evidence to the contrary and these beliefs are not ordinarily accepted by other members of the person's culture or subculture.

There are numerous problems with this definition: for example, delusions may not be beliefs and, even if they are, what are beliefs? Perhaps, a pragmatic approach might help: what are beliefs for? One function they might serve is in representing

and organizing information and thus coordinating adaptive responses, that is, beliefs might be a special kind of memory.

This definition of belief entails a close relationship between beliefs and actions. To this end, some object to delusions being beliefs because individuals with delusions do not act consistently with their beliefs; a patient with Cotard delusion believes that she is dead (note that in describing delusions, one cannot help but use terms like belief!), she will nevertheless eat and move (unlike typical dead people); a patient with Capgras delusion who is convinced that his/her spouse has been replaced by an imposter will share the house with the apparent imposter and will not search for the 'real' spouse. Of course, some patients act on their delusions with violent and tragic consequences. Those who favor the doxastic (belief-based) account of delusions point to the inconsistency with which even healthy individuals act upon their beliefs and the intractable computational power that would be required to act with complete consistency on all of our beliefs all of the time.

The consistency argument also extends to fixity. Delusions are defined as tenacious, fixed in the face of contradictory evidence. Yet, patients' assent waxes and wanes, so fixity or strength is not pathognomic of delusions (despite being an important feature and one that engenders a great deal of distress for the sufferer, and their family and friends).

Next, delusions do not have to be about external reality, for example, patients can be deluded about their internal states; an individual may believe, based on his/her internal sensations, that he/she has a nuclear reactor inside the stomach. Furthermore, emotional factors may guide delusion formation and maintenance and, while these may be responses to external events, they nevertheless involve internal sensations that may or may not be veridical.

Finally, delusions do not have to be based on incorrect inference; a patient who is convinced that his/her spouse is being unfaithful (often called Othello syndrome) may be correct. However, although the belief may be correct, the key

point is that the evidence on which it is predicted is false. This is particularly difficult to discern, as patients often cannot describe the data that support their contentions.

So, is there hope for a scientist who studies delusions? How can one explore the cognitive and neural mechanisms of something that cannot be defined? The answer involves making certain assumptions that may amount to delusions in themselves! One approach that has proved fruitful in recent years involves cognitive neuropsychiatry; that is, we attempt to understand a mental symptom in terms of a dysfunction to one or many cognitive modules; delusions may be understood as aberrations of normal belief function.

The remainder of this article is concerned with the variety of cognitive neuropsychiatric models of delusion, and their strengths and weaknesses. We conclude by suggesting that a unifying theory may be possible but that further empirical and theoretical work is essential to make this a reality.

Perception

One category of models holds that delusions are a normal and rational response to an abnormal percept or percepts. That is, the delusion represents a belief that is formed to explain away an unusual experience. Maher conceives of this perceptual kernel as a 'surprise' that demands explanation and that the particular explanation would be generated by all of us, were we to experience the same surprise. This model has found favor with cognitive neuroscientists and has garnered support from functional imaging studies of belief formation and paradigms that involve the administration of psychotomimetic drugs like ketamine, amphetamine, and cannabis to healthy volunteers. These treatments engender alterations in visual and auditory perception as well as affective responses and, while they also impair cognition and decision-making, there is at least some evidence relating the degree of perceptual aberration they induce to the degree of delusion-like ideation. These studies suggest that all of us have the capacity to experience delusions given the correct perturbation; however, these studies have not demonstrated the primacy of perceptual aberration. Furthermore, top-down cognitive manipulations can also engender delusion-like ideation, for example, hypnosis. Finally, the delusion-like ideas that subjects express are not identical with clinical delusions (although some subjects do lose insight and report considerable conviction). Perhaps it is best to consider these manipulations modeling the very early phases of delusion formation, the delusional mood, in which the world feels changed, strange, and puzzling, pregnant with new meaning, though these experiences have not yet crystallized into a delusion.

One influential neurobiological model of delusions explains this process in terms of the brain systems that ascribe importance or salience to stimuli, thoughts, and percepts. Salience represents the capacity for an experience or idea to grab attention and drive goal-directed action. In a drive for consilience, theorists sought to relate a candidate neurotransmitter, dopamine (implicated in the deluding process, because when its activity is blocked in psychotic patients, delusions resolve), to the phenomenology of having delusions. While it is an admirable effort that garnered some empirical support, the heuristic

explanation of 'too much dopamine, leads to too much salience leads to delusions' has been supplanted by more mechanistic explanations that are capable of explaining more of the empirical data.

Surprising experiences that demand explanations are also salient, and they lie at the heart of a category of delusion models that are grounded in formal animal learning theory. Building upon preclinical data from laboratory animals learning to predict their environment and respond appropriately, these models identify the mismatch between expectation and experience or prediction error as crucial for learning and attentional allocation. These accounts were applied to human causal belief formation in the 1980s with demonstrations that human subjects acquiring cause-effect beliefs showed evidence for the same biases and patterns of responding as experimental animals confronted with contingencies between arbitrary stimuli (lights and tones) and the delivery of salient events (food, water, electric shocks, etc.).

Central to these behavioral effects is prediction error – subjects learn most when their expectancies are violated, and without prediction error, no learning occurs. On the other hand, if there is too much prediction error that is inappropriately timed relative to environmental cues and context, then an organism may learn inappropriately. Delusions form when prediction errors are signaled inappropriately, driving attention toward irrelevant stimuli, forging maladaptive beliefs. There is empirical support for this model from pharmacological model psychoses and from patients with first-episode psychosis; in both cases, aberrant prediction error signals correlated with the severity of delusions.

More recently, this model has been extended in an attempt to explain the fixity of delusional beliefs. Briefly, if delusions form as schemas to explain aberrant experiences, then, once formed, they are deployed to explain future experiences. This process involves activating the delusion representation and adventitiously reinforcing it such that, even when the logical predictions of the delusion are not borne out, the fact that the delusion was reevoked and ruminated upon dominates over any new learning that the delusion is untrue. There are preclinical data that suggest that prediction errors also govern this reactivation and reconsolidation process, and some clinical data to suggest that the phenomenology of delusions conforms with a reconsolidation-like mechanism for delusion maintenance. For example, confronting patients with evidence that contradicts their beliefs induces belief 'elasticity'; they will engage in quite impressive explanatory feats to encompass or explain away the contradictory data, often incorporating the information or the confronting individual into the delusion.

Additionally, as delusions resolve, patients describe a 'double-awareness' in which they endorse the delusion but also reject it, a duality of belief and disbelief. In preclinical animal learning theory, dual representations exist following extinction of prior learning (hence the spontaneous renewal of fear responses after extinction), as well in animals over-trained on instrumental contingencies. Here, there are at least two representations competing for expression in behavior: a flexible goal-directed representation that is sensitive to the value of the outcome of an instrumental response and a more rigid response tendency controlled by contextual cues and insensitive to outcome value (a habit). It is possible that the

fixity of delusional beliefs is explicable if we conceptualize them as instrumental habits that compete with and overwhelm an impaired cognitive system that is attempting to impose a veridical view of the world. Neurobiologically, boosting dopamine function in the prefrontal cortex can switch an animal from habitual responding back to more flexible, goal-directed behavior. Perhaps delusions may be ameliorated by increasing the sufferers' capacity for top-down executive control. In the next section, we discuss such high-level executive cognitive factors in more detail and how they may contribute to the psychopathology of delusions.

Cognition

Perceptual models of delusion formation suggest that delusions represent a rational inferential response to an unexpected percept. While there are empirical data supporting the notion of peripheral perceptual dysfunctions that conform to the thematic content of a patient's delusions, and even nondeluded individuals are suboptimal when it comes to probabilistic inference, there are theories of delusions that appeal to inferential disruptions generating these aberrant beliefs and mediating their maintenance. In this section, we discuss those models.

Reasoning involves the purposeful manipulation of relevant details from previously acquired stored information. Psychotic patients report that the logical sequence of their ideas was replaced by sequences of merely associated thoughts, and the reasoning process therefore became increasingly concrete. Psychotic reasoning involves 'a lack of the inhibition of peripheral ideas necessary for effective abstraction.' Some patients report that almost every thought immediately and automatically suggested an enormous number of associated ideas. Some enjoy this enhanced ability to associate, feeling endowed with enhanced mental reactions and a more sophisticated problem-solving ability; indeed, delusions of grandeur often develop from the apparent insights that accompany this hyperactivity of association.

Chapman reported that most patients who experienced the changes outlined previously reported that, for a time, everything around them looked fascinating and that objects stood out vividly against the background. They regarded everything as significant and found themselves attending to many irrelevant aspects of the environment. There was a general tendency for their interest to be turned to ruminating about psychology, philosophy, art, and literature. Those patients who experienced perceptual and attentional aberrations also experienced hyperactivity of associations. Matussek's patient (R) illustrates this concept clearly: "Out of these perceptions came the absolute awareness that my ability to see connections had been multiplied many times over." These experiences are appraised positively at first; however, as they persist, patients become increasingly anxious. Attempting to account for their bizarre experiences, they arrive at irrational conclusions. Paranoid ideas and delusions of various kinds develop in response to the various alterations of sensory and attentional experience.

Heuristics

Human judges are not always rational. People tend to jump to conclusions, employing shortcuts and heuristics, some of

which are relevant to the present discussion. For example, people tend to assume that the features of a causal event should resemble the features of its outcome (the representativeness heuristic). Unpleasant effects should have unpleasant causes. Furthermore, peoples' causal judgments tend to be greatly influenced by their a priori theories about causation: If someone has the idea that many unpleasant events in the outside world reflect the activities of an international terrorist conspiracy, those same terrorists may be held responsible for unpleasant internal events as well. Thus, in seeking an explanation for their distressing anomalous experiences, the psychotic individual experiencing them may be especially likely to focus on members of out-groups, individuals, and classes of people who are generally feared in his or her culture. It seems possible to appeal to an associative mechanism to explain this heuristic, a particular personal bias may be mediated by associations; the increased salience of a particular out-group may increase the propensity to form associations between that group and events in the environment.

The simulation heuristic posits that the basis for judgment is the ease with which a plausible scenario can be constructed mentally. Judgments of causality are affected by the ease with which the person can imagine a path from a presumed cause to a known effect. When unpredicted events occur, the simulation process traces causal links back to prior causes. Consider a psychotic patient searching the environment for a likely cause for anomalous experiences. Salient objects and events – a honk or a wave from a passing driver, perhaps a member of a minority group standing on a street corner – will inevitably draw attention, and be given special weight as a likely cause of their troublesome internal events. If there is nothing perceptually salient, events may be retrieved from memory – a curse uttered in anger by a coworker or a sin unconfessed to a priest. If no suitable cause is generated through perception or memory, the simulation process may be invoked. The person may imagine possible causes and grasp the first one that comes to mind as the most likely explanation.

It is plausible that the simulation heuristic may be mediated by associative mechanisms, namely, the retrieval of associative chains such that the individual can mentally trace the associations from outcome to cause. A computationally intensive Bayesian tree-search mechanism located in the prefrontal cortex outlined by Daw and colleagues may underpin this heuristic. This mechanism may be invoked to account for the apparent relatedness of stimuli and events or the aberrant attentional salience of previously irrelevant background stimuli.

While the heuristics described are involved in the initial generation of a causal explanation, anchoring and adjustment might be involved in the maintenance of delusional beliefs. Many judgments begin as hypotheses – tentative conclusions that can be revised on the basis of newly acquired evidence. However, it has long been appreciated that final judgments are inordinately influenced by first impressions: the initial judgment serves as an anchor for the final one, and there is very little subsequent adjustment. The anchoring and adjustment heuristic reflects a general tendency to rely on initial or partial judgments, giving too little weight to newly acquired information. By virtue of its use, judgments of causality tend not to accommodate new information that should instigate revision.

Instead, knowledge gained subsequent to the initial judgment may be distorted so as to fit the original causal theory; subjects adopt suboptimal verificationist strategies, seeking and paying special attention to information that is consistent with their hypothesis. As many researchers will attest, when confronted with evidence that counters a cherished belief, individuals often react by challenging the evidence. Once an explanation for odd perceptual and attentional phenomena is arrived at, the patient experiences relief from anxiety. The experience of insight relief diminishes the person's subsequent motivation to question his or her original conclusions and increases resistance to contrary information. This theme is represented in Miller's associative learning-based account of psychosis. He argues that arriving at a causal explanation that accounts for aberrant experiences is so rewarding/relieving that it is accompanied by a surge of dopamine. Dopamine also impacts upon the consolidation of memories and as such, a delusional conclusion may be 'stamped-in' to long-term memory by dopamine, rendering it relatively impervious to disconfirmatory evidence.

Jumping to Delusions?

A prominent cognitive theory of delusion formation involves the 'jumping to conclusions bias.' Deluded individuals tend to make decisions hastily, on the basis of little evidence. Empirical evidence for this account comes from investigations of patient performance on probabilistic reasoning tasks; typically, participants are presented with two jars holding colored beads in different proportions. The jars are removed from view and subjects are presented with beads, drawn one at a time, from a jar and patients are asked to predict from which jar the beads are coming. Deluded individuals tend to make a decision after only one bead. However, rather than maintaining their hasty conclusion, patients also tend to overadjust their judgments in the light of potentially disconfirmatory evidence.

A liberal acceptance bias might account for apparent jumping to conclusions. When only two mutually exclusive options are available (like the beads task), patients rapidly *accept* that the beads are coming from a particular jar, but they do not *decide* that they are to the exclusion of other possibilities. This account allows for patients' overadjustment following contradictory evidence, since although they have strongly accepted one conclusion (the beads are from one jar), they do not exclude the alternative conclusion (that the beads are coming from the other jar). When given more than two alternatives (e.g., in a thematic apperception task, where participants are shown pictures and asked to rate the plausibility of particular interpretations), psychotic patients entertain a broader range of possible interpretations (rating multiple alternatives as excellent or good interpretations of a particular scenario), whereas healthy participants are more cautious and effectively narrow down the set of possible alternatives. Hence, psychotic individuals might entertain a broader range of possible explanations for their experiences and an absurd idea may prevail. This broadening of plausible explanations may be a manifestation of Miller's inappropriate relatedness of entities, but at a higher, representational level, leading to the entertainment of implausible or absurd accounts for a particular set of circumstances.

However, jumping to conclusion biases are not specific to deluded patients and they do not account for the fixity of delusional beliefs (since patients overadjust following disconfirmatory evidence). It is possible that patients' performance on probabilistic reasoning tasks may reflect the bizarre and unlikely nature of delusional conclusions rather than their fixity.

Self-Serving Bias

Since anomalous perceptual and attentional experiences may be unpleasant, it is important to consider the biases that distort causal judgments about negatively valenced events. For example, when humans make causal attributions, they tend to suffer from a benefactance bias, such that they internalize the cause of positive events and externally attribute negatively valenced events. Hence, psychotic individuals seeking an explanation for their unpleasant anomalous experiences will most often look to the environment outside them.

In an fMRI study of the self-serving bias in healthy individuals, subjects silently read sentences describing positively and negatively valenced social events, then imagined the event happening to them, and finally decided the cause of the event, whether internal (Was it something about you?) or external (Was it something about your friend?/Was it something about the situation or circumstances?). Self-serving biased attributions (internal attribution of positive and external attribution of negative events) were associated with striatal activation, previously implicated in the motivational control of behavior as well as in the mediation of hallucinations and delusions.

The cognitive biases outlined are not specific to individuals with delusions, being present in individuals with schizophrenia but not related specifically to delusion severity (like the jumping to conclusions bias) or being present more generally in the population and being engaged by the need to explain an odd percept or experience in an individual developing delusion (like self-serving and simulation). What then is the evidence for an inferential deficit in individuals with delusions and how might that deficit relate specifically to their belief pathology?

Belief Evaluation Deficits

Perhaps the strongest evidence in favor of an inferential deficit related specifically to delusions comes from the elegant work emanating from the Macquarie Center for Cognitive Science, specifically, the Belief Formation program, under the direction of Max Coltheart. This work focuses on neuropsychological delusions, delusions that arise as a result of some sort of head injury or neurological insult, although attempts have been made to extend it to the delusions that occur in the context of schizophrenia. They advocate a two-factor approach in which perceptual and reasoning abnormalities combine. The latter derive from observations that neurological patients with delusions often have two sites of damage: (1) a lesion in a perceptual region (such as the fusiform face area) and (2) an additional lesion in 'belief evaluation' regions, possibly in the right frontal cortex. The first damage engenders odd percepts and the second generates bizarre explanations. The second factor is necessary because there are individuals with damage

to factor 1, engendering aberrant percepts, who nevertheless remain without delusions; for example, subjects who have suffered haptic deafferentation and therefore do not perceive sensory feedback from the actions they perform. While the haptically deafferented subjects have problems performing actions, they do not feel that their actions are under the control of another agent. Two-factor theorists equate the inappropriate prediction error signals reported in the dorsolateral prefrontal cortex with the aberrant belief evaluation process or factor 2.

However, it is important to emphasize the potential consequences of prefrontal cortical damage alone (their factor 2) as well as peripheral perceptual dysfunction (their factor 1); there are patients who suffer from delusion-like spontaneous confabulations following damage to the ventromedial and lateral prefrontal cortex and at least one patient in whom peripheral sensations are perturbed (following damage to the brachial plexus) who has somatic delusions in the absence of any apparent structural damage, and by extension, any deficit in factor 2.

Top-Down Theories

In addition to the probabilistic reasoning dysfunctions outlined earlier (about which the empirical data are equivocal), there are theories of delusion that invoke top-down factors alone. According to such theories, deluded individuals confuse belief with imagination. Individuals susceptible to delusions do tend to confuse the items they perceived with the events they imagined. Such theories are also popular because they allow for the inconsistency observed in patients between their beliefs and actions; if a delusion is aberrant imagination, then the deluded individual need not act upon it. However, these theories do not allow for the role of perceptual dysfunctions in the formation of some delusions outlined previously.

Is there any way to reconcile these groups of explanations? Perhaps, a hybrid model in which bottom-up experiential- and top-down expectancy-based processes can both contribute to delusion formation and maintenance. Such a model involves taking a Bayesian approach to perception, cognition, and brain function. In the next section, we discuss such models.

Bayesian Models

Thomas Bayes was an English mathematician and minister whose theorem on probabilities was published posthumously. The theorem has had an incredible impact on science, in particular, cognitive and neural science, in recent years. In the paper, Bayes' stance on probability is as follows:

The probability of any event is the ratio between the value at which an expectation depending on the happening of the event ought to be computed, and the value of the thing expected upon its happening

Why should a cognitive scientist care about such an arcane mathematical theory? Bayes theorem might help us, as scientists, to reason about new data and evaluate our a priori hypotheses: according to Bayes rule, the probability that a hypothesis is true given the observed data (the posterior probability) is proportional to the likelihood (the probability of those data given that the hypothesis is true) multiplied by the

prior probability (the probability that the hypothesis was correct before the data were seen). For simplicity, the 'prior probability' is often abbreviated as the *prior*.

More formally, we can express the relationship between a hypothesis and some new data as

$$P\left(\frac{H}{D}\right) = \frac{P(D/H)P(H)}{P(D)}$$

where H is the hypothesis and D is the data. $P(H)$ is the prior probability of H : the probability that H is correct before the data D was seen. $P(D/H)$ is the probability of seeing the data D given that the hypothesis H is true. $P(D/H)$ is the likelihood. $P(D)$ is the probability of observing the data D and $P(H/D)$ is the posterior probability.

Hence, surprising data might be discredited in the face of overwhelming prior experience, or it might demand explanation and an updating of our priors. Herman von Helmholtz was a physician and physicist who constructed prescient theories of visual perception that appear steeped in Bayes theorem; Helmholtz postulated that perception was a process of unconscious inference; that the brain entertains hypotheses about possible inputs and compares them with incoming sensations. Through experience, particular candidate hypotheses can come to be favored over others, based on their minimizing the uncertainty or free energy associated with a given situation. A compelling demonstration of this phenomenon involves observing a rotating hollow face mask: the binocular depth inversion illusion. Since our overwhelming experience of faces is that they are convex, the backside of the mask is perceived as convex when it rotates into view, even though the sensory information incident on the retina indicates a concave object.

An important distinction, within Bayesian models, is between prediction errors per se and the precision or uncertainty about those errors. These processes may have separable neurobiological bases and cognitively, these processes may mediate inference and learning, respectively. While inference and learning are intimately connected, they are dissociable to some extent. Inferences involve short-term decisions, like unconscious perceptual inductions, where one perceptual hypothesis is favored over another, for example, the Necker Cube. On the other hand, learning represents the set of prior expectancies brought to bear on current processing; the set of learned predictions that drives healthy individuals to perceive a hollow mask as a convex face.

While Bayesian models are often considered rational and optimal, they have nevertheless been deployed to explain irrational processes such as the spread of panic and rumor within a crowd (which occurs rapidly in salient situations with few explanatory priors). Delusions may involve a disruption to the normal Bayesian predictive mechanisms of the brain such that predictable and irrelevant events mismatch with expectancies and their salience demands new learning and explanation; a delusion represents an explanatory mechanism, an attempt to impose order on a disordered perceptual and cognitive world.

Delusions and the Self

Delusions often involve disruptions to the representation of self. Wegner and others hypothesize that a sense of self-agency and free will may be learned through experience; having an

intention to act very frequently precedes the action itself and this contiguity binds intentions with actions through associative learning. Subjects judge the time between performing an action and producing an outcome as shorter when the action was intentional, a process of action–outcome binding. Patients with delusions show a hyperbinding effect, an exaggerated binding between their actions and the outcomes they produce, consistent with a disturbed agency account of paranoia. This process of learned intentionality has been modeled using Bayesian mechanisms; in essence, the task of inferring causal agency involves conditioning the evidence (whether the outcome occurred?) over the priors (was there an intention to act and would the outcome be consistent with the outcome performed?). Inappropriate engagement of this inference mechanism could account for excessive and inappropriate agency underpinning, for example, beliefs in telekinesis or telepathy, but what about delusions of passivity or external control?

Producing movements over which we feel a sense of agency also involves predictive learning and prediction error; an internal ‘forward’ predictive model of motor commands or efference copy is used to predict the sensory consequences of movements, and these predictions are compared with the actual sensory feedback during movement execution. Impairment in such a predictive system would result in a failure to attenuate the sensory consequences of self-produced actions, making them appear indistinguishable from externally generated sensations and engendering the inference that one’s own movements were externally caused. This theory provides an elegant explanation for why we cannot tickle ourselves, since we cancel the predicted sensory consequences of the action. However, patients experiencing passivity phenomena rate self-generated stimulation as ticklish.

Delusions and Others

Observing, imagining, or in any way representing an action excites the motor program used to execute the same action. Mirror neurons discharge not only during action execution but also during action observation. Implicit in their description is the idea that information is passed by forward connections from low-level representations of the movement kinematics to high-level representations of the intentions subtending the action. Formally, this is a recognition model that operates by the inversion of a generative model. A generative model will produce an estimate of the visual consequences of an executed action given the causes or goals of that action. By inverting the model, it is possible to infer the cause or goal of an action, given the visual input.

Again, bottom-up or top-down biases in this inference process would lead to gross misrepresentations of other’s intentions. Those biases may arise due to aberrant prediction error signals. Such signals would drive learning of maladaptive social expectations. These would manifest phenomenologically as intense feelings of social uncertainty and ultimately, paranoia.

Stress, Need for Closure, and Self-Deception

The impact of our desires and preferences upon our ordinary, everyday beliefs is well documented. Motivational approaches view delusions as extreme instances of self-deception, as

defensive efforts to relieve pain and distress. For example, a motivational explanation of the Fregoli delusion, the belief that strangers one encounters are deceased family members in disguise, would point to the Freudian psychodynamic process of wish fulfillment, gratifying their wish that their dead relatives are still present. Of course, not all Fregoli sufferers believe that they are encountering disguised and deceased relatives so this is not a general explanation; however, it highlights the potential contributions that motivational processes might make to delusion formation.

Motivational models are perhaps more appropriate in the domain of paranoid and persecutory beliefs. Here, persecutory beliefs represent a defense against low self-esteem, hence, those with persecutory delusions should have high overt self-esteem and relatively low unconscious, covert self-esteem. Empirical data from an Implicit Association reaction time task suggest that this is the case.

One construct that may provide consilience between Motivational and Bayesian models of delusions is the need for closure – a motivational construct, associated with a preference for certainty and predictability. Patients with persecutory delusions have a higher need for closure. To ground this psychodynamic process in Bayesian terms, the need for closure may represent a drive to minimize prediction error; in this case, a mismatch between desired and actual self-representation.

Encapsulation, Scaffolding, and Delusion Contents

Early life experiences significantly shape the adult’s understanding of and reactions to the world. Via the process of scaffolding, early sensorimotor experiences serve as a foundation for the later development of more abstract concepts. Scaffolding refers to the process through which humans readily integrate incoming information with extant knowledge structures – a passive natural process through which new concepts are formed, especially in early childhood. Features of abstract or less-understood concepts are mapped onto existing and well-understood concepts such that the structure of the developmentally earlier, primary concept is retained in the newly constructed concept. This structure imbues the newer concept with meaning. This interchange mirrors the updating of priors by new experience in Bayesian learning. Indeed, category formation and the association of categories may proceed by minimizing prediction error.

Delusion proneness may manifest in development as a different set of learned priors predicated on aberrant sensorimotor interactions with the world. These priors may underpin an alternate set of what Wittgenstein called *bedrock beliefs* in delusion-prone individuals. Bedrock beliefs (or priors) are a framework of foundational and indubitable propositional certainties (‘I am Phil Corlett’; ‘The world is very old’; ‘My parents are human’) which globally constrain other empirical beliefs and provide the terms for their rational interrogation.

The alteration of particular bedrock beliefs in isolation might allow for the encapsulation of delusions. That is, although delusions permeate many domains of cognition, deluded individuals tend not to be deluded about all information they come across. Rather they have delusions but retain normal beliefs too and can recognize the absurdity of other’s delusions. Previously, we have speculated that homeobox genes that pattern cortical

development could predispose individuals toward particular delusional content and not others. Psychological scaffolding is a potential cognitive mechanism for this encapsulation process. This speculation has much in common with Gerald Edelman's neural Darwinism and the idea that particular representational categories are sculpted through interaction with the world. Under the influence of aberrant prediction error, present during critical developmental periods, individuals would form aberrant bedrock beliefs or priors on which subsequent delusions are scaffolded.

Conclusion

In considering delusions, we had to make a number of simplifying assumptions. Taking a reductionist cognitive neuroscientific approach, we highlighted the importance of dysfunctions in predictive learning for delusion formation and maintenance. These same processes may account for the perceptual, affective, and social disruptions that attend delusions. In deluded individuals, the ability to use learned information to constrain current experience is impaired, resulting in aberrations of sensory and affective perception as well as cognition. Delusions arise as an explanation for these odd happenings and they engage new learning. They bring such relief that they are stamped into memory and become a new explanatory scheme for the sufferer, that is, delusions are elastic; they encompass new experiences and maintain a certain consistency of the world for the patient. In terms of the Bayesian model we outlined, delusions become the sufferer's new priors, and they are used to predict and explain future experiences. We believe that the same prediction error-driven learning mechanisms can account for the fixity of delusional beliefs, since, now, when subsequent physiological noise elicits a reactivation of the delusion, it is reinforced and reconsolidated more strongly.

However, Brendan Maher, Emeritus Professor of the Psychology of Personality at Harvard, astutely aligned delusions with scientific theories, suggesting that scientists, like individuals with delusions, were extremely resistant to giving up their preferred theories even in the face of damningly negative evidence. While the account outlined is a preferred (some might say cherished!) explanation of delusions, we hope to engender discussion, debate, and investigation. As Maher says

of science and psychosis: "Puzzles demand an explanation; the search for an explanation begins and continues until one has been devised." We hope this article provides some closure on the puzzle, but it is clear that we have much more explanatory work ahead of us.

Glossary

Agreeableness Personality trait defined by interest in maintaining social harmony. One of five general trait domains in the five-factor model of personality, and theoretically related to dependency. Low levels generally characterize individuals with personality disorder.

Autonomy Personality trait defined by low interpersonal orientation (separation and individuation from others) and high self-governance (e.g., making own decisions without others' advice). Some researchers hypothesize autonomy and dependency to be opposite ends of the same dimension.

Dependency (trait) Personality trait defined by the central motivation to locate and maintain affiliative relationships with specific individuals. Multiple models of dependency exist, but to varying degrees all emphasize lack of self-confidence coupled with overreliance on others. Some researchers hypothesize autonomy and dependency to be opposite ends of the same dimension. Trait dependency overlaps significantly with dependent personality disorder.

Dependent personality disorder (DPD) Personality disorder is defined in the DSM and ICD as pervasive patterns of inner experiences and behavior that are maladaptive, differ from the norm, and cause significant personal or interpersonal distress. In the DSM, Dependent, Obsessive-compulsive, and Avoidant PDs comprise the 'Anxious' cluster of personality pathology. Like trait dependency, DPD is characterized by a view of the self as incompetent/incapable, coupled with neediness and overreliance on others.

Diagnostic and Statistical Manual of Mental Disorders (DSM) Research-based manual published by the American Psychiatric Association (APA) that provides definition, description, and standardized criterion sets for the diagnosis of mental disorders. The current edition is the DSM-IV; 10 personality disorders are detailed on 'Axis II' of this manual. Modifications for the next edition (DSM-5) are currently under way.

Factor A component dimension of a larger structural model that is statistically distinct. A factor is defined by an interrelated set of variables such as items on a trait

dimensional measure, or diagnostic criteria such as those from dependent personality disorder.

Factor analysis A set of statistical procedures used to identify the component dimensional structure of sets of putatively interrelated variables (exploratory factor analysis) and/or to test the replicability of such a structure (confirmatory factor analysis).

Five-factor model (FFM) A dominant model of normal personality consisting of five general trait domains (factors): Neuroticism, Extraversion, Openness (to experience), Agreeableness, and Conscientiousness. The five factors have been shown to be relatively stable across time, culture, and gender, and nonhuman organisms, and provide a broad basis for conceptualizing normal and abnormal personality.

International Statistical Classification of Diseases and Related Health Problems (ICD) A manual published by the World Health Organization (WHO) that provides definition, description, and standardized codes for diagnosing all medical conditions, including mental disorders. The current edition is the ICD-10.

Personality disorders in the ICD roughly correspond to those found in the DSM. Modifications for the next edition (ICD-11) are currently under way.

Neuroticism The tendency to experience negative emotions such as fear, anxiety, anger, guilt, sadness, and irritability. One of five, general trait domains in the five-factor model, and moderately related to dependency in most research. High levels generally characterize personality disorders.

Personality disorder (PD) A diagnosis of a mental disorder currently defined as a pervasive pattern of maladaptive inner experiences (e.g., thoughts, feelings, motivations) and interpersonal behaviors that deviates from the norm (see 'DSM' and 'ICD-10').

Personality trait A defined set of interrelated thoughts, feelings, and behaviors that (1) describe an important quality of individual differences (i.e., can be used to differentiate one organism from another); (2) are stable over time; (3) are consistent across multiple environments; and (4) can be meaningfully linked to functional outcomes and/or behavior.

Dependent personality is defined diagnostically in the *Diagnostic and Statistical Manual*, 4th Edition (DSM-IV), as dependent personality disorder (DPD): "A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation" (American Psychiatric Association, APA). Specific criteria include the following:

1. Difficulty making everyday decisions without excessive reassurance;

2. Dependence on others to take responsibility for important parts of one's life;
3. Difficulty expressing disagreement with others due to fear of losing approval or support;
4. Difficulty beginning and completing tasks/projects due to lack of self-confidence;
5. Excessive seeking of support from others;
6. Discomfort when alone due to fear of not being able to care for oneself;

7. Quick seeking of a replacement source of care and support when one close relationship ends; and
8. Preoccupation with fear of being left alone and inability to care for oneself.

Per the DSM-IV, an individual may be diagnosed with DPD if five of these eight criteria are met. DSM diagnostic criteria are similar to those defined by the World Health Organization in the International Statistical Classification of Diseases and Related Health Problems (ICD-10), which is used internationally to diagnose medical conditions. The ICD-10 requires only three or more of the following criteria for diagnosis:

1. Dependence on others to make one's important life decisions;
2. Subordination of one's needs to those of others on whom one is dependent (i.e., compliance);
3. Inability to make demands of others on whom one is dependent;
4. Feeling of discomfort when alone due to fears of not being able to care for oneself;
5. Preoccupation with fears of abandonment; and
6. Limited capacity for decision making without excessive advice/reassurance.

Both manuals also require that individuals meet general descriptions of personality disorder, which emphasize evidence of significant psychological distress, maladaptive behavior, relative stability of the disorder over time, and broad deficits affecting multiple domains.

A review of these criteria suggests the following basic components of DPD common to both diagnostic systems: First, individuals with DPD present with a self-image of inadequacy, helplessness, and inability to cope, and they view others as much more capable, able to cope, and dominant. Juxtaposed, these views of self and others lead to overvaluing significant relationships and prioritizing the needs of others to maintain the dependent relationships. Thus, DPD necessarily reflects a combination of personal and interpersonal deficits. Theoretically, this may lead to any number of behaviors – even seemingly ‘independent’ behaviors such as decision making – in service of maintaining affiliative relationships. However, the exact behaviors related to dependency have been somewhat less studied, and it is unclear how frequently behavior would deviate from the clinical pictures described in the DSM-IV and ICD-10.

In various forms, dependent personality has been included in all modern formal diagnostic systems. Historically, ‘dependent personality’ is linked to early Freudian theory, specifically to frustration in the oral stage during which the conflict of dependence–independence was expected to be resolved. Since that time, all versions of the DSM and ICD have referenced dependency and dependent PD (in the DSM): first as a subtype of passive–aggressive PD, later as a part of asthenic PD, and, finally, as a separate diagnostic category. Material from the DSM-5 website – which provides the most up-to-date proposals for changes to its psychodiagnostic models – also proposes the inclusion of dependency, although as component traits (submissiveness, anxiousness, separation insecurity) that may characterize personality disorder, rather than as a separate diagnostic category. The proposed change is representative of

a general shift in diagnostic methods from a categorical to a dimensional model for personality disorder, and is not specific to DPD.

Antecedent Validators for Dependent Personality Disorder

Very little research has been done establishing any clear antecedent to DPD per se, and data for biological or genetic antecedents are particularly sparse. Some evidence has suggested that dependent traits are consistent within families, but these results emphasized patterns of interactions and behaviors and did not identify DPD or define dependency specifically. Notably, dependency within families overlapped with avoidant PD traits, with which it shares both low self-esteem and need for social contact. Some researchers suggest that – despite this overlap – the fundamental distinction between avoidant and dependent PD is that, although both desire close relationships, those with avoidant PD nevertheless withdraw from contact. However, among the relatives of the DPD patients studied, withdrawal from contact was found in virtually the same frequency as the dependent characteristic of passively allowing others to assume responsibility for major life areas. On the other hand, the least frequently observed of all the avoidant and dependent criteria was the unwillingness to form relationships unless such relationships guaranteed acceptance, providing some measure of support for this avoidant–dependent distinction.

Nevertheless, in the aforementioned research, immediate family members of DPD-only patients were more likely to report high dependency as compared to control and ‘near neighbor’ samples. These data suggest that DPD patients may have some family-history liabilities. However, much more research is necessary to establish the aggregation of DPD/dependency within families. We did not find any twin or adoption studies examining the heritability of DPD, nor any examining biological or genetic material directly.

Similarly, little research is available on demographic or cultural factors that influence or characterize DPD, except for gender, with self-reported DPD reportedly more common in women than in men. Although the DSM-IV also makes this distinction, some evidence suggests that gender differences may be due to effects of gender stereotyping and/or sex-role identification rather than true differences. For instance, self-report and other rating scales are more likely to yield gender differences than direct behavioral observations of dependent behaviors, perhaps because it is more socially acceptable for women than men to self-report dependency. This hypothesis has yet to be fully explicated. Similarly, when gender is not specified in written patient descriptions that include dependency traits and/or dependency-relevant behaviors, diagnosticians are reportedly more likely to believe the patient is female. This suggests there may be some bias in attention and attribution of patients’ dependent behavior by clinicians.

Moreover, some researchers have not found evidence for gender bias in DPD using patient samples. Such studies also report on age, and find that as compared to other personality disorders DPD is more likely to occur in older patients (>40 years). It is unclear to what extent this is due to naturally

occurring reliance on others over time (e.g., strengthening family relations and decreased physical independence). Although numerous articles discuss the importance of culture in understanding and interpreting dependent behavior, especially in the psychological anthropology literature, this research is largely qualitative or theoretic-analytic. Very little formal research currently exists that examines pathological dependency, as it is conceptualized in DPD.

Much of the research in the epigenesis of DPD has focused on environmental risk factors. For example, research shows that male patients diagnosed with (vs. without) DPD are more likely to report poor home functioning and lower socioeconomic status (SES). The latter (low SES) has been replicated multiple times, and may be mediated by differing parenting styles reported in such families. Overprotective and authoritarian parenting styles may be particular risk factors for later development of DPD. For example, retrospective studies of family environments of females with histrionic and dependent PDs (relative to other psychopathologies and normal controls) have been conducted. These studies show that individuals with DPD reported high-control and low-independence environments compared to both groups. Another study showed similarly that high control and low expressiveness uniquely characterized the early family environment of females with DPD.

Overall, it is clear that little research exists establishing antecedents to DPD. What research there is often uses correlational models, which are insufficient to establish the direction of causality. Although some environmental risk factors have been implicated – most notably authoritarian parenting and control – it remains unclear to what extent such factors interact with or are the result of actions perpetrated by the individual, or are based on biased retrospective recall of individuals with DPD.

Predictive Validators and Treatment for Dependent Personality Disorder

There is no specific or established recommended treatment protocol for DPD. It is widely accepted that clients with personality disorder generally present with unique challenges to therapy, including increased distress and severity of symptoms. With respect to DPD, for example, patients with depression and comorbid DPD are more likely to report suicidal thoughts and attempts than are patients with depression alone. Patients with DPD also report significant functional impairment in their day-to-day lives. Such impairments include difficulty with (or lack of) decision making, task completion, and emotion regulation, and dependency often interferes with the ability to hold a job, complete education, or maintain healthy relationships with significant others.

Research on treatment generally falls into two categories: research protocols/reviews and individual-case or small-sample studies. Both sources suggest that DPD may be treated using cognitive-behavioral, interpersonal, or psychodynamic models of therapy. However, little research has been published using sufficient sample sizes to comment conclusively about specific treatments. In a recent review of treatment for cluster of personality disorders that includes DPD, results were based on only 15 studies of treatment effects for DPD with these

therapies. Results from this study showed little difference in treatment outcomes for specific PDs: all benefited the most from therapy that included components of social skills training, and few showed complete remission of symptoms. It has also been suggested that patient dependency may have an initial positive effect on therapeutic outcome (e.g., due to patients' efforts to please the therapist), but it is likely to inhibit progress over time because the patients' behavior is maintained through interaction with the therapist rather than by 'real-world' environmental outcomes.

In exception to the above, one large-sample study on personality trait change and personality predictors of change in depression severity (over a 20-session cognitive-therapy protocol) has been published. These researchers showed that trait dependency decreased significantly over the 20 sessions. However, higher initial trait dependency predicted less reduction in depressive symptoms for these clients. Overall, studies such as this typically do not report on DPD per se; instead, they report on traits theoretically related to DPD. Thus, treatment options and response to treatment have yet to be established for DPD.

Concurrent Validators for Dependent Personality Disorder

There are currently no published data on biological markers (e.g., molecular genetics, neural substrates) of DPD. In contrast, there is a fair body of research that addresses relations between DPD and other diagnoses, particularly depression. In fact, in the 1980s, researchers were suggesting that dependency and depression were so highly related as to be interchangeable for some clients. However, many such studies used dependency scales that are embedded within depression measures (e.g., dependency/self-criticism in the Depressive Experiences Questionnaire) rather than stand-alone measures of DPD or trait dependency. As such, it remains unclear to what extent DPD and dependency uniquely relate to depression.

In any case, later research suggests that DPD is more broadly related to psychopathology than just depression. Although some researchers replicated a strong relation between depression and dependency, literature reviews more typically reveal only moderate overlap between them; on the other hand, they find notable overlap of DPD with other psychological disorders, including agoraphobia, phobias in general and social phobia in particular, alcoholism, eating disorders, smoking, drug and alcohol abuse, suicidal ideation and attempts, and somatization disorder. DPD is also highly comorbid (overlapping or co-occurring) with other personality disorders, including avoidant and borderline PDs. Such studies strongly indicate that dependency can and does play a broad role in clinical diagnoses.

Research on this issue supports the role of DPD in the development and course of clinical disorders. When multiple DSM-IV disorders are assessed with structured interviews, DPD is typically associated with a broad range of disorders of many different types. Moreover, DPD is not specifically related to any particular disorders above and beyond their associations with other personality disorders. Taken together, these results suggest that DPD may reflect maladaptive traits that are important to virtually all personality pathology, and that it likely taps an even more general, cross-cutting psychological distress.

The DSM-IV states specifically that individuals diagnosed with DPD are likely to be also diagnosed with comorbid anxiety disorders, an association that was found early on and has continued to be supported by subsequent research. Significant relations have been found between DPD and generalized anxiety disorder, separation anxiety disorder, social phobia, obsessive-compulsive disorder, and panic disorder. It must be noted, however, that the meaning of DPD's overlap with anxiety disorders has been questioned because of methodological and conceptual concerns, most notably that dependency on others is a frequent concomitant of anxiety. As such, diagnosable DPD in these studies may reflect functional impairment due to anxiety rather than individual differences in dependency.

As noted previously, DPD also shares diagnostic similarity and comorbidity with other personality disorders, most notably borderline (BPD) and avoidant PDs (AVPD). Interestingly, relations with these disorders may be attributable to correlations between dependency facets (discussed further below) as found in trait measures and DPD criteria. That is, BPD appears to share the 'emotional neediness' component of dependency and even in 'remitted' BPD patients, DPD is more often observed than any other personality disorder (although this relation is not exclusive, as AVPD and self-defeating PD are also observed frequently in these samples). In contrast, AVPD appears to tap the 'perceived incompetence' facet of dependency. For example, in a factor analysis of all DSM-IV PD criteria, AVPD and DPD criteria form a single factor with minimal cross-loadings, which was termed 'neurotic avoidant.' Replications of this research show that AVPD correlates with DPD criteria that addressed perceived incompetence, but not with those pertaining to emotional neediness and attachment. These data underscore the fact that dependency may be conceptualized best as a two-facet dimension. It thus has been suggested that DPD can be differentiated from other PDs when the full dimensionality of dependency is assessed.

Dependent Personality Disorder and Trait Dependency

Dependent PD is one of only a few among the DSM-IV PD diagnoses that are both conceptually defined and empirically represented by a single personality trait, dependency, and its concomitant behaviors. In early analyses, multiple researchers found DPD to be among the more internally consistent of the DSM-III and DSM-III-R PDs, making DPD one of only three DSM-III and DSM-III-R PDs (along with antisocial and borderline PDs) that had sufficiently acceptable psychometric properties, including discriminant validity, to be considered measures of coherent dimensions that were distinct from other personality disorders. More recently, examinations of all the DSM-IV PD criteria using both exploratory and confirmatory factor analyses have been conducted. These studies have found that DPD was best represented by a single latent trait dimension in both types of analyses.

Thus, current research indicates that DSM-III, -III-R, and -DPD criteria, all essentially reflect the characteristics of a single dimension. Later analyses of the DPD criteria alone, however, have indicated that this dimension can be subdivided into two correlated factors. These factors have

been found by others as well, and have been termed variously as (1) attachment/abandonment, emotional neediness, active-emotional, insecure attachment, and separation insecurity; and (2) dependency/incompetence, self-perceived incompetence, passive-submissive, and submissive.

Importantly, DPD as defined in the DSM and trait dependency as defined in the personality literature bear more than definitional similarity. Studies that use both DPD and trait dependency measures consistently find similar results for these variables. In a meta-analytic review of relations between measures of personality disorder and the dominant model of personality, that is, the five-factor model (FFM), comparable results were found for studies that used self-report and interview measures of DPD, as well as trait dependency questionnaires. These data have been replicated multiple times, including in a meta-analysis of dependency and DPD measures in relation to the FFM. Follow-up research indicates that both trait dependency and SCID-II DPD scores accounted for similar variance in depression in an undergraduate sample.

Taken together, these results suggest that (1) DPD can be well modeled using a single trait dimension (perhaps with two subfacets) and (2) current measures of DPD and trait dependency are virtually interchangeable. However, it is noteworthy that, although dependency is well established as a risk factor for a range of psychological disorders, there is a paucity of research on this topic with DPD itself. Indeed, at the time of writing of this article, PsycInfo search of 'dependent personality disorder' in any field (e.g., abstract, keywords, title, etc.) yielded only 223 hits. This is in contrast to similar searches for other personality disorders, such as obsessive-compulsive, schizotypal, borderline, or antisocial PDs (574, 1248, 4765, and 4247 hits, respectively).

Trait Dependency, Temperament, and Normal Personality

Although most PD research suggests that personality pathology is best modeled using traits, it nonetheless can be argued that current trait models do not fully capture all information relevant to currently recognized personality disorders. This may be because models such as the FFM that are designed to reflect normal population variation fail to assess traits specific to personality pathology. Dependency is particularly problematic in this regard. Few measures of normal-range personality contain scales to assess dependency. Moreover, there is currently no official consensus regarding a working definition of dependent personality.

Of further concern is the inconsistency in the empirical relations between dependency and theoretically related traits. Specifically, it has been hypothesized that dependency, which is characterized by a need for approval and prioritization of others' desires, should relate reliably to the FFM trait of agreeableness – the tendency to be motivated by social harmony and minimizing conflict. Moreover, the placement of DPD in the 'anxious' cluster of personality disorders and the fact that the primary affective state associated with dependency is worry/anxiety, suggests a significant overlap with FFM neuroticism or negative affectivity (N/NA) – the tendency to experience negative emotions such as anxiety, sadness, and anger.

This is also reflected by inclusion of 'anxiousness' in the trait description of DPD proposed for the next edition of the DSM (DSM-5). However, only the latter theoretical relation (i.e., that with N/NA) has received empirical support, with one exception, described below.

In patients, moderately high neuroticism has been found to characterize those diagnosed with DPD. This is unsurprising, in that DPD criteria contain clear references to neuroticism correlates (e.g., discomfort, difficulty, and fear). Moreover, when comparing structures of PD and FFM traits from 33 previous datasets, researchers found DPD to have the highest loading on the largest factor, which was identified as akin to neuroticism. Similarly, DPD typically has a high (second or third highest) correlation with neuroticism in meta-analyses of PD–FFM relations. However, these data do not distinguish DPD from the other disorders that are also associated with high neuroticism; moreover, correlations between DPD and neuroticism tend to be moderate. As discussed later, lower order (aka facet-level) traits appear to be needed to diagnose DPD distinctly from other disorders.

In contrast, DPD neither loads (in factor analyses) nor correlates with agreeableness in most of the published research on this topic. Indeed, correlations with agreeableness generally fall in the near-zero range and, in some cases, stronger relations have been found between measures of DPD and the FFM when all agreeableness facets were removed, and neuroticism and conscientiousness facets were added. However, one recent study demonstrated that a 'maladaptive agreeableness' scale – created by altering agreeableness items so that they measure a maladaptive version of same content – correlated more highly, although still only moderately, with a wider range of dependency measures than did the original scale. Thus, somewhat different results might have been found in the other studies if 'maladaptive agreeableness' had been used. Alternatively, different results may obtain simply because the revised scale capitalizes on its conceptual and empirical similarity to neuroticism.

Models of Dependency

Four Factors

As noted previously, when modeled as a single trait, dependency is not well represented in trait models such as the FFM. However, current research suggests that dependency is best modeled as multiple factors. For example, current definitions hold that dependency has at least four principal interrelated components: *motivation* – strong desires to obtain and maintain supportive relationships with others; *cognition* – a perception of oneself as ineffective and incapable, in contrast to a perception of others as effective and capable; *affect* – anxiety and worry in the absence of support from others; and *behavior* – interpersonal yielding, and help and approval seeking. Theoretically, this description of dependency suggests an FFM. However, dependency items generally contain multiple domains, and to date there are no four-factor measures of dependency. Although the APA notes that self-reported dependency is higher in women than in men, there is no hypothesized, gender-based difference in trait content or structure.

Three Factors

In contrast to the four factors described above, early research conceptualized and assessed dependency as having three facets: low self-confidence and emotional reliance on others versus assertion of autonomy, which was thought specifically to assess the opposite or low end of the dependency dimension. The Interpersonal Dependency Inventory (IDI) is based on this model. The IDI autonomy scale's items suggest a pathological rejection of and inability to connect with others, and it is one of only a few attempts to capture the low end of dependency. However, recent research in student samples (some of which utilize the IDI) suggests that autonomy and dependency capture distinct trait variance, and are best modeled separately rather than as opposites.

Yet another three-factor model of dependency draws from interpersonal theory and the interpersonal circumplex (IPC), which conceptualizes interpersonal behavior as reflecting two underlying dimensions of agency and communion. This model also draws from the FFM, of which extraversion (the tendency to be sociable and to experience positive emotions) and agreeableness dimensions represent an alternative rotation of the IPC dimensions. The IPC model reflects three vectors of dependent personality: *love dependency*, characterized by warmth, nurturance, and a need for social interaction; *exploitable dependency*, characterized by being unassuming and by fear of judgment or evaluation; and *submissive dependency*, characterized by unassertiveness and the tendency to yield to others. The resultant measure – the Three-Vector Dependency Inventory (3VDI) – contains items to measure three types of dependency following this model.

It is important to note that, unlike other conceptualizations of dependency, these vectors all hypothetically stem from the same motivation – obtaining and maintaining personal relationships – as manifested in different behavioral and psychological strategies. The authors presented evidence that each dependency facet was associated with a relatively distinct behavioral phenotype (e.g., attachment style and behavior, parental representations, loneliness [in men only], location in the IPC). Further, data show that the FFM traits of openness and conscientiousness related meaningfully and differentially to the three dependency factors. Only high neuroticism typifies all three types of dependency, again suggesting that increased neuroticism is the FFM domain that most clearly and consistently marks *pathological* dependency.

Finally, a later study sampled more widely from the dependency domain, and proposed a model consisting of three single-dimension dependency-relevant constructs reflecting the four-factor multicomponent view of dependency. Thus, the Relationship Profile Test (RPT) models dependency as consisting of three types: destructive overdependence (pathologically high dependency), healthy dependency, and dysfunctional detachment. Contrary to frameworks that conceptualize dependency and detachment as opposing traits, the two dysfunctional types were found to be orthogonal rather than opposed. The RPT has shown moderate levels of test–retest reliability over 85 weeks and 3 years, as well as expected relations to measures of interpersonal relationships. Interestingly, it is also the only current measure to include a formal scale of 'healthy' dependency, or dependency as manifest in

normative interpersonal relationships (e.g., as in a marriage or in a family).

Two Factors

The concept of dependency as a multifaceted structure also is reflected in a considerable body of research on depression. Much of this research has used the term 'sociotropy' rather than 'dependency,' but the constructs appear to be nearly identical in that it emphasizes nurturance and an excessive need to please others. Factor analysis of the sociotropy items of the Sociotropy-Autonomy Scale (SAS) yields three distinct subscales: concern about disapproval, attachment, and ingratiation. Analyses of the (nonoverlapping) set of autonomy items yielded three different subscales. In contrast, later research presents a personality-based model of depression that relies heavily on two correlated dependency facets: dependency, or excessive reliance on interpersonal support; and self-criticism, or excessive emphasis on achievement and fear of failure. These bear superficial similarity to emotional reliance and low self-confidence, the two dependency scales of the IDI. Measures of depression typically do not emphasize autonomy as (negatively) related to dependency.

Several two-factor models for dependency have also been posited in the personality literature. First – and as noted in the RPT – one can conceptualize dependency at both adaptive (connectedness) and maladaptive (neediness) levels, a distinction also reflected by 'love dependence' and 'submissive dependence.' Another measure, the Dimensional Assessment of Personality Pathology (DAPP) also posited two components of trait dependency as separate scales in a multidimensional measure of personality pathology: submissiveness, which also encompasses low self-esteem and need for advice/approval; and insecure attachment, consisting of need for affection, security, and proximity to an attachment figure. The scales show high internal consistency and strong dependability (i.e., short-term stability) over a 3-week test-retest interval, and have been shown to relate meaningfully to other measures of dependency such as that of the Schedule for Nonadaptive and Adaptive Personality (SNAP/SNAP-2).

A two-factor structure for dependency was also found in factor analyses of the diagnostic criterion for DPD both with and without criteria from other PDs. When factored with criteria from other PDs, the DPD criteria did not cohere, but split between those reflecting incompetence or lack of self-confidence (DSM criteria 2, 3, and 4), which formed a factor with most of the avoidant PD criteria, and those reflecting emotional neediness and fear of being alone (DSM criteria 6, 7, and 8), which formed a factor with three criteria from borderline PD. These results were later confirmed by other researchers, who also conducted exploratory analyses using PD criteria from the DSM-IV. Again, most criteria from dependent and avoidant PDs grouped to form a single factor, which the authors named 'neurotic/avoidant.' Notably, this factor had the strongest negative correlation with daily functioning, suggesting that these types of dependent characteristics are quite detrimental to overall functioning.

Taken together, these results indicate that DPD as a diagnosis has a clear two-factor structure ('perceived incompetence' and 'attachment/abandonment') reflecting the distinction posited by the DAPP, but with two of the eight diagnostic

criteria – Criterion 1 (difficulty making decisions) and Criterion 5 (going to excessive lengths to ingratiate oneself to others) – not highly related to either factor. Similar findings emerged in a subsequent confirmatory factor analysis of DPD criteria alone, where a two-factor model of 'perceived incompetence' and 'dysfunctional attachment' provided the best fit for DPD. In these data, Criterion 5 again related only weakly to other criteria, and Criterion 3, difficulty expressing disagreement, correlated more strongly with avoidant than dependent PD. This suggests that the criteria for DPD could be best revised by eliminating Criteria 3 and 5, thus reducing the disorder's bifactorial nature. An alternative conclusion would be that the disorder is best represented by two trait dimensions.

Similar results have been found in student samples, suggesting that the structure of dependent personality (and DPD) is consistent across normal and abnormal populations. One such study combined and assessed all previously described measurement models, using measures consisting of one, two, or three dependency factors. Factor analysis at the scale level yielded three interpretable factors. The first factor consisted of both pathological dependency (e.g., SNAP-2 dependency scale) as well as lack of self-confidence or willingness to assert oneself in the presence of others (e.g., IDI low self-confidence), and was termed 'passive-submissive dependency' ('P-submissive'). The second factor primarily comprised measures tapping emotional neediness in personal relationships (e.g., 3VDI love dependency, DAPP insecure attachment), and was termed 'active-emotional dependency' (A-emotional). The final factor consisted of only two scales that measured theoretically low-end dependency, and was named 'detachment/autonomy' after the two scales' names. All but one scale loaded strongly on only one factor and the factors were moderately correlated, supporting the notion that dependency is at least bifactorial and not simply a single unified construct.

It is noteworthy that dependency scales purporting to reflect DPD as conceptualized in the DSM-IV (e.g., SNAP-2 dependency) all loaded solely or primarily on P-submissive (the first two scales also having moderate negative loadings on autonomy/detachment). This suggests that current self-report DPD diagnostic measures assess low self-confidence (P-submissive) more than emotional neediness (A-emotional), despite the fact that some of the diagnostic criteria for DPD appear to be highly affective/needy in nature. In fact, three (of its eight) DSM diagnostic criteria specifically mention neuroticism in some form. These results are in contrast to those reported previously, where DPD criteria formed two dimensions, which may be due to differences in the study methods: In the study finding two factors, the DPD data were derived in the context of a structured interview for all DSM-IV PDs, and were analyzed at the criterion level, thus increasing the possibility that a given set of PD criteria could load differentially on distinct factors, whereas in the student sample, the data were analyzed at the scale level, which may have favored emergence of the most dominant component of each scale.

One factor

Despite these results, DPD as a diagnostic category has remained a unitary construct, and measures assessing DPD as a disorder necessarily reflect this conceptualization. That is,

ultimately a diagnosis is either made or not made, and the categorical diagnosis does not reflect varying levels of dependency as a trait, nor is the possible bifactorial nature of dependency reflected in the diagnosis (i.e., the diagnosis alone does not indicate the balance of 'perceived incompetence' vs. 'dysfunctional attachment'). One such measure, the Dependent Personality Questionnaire (DPQ), was developed specifically to reflect DPD as in the DSM-IV and ICD-10. Although the authors also took into account research defining trait dependency, and the measure yields dimensional scores, the DPQ consists of eight items essentially reflecting the eight diagnostic criteria for DPD, and the criteria are used to provide a diagnosis. The DPQ was normed on a patient sample and showed high levels of specificity and sensitivity in this population, but its reliability over time has yet to be established.

Similarly, the DPD scale of the Wisconsin Personality Disorders Inventory (WISPI) is a self-report questionnaire rationally derived from the DSM-III-R PD criteria, and is intended to diagnose DPD from an interpersonal perspective, that is, based on interpersonal and trait theory. Nonetheless, the WISPI-DPD scale ultimately yields information about the presence or absence of dependency as a disorder, and not as trait dependency. The scale shows a high level of internal consistency in patient populations, has demonstrated acceptable levels of specificity and sensitivity, and relates meaningfully to established measures of dependent personality.

Notably, several recent measures of trait dependency also treat dependency as a unitary dimension. For example, the Schedule for Nonadaptive and Adaptive Personality, Version 2 (SNAP-2) contains a single unidimensional dependency scale, primarily reflecting decision making and (low) self-confidence, and includes few items assessing pathological attachment. This is similar to the way in which dependency is assessed by measures drawing strictly from the ICD-10 and DSM-IV. For this measure, internal consistency (α) in two psychiatric patient samples was very high, and retest reliability was acceptable across multiple time frames (e.g., 1 week, 1–3 months, 6 months) in a wide variety of patient and student samples.

Detachment/Autonomy

Although not technically part of dependent personality, detachment/autonomy appears regularly in the dependency literature (as detailed above) and thus deserves some mention in this article. Initially, detachment/autonomy and dependency may appear to exist along a single conceptual dimension. However, as indicated earlier, evidence suggests that – at least as concerns measures of detachment/autonomy that have been developed in the context of assessing dependency – they are uncorrelated phenomena with distinct variance. In studies of all personality disorder criteria, the criteria pertaining to aloof detachment and dependency do not form a single factor, and do not appear to represent a single dimension.

Notably, the scales reported in such studies represent only a portion of the larger body of research on trait detachment/autonomy, much of which exists separate from that on dependent personality. In general, results from studies on detachment suggest that detachment itself is a multifaceted construct that includes a dimension termed self-governance, which

correlated strongly with FFM extraversion and conscientiousness. Thus, it may be better to conceptualize the opposite end of pathological dependence simply as healthy levels of dependency rather than as pathological independence. However, more research is needed to confirm this conclusion.

Dependency and the DSM

DPD relates significantly to a wide range of psychopathology and, not surprisingly, trait dependency appears to have similar relations with these disorders. Specifically, in addition to being associated with DPD and other personality pathology, trait dependency has been linked also with mood disorders, suicidal ideation and attempts, anxiety disorders, eating disorders, and adjustment disorder.

Reconceptualizing DSM-V PDs dimensionally – more specifically, multidimensionally – would likely facilitate exploration of the role of personality in these disorders, without the difficulties entailed in examining comorbid diagnoses. As indicated earlier, many researchers have suggested using the FFM for assessing personality in DSM-V. Although this has the drawback that the FFM does not assess dependency per se, use of the 'maladaptive agreeableness' dimension would ameliorate this issue, at least to some extent. Dependency perhaps could more easily be evaluated as a facet or correlate of neuroticism, as is suggested in the proposed changes for the DSM-5.

Interestingly, some researchers have proposed inclusion of more specific FFM components to address the incomplete relation of FFM traits to current DSM-IV PD diagnoses. These components cast a broader net than standard FFM measures to encompass domains of functioning and the environment and to include basic tendencies, characteristic adaptations, self-concept, objective biography, and external influences. Inclusion of such components may provide an alternative framework in which to conceptualize personality disorder in general and traits such as dependency in particular. Some evidence supporting a more detailed approach to maladaptive-range personality traits has already been demonstrated. For example, the two factors of dependency (dependency/incompetence and attachment/abandonment) have been found to relate differentially to maladaptive cognitive schemas in patients. Similarly, more significant correlations are found between dependency and the FFM when more specific (facet) scales are used. The field would benefit from further research exploring relations of the identified two-factor structure of trait dependency with both the 'standard' FFM and an expanded FFM with coverage of the broader domains mentioned above. This is particularly true given that dependency is primarily viewed as a pathological trait, and thus is situated in and reflects current psychopathology research more than normal-range personality research. Integrative research that bridges across the adaptive and maladaptive ranges of this personality traits would be especially beneficial.

Depression

R Ingram, University of Kansas, Lawrence, KS, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Anhedonia A lack of interest in daily activities, or the ability to gain pleasure from these activities.

Bipolar disorder An affective disorder that is divided into Bipolar I disorder, which is characterized by the occurrence of mania, and Bipolar II disorder which is characterized by hypomania.

Cardinal features Symptoms that must be present to qualify for a diagnosis of depression. The cardinal features of depression are either sad mood or a lack of interest in daily activities.

Epidemiology Information about the prevalence of disorders in a population. In the case of disorders such as depression, a prevalence rate refers to the number of people who have the disorder during a particular time period (e.g., the percentage of people in a given location diagnosed with major depressive disorder within a 1-year time period). Socioeconomic status differences are quite small.

Hypomania Episodes characterized by the same symptoms as manic episodes, but that are shorter and associated with less impairment.

Mania A state that frequently includes increased energy, inflated self-esteem, a decreased need for sleep, and involvement in potentially harmful activities.

Negative affectivity The tendency to be chronically distressed and to chronically view oneself negatively. Negative affectivity may be a precursor to both depression and anxiety.

Nosology The diagnosis of disorders into discrete entities with the assumption that each disorder that is nosologically classified will have a different cause, course, prognosis, and treatment response.

Unipolar disorder An affective disorder that is characterized by depression without any evidence for the occurrence of manic episodes.

Depression

Depression has been recognized for as long as history has been recorded. Indeed, in the fourth century B.C., Hippocrates described depression and located its cause in an excess of black bile. Descriptions of what appear to be depression can also be found in the Bible, while other historical references show that around 120 AD, Aretius of Cappadocia described sadness, suicidal tendencies, and apathy as symptoms of depression. More 'modern' accounts show that Freud's descriptions of melancholia resemble contemporary accounts of depression, and that he recognized that the emotional and psychological factors play a role in this state.

Today, depression means different things for different people. To many members of the general public, depression can mean feelings of unhappiness or sadness, for example, "I'm feeling a little depressed today." For mental health professionals, on the other hand, depression is a disease or a psychiatric disorder characterized by depressed mood that interferes with living, and that is associated with symptoms such as loss of appetite, lack of concentration, and suicidal thoughts. In 1987, Kendall, Hollon, Beck, Hammen, and Ingram summed up the various meanings of depression in this way:

The professional use of the term *depression* has several levels of reference: symptom, syndrome, nosologic disorder. Depression itself can be a symptom – for example, being sad. As a syndrome, depression is a constellation of signs and symptoms that cluster together (e.g., sadness, negative self-concept, sleep and appetite disturbances). The syndrome of depression is itself a psychological dysfunction but can also be present, in secondary ways, in other diagnosed disorders. Finally, for depression to be a nosologic category, careful diagnostic procedures are required during which other

potential diagnostic categories are excluded. The presumption, of course, is that a discrete nosologic entity will ultimately prove to be etiologically distinct from other discrete entities, with associated differences likely in course, prognosis, and treatment response.

(Beck, 1967, p. 290)

The focus of this article is the nosologically defined disorder of depression, in particular, the idea that depression, as it is used by mental health professionals, is an affective or mood disorder that exceeds normal sadness and mood fluctuations. Even more specifically, the focus will be on unipolar mood disorder or major depressive disorder, even though the other classifications of mood disorder will be noted.

Definition of Depression

Symptoms of Depression

Professional definitions of depression in the United States begin with the fourth edition, text revision, of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR). The DSM-IV is the official diagnostic classification system of the American Psychiatric Association and provides the criteria that are used to diagnose depression. The DSM-IV-TR will soon be replaced by the fifth edition of the DSM, but it is unlikely that any fundamental changes in the definition of depression will take place.

The 'cardinal features' of depression are either sad mood or a lack of interest in daily activities or the ability to gain pleasure from these activities (known scientifically as *anhedonia*). Cardinal features are those features that must be present before the disorder can be diagnosed. Beyond these cardinal features, symptoms of depression fall into several categories that are

Table 1 Symptoms of depression according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn. Text Revision

1. Depressed mood for most part of the day
2. Diminished interest or pleasure in activities
3. Significant weight loss or gain, decrease or increase in appetite
4. Insomnia or hypersomnia
5. Psychomotor retardation or agitation
6. Fatigue or loss of energy
7. Feelings of worthlessness or excessive or inappropriate guilt
8. Diminished ability to concentrate or think
9. Recurrent thoughts of death, suicidal ideation, a specific plan, or a suicide attempt

grouped together based on their similarities. As would be expected, mood symptoms represent predominant features of depression and are reflected in sad mood. Motivational symptoms include behaviors that are related to goal-directedness. Depressed people often suffer a deficit in this area and some may find it difficult to do even the smallest task. Somatic symptoms refer to the physical changes that may accompany depression and include changes in sleeping patterns, appetite disturbances, and loss of sexual interest. Cognitive symptoms reflect the ability to concentrate and make decisions.

Symptoms of depression may vary according to an individual's age and culture. Children who are depressed, for instance, may express symptoms of irritability rather than sadness or they may fail to make expected weight gains rather than lose weight. On the other end of the age continuum, older adults are more likely than younger adults to experience symptoms such as loss of appetite, loss of interest, and thoughts of death. Cultural differences also exist in the report of depressive symptoms. One study, for example, found that depressed Jewish patients reported more somatic symptoms and less guilt than did non-Jewish patients. Another study that examined depressive symptomatology in American, Korean, Philippine, and Taiwanese college students found that Taiwanese students reported the lowest numbers of somatic symptoms and the highest numbers of affective symptoms. Hence, one's age and culture seems to affect not whether depression is experienced, but rather how it is expressed.

DSM-IV-TR lists nine 'officially recognized' symptoms of depression (see Table 1), although it is important to note that this list does not include all possible symptoms. Pessimism, for example, is often seen in depressed individuals, but is not included in the list. In order to receive a diagnosis of depression, the individual must evidence at least five of the nine symptoms, and one of these symptoms must be either depressed mood or anhedonia. Moreover, these symptoms must be experienced for at least a 2-week period before a diagnosis can be assigned. Given the five symptom cutoff for a diagnosis, it is important to note that even though there are nine recognized symptoms, not all depressed people will experience all nine of these symptoms.

The Relationship Between Depression and Anxiety: Comorbidity

Comorbidity refers to the occurrence of more than one disorder at the same time. Although researchers and clinicians

generally acknowledge depression as a distinct disorder, it does overlap with a variety of other difficulties such as substance abuse. However, much research on this overlap has focused on the relationship between anxiety and depression. This is not surprising, given the high rates of comorbidity found in studies of the two disorder types. One possible explanation provided for such overlap lies in the concept of 'negative affectivity.' Originally proposed in 1984, Watson and Clark described individuals with high levels of negative affectivity as having a tendency "to be distressed and upset and have a negative view of self, whereas those low on the dimension are relatively content and secure and satisfied with themselves" (p. 465). Other characteristics of high negative affectivity include nervousness, tension, worry, anger, scorn, revulsion, guilt, self-dissatisfaction, rejectedness, and sadness.

Both anxiety and depression seem to consist of high negative affectivity (general distress). There are, however, important differences between depression and anxiety. While both depression and anxiety are characterized by high levels of negative affect, only depression is related to low levels of positive affect. Thus, depressed individuals tend to display both high negative affect and low positive affect, whereas anxious individuals display high negative affect and may or may not have low positive affect. Anxious people are also untiringly characterized by physiological hyperarousal. These distinctions have been characterized as a tripartite model that describes those features that are common to both depression and anxiety as well as those features that are unique to each disorder.

Classification of Mood Disorders

Normal Depression

Depression can be classified on a continuum ranging from normal depression to major depressive disorder. Normal depression refers to the mood swings that every individual experiences and is usually expressed as sadness. Normal depression is generally viewed as a symptom and thus, beyond sad mood, few if any of the other depression symptoms are present.

Subclinical Depression

Subclinical depression is a more severe form of depression that includes not only sad mood but also some of the other symptoms of depression. There are differences in terminology, so subclinical depression is similar to 'minor depression' which is an exploratory category of possible depression diagnoses (discussed later in this article). Subclinical depression usually refers to an elevation of depressive symptoms that usually do not warrant treatment but that may nevertheless interfere with an individual's ability to function effectively.

Earlier the DSM-IV-TR was noted. Although there are a number of mood disorders included in DSM-IV-TR (e.g., 'mood disorder not otherwise specified'), the manual lists five major types of mood disorders. These include (1) major depressive disorder, (2) dysthymic disorder, (3) bipolar I disorder, (4) bipolar II disorder, and (5) cyclothymic disorder.

Major Depressive Disorder

As noted, for a diagnosis of major depressive disorder, DSM-IV specifies that at least five symptoms must occur for a period of at least 2 weeks. Major depressive disorder can be further classified according to *severity* (i.e., mild, moderate, severe without psychotic features, severe with psychotic features), *course* (e.g., single episode versus recurrent episodes), and *presentation* (e.g., with catatonic features, with melancholic features). Psychotic features of depression include such experiences as delusions (i.e., false beliefs) and hallucinations (i.e., sensory experiences which have no basis in reality). Catatonic features of depression involve psychomotor disturbances such as excessive movement or stupor. Melancholic features include the inability to experience pleasure even when good things happen and a lack of interest in previously pleasurable activities. No matter what the specific characteristics of a given individual's disturbance, major depressive disorder is, by definition, extremely distressing to the sufferer and is associated with significant impairment in important areas of the person's life (e.g., at work, home, or school).

Dysthymic Disorder

Dysthymic disorder is characterized by a chronic depressed mood which lasts at least 2 years in adults and at least 1 year in children and adolescents. According to DSM-IV-TR, this depressed mood is accompanied by at least two of the following six depressive symptoms: (1) poor appetite or overeating, (2) insomnia or hypersomnia, (3) low energy or fatigue, (4) low self-esteem, (5) poor concentration or difficulty making decisions, and (6) feelings of hopelessness. Because fewer depressive symptoms are required to make a diagnosis, dysthymic disorder is often considered a milder form of depression than major depressive disorder. However, it can be just as upsetting to the sufferer and can cause just as much impairment. In addition, when dysthymic disorder occurs along with major depression, the individual is considered to be suffering from a 'double depression.' The co-occurrence of major depressive disorder and dysthymia is not uncommon.

Bipolar I Disorder

The hallmark characteristic of bipolar I disorder is mania. According to DSM-IV-TR, a manic episode is characterized by elevated, expansive, or irritable mood that is persistent and distinctly different from normal elevated or irritable moods. This period is accompanied by at least three of the following seven possible symptoms: (1) inflated self-esteem, (2) a decreased need for sleep, (3) unusual talkativeness, (4) the feeling that one's thoughts are racing, (5) increased distractibility, (6) increased activity, and (7) involvement in pleasurable but potentially harmful activities (e.g., sexual indiscretions).

Bipolar I disorder is typically recurrent; according to DSM-IV-TR, additional episodes occur in more than 90% of individuals who have had a single manic episode. The manic episodes of those with bipolar I disorder are often intermixed with periods of depression. Like those with major depressive disorder, people with bipolar I disorder may exhibit psychotic, catatonic, and melancholic features as part of either their mania or their depression.

Bipolar II Disorder

Bipolar II disorder is characterized by periods of hypomania intermixed with periods of depression. Hypomanic episodes are characterized by the same symptoms as manic episodes. However, hypomanic episodes may be shorter (e.g., 4 days in duration) and are associated with less impairment. Whereas manic episodes may include psychotic features, interrupt daily functioning, and require hospitalization, hypomanic episodes typically do not. The depression experienced as part of bipolar II disorder, however, can be just as severe as that experienced in major depressive disorder and bipolar I disorder.

Cyclothymic Disorder

Cyclothymic Disorder is characterized by hypomanic periods intermixed with depressive periods that are not as severe as those experienced in major depressive disorder, bipolar I disorder, and bipolar II disorder. In cyclothymia, the periods of mood disturbance may alternate rapidly, with little respite from affective difficulties. For a diagnosis of cyclothymia, these periods of shifting moods must be problematic for at least 2 years in adults and at least 1 year in children and adolescents.

Exploratory Categories of Depressive Disorders

In addition to the five official diagnoses, DSM-IV-TR has denoted four classifications for further study that include depression as a significant component. It remains to be seen whether, and in what form, these syndromes will be included in DSM-V. Even though they are currently exploratory, they are described here because these may represent serious problems. They are (1) premenstrual dysphoric disorder, (2) minor depressive disorder (MDD), (3) recurrent brief depressive disorder (RBDD), and (4) mixed anxiety-depressive disorder.

Premenstrual dysphoric disorder

Premenstrual dysphoric disorder is characterized by several hallmark symptoms of depression (e.g., decreased interest in usual activities, depressed mood, difficulty sleeping, or sleeping too much) in addition to symptoms such as affective lability, feelings of being overwhelmed or out of control, and food cravings. In order to meet the criteria that have been proposed for this diagnosis, such symptoms must have occurred during the late luteal phase of most of a woman's menstrual cycles in the past year. As a number of authors have pointed out, such a classification has potentially serious social, political, and legal ramifications for women. For example, some have argued that if this classification is adopted as an official diagnosis, then women might be stigmatized as more unstable than or inferior to men. Arguments such as these keep the classification of premenstrual dysphoric disorder a topic of considerable debate.

Minor depressive disorder

MDD is characterized by fewer depressive symptoms than are seen in major depressive disorder. The level of impairment is also less than that associated with major depressive disorder. To meet the proposed criteria for MDD, a person must

demonstrate either a depressed mood or loss of interest and two additional symptoms of a major depressive episode. If this classification were included in future DSM editions as a disorder, it would constitute a residual category to be used only after the other mood disorders have been ruled out.

Recurrent brief depressive disorder

The principal difference between RBDD and major depressive disorder is one of duration. RBDD is characterized by periods of depression that meet all of the criteria for a major depressive episode except for duration requirement. While in major depressive episodes, symptoms must last at least 2 weeks, in recurrent brief depressive episodes, symptoms must last at least 2 weeks but less than 14 days. In addition, these brief episodes must occur at least once a month for 12 months to meet criteria for the classification of RBDD. RBDD is quite similar to major depressive disorder in its age of onset and family incidence rates, thus raising questions as to whether this should be considered a distinct disorder.

Mixed anxiety–depressive disorder

The impetus behind a mixed anxious–depressed category lies in the finding that there are many people suffering from symptoms of anxiety and depression who do not meet criteria for any DSM anxiety or mood disorder, but who are nonetheless significantly impaired by their difficulties. The classification of mixed anxiety–depressive disorder (MADD) is characterized by a dysphoric mood for at least 1 month in addition to at least four additional symptoms that primarily reflect anxiety (e.g., mind going blank, worry, hypervigilance). The primary argument in favor of adopting this proposed disorder is that it would cover the large number of people who have significant impairment linked to depression and anxiety but who do not fall into any currently existing diagnostic category. The primary argument against this classification is that people suffering from both depression and anxiety could in fact be categorized into already existing disorders with the use of more precise assessment methods.

Epidemiology

Epidemiology refers to information about the incidence and prevalence of disorders in a population, while a prevalence rate refers to the number of people who have a given disorder during a particular time period (e.g., the percentage of people in a given location diagnosed with major depressive disorder within a 1-year period of time). An incidence rate refers to the number of new cases of a disorder which occur during a given time period (e.g., the number of people diagnosed with dysthymic disorder during April 2010). Because the distribution of a disorder can be examined to determine whether it correlates with other factors or not, epidemiological information can be important for understanding some of the possible causes and correlates of depression.

To assess the prevalence, three major epidemiological studies have been conducted to determine the rates of psychiatric disorders, including depression, in the United States. The first, the National Institute of Mental Health Epidemiologic Catchment Area (ECA) study, interviewed more than 20 000

community and institutionalized adults in five sites, including New Haven, Connecticut; Baltimore, Maryland; St. Louis, Missouri; Durham, North Carolina; and Los Angeles, California. The second major study to examine the rates of psychiatric disorders was the National Comorbidity Survey; the third epidemiological study was the NCS-Replication which surveyed approximately 9000 individuals over the age of 18.

Prevalence

Prevalence in the United States

The ECA study found the lifetime prevalence of major depression (i.e., the number of people experiencing major depression during any point in life) to be 4.9% and the lifetime prevalence of dysthymia to be 3.2%. Alternatively, the national comorbidity survey (NCS) reported much higher prevalence rates: approximately 15% for lifetime major depression, while the NCS-R found a rate of 16.6%. Other studies have reported rates as high as 25%.

Discrepancies between studies are probably accounted for by different assessments, different definitions, and different samples. For example, differences between the ECA and the NCS studies can be found assessment instruments used, slightly different diagnostic criteria, and different age ranges studied (i.e., the ECA sample was 18 years of age or older, whereas the NCS sample ranged in age from 15 to 54 years). Given the various estimates across studies, Kessler has suggested that the actual prevalence rate of major depressive disorders is around 17%.

International prevalence rates

International lifetime prevalence rates vary widely across a variety of different studies (e.g., from a low of 3.3% in Seoul to a high of 15.1% among New Zealand residents aged 25–46). Such differences may indeed reflect true international differences in the occurrence of depression, but other factors such as cultural differences in the sensitivity of the instruments used to assess depression, and different sample ages may also account for this range. Some data on point prevalence (the incidence of a disorder at a particular point in time) are available from the WHO's international consortium on psychiatric epidemiology (ICPE). The ICPE seeks to consolidate data from international epidemiological surveys and finds that point prevalence rates are between 2% and 4% for various samples of adults across countries.

Gender, Age, and Culture

Gender

There are consistent and substantial gender differences in depression rates; roughly twice as many women as men suffer from major depression, and women tend to report more severe depression than men. Furthermore, the gender difference occurs in different and across demographic and cultural groups. These differences tend to be observed around the age of 12 or 13 years (around the time of puberty). Prior to this age, depression is uncommon, although when depression sets in, girls and boys are equally affected. Moreover, in adults, recurrence rates tend not to differ, so that even though women are more likely to experience an initial onset, once an onset has

occurred, men and women experience generally equivalent rates of depression. Additionally, there do not seem to be differences in the length of depressive episodes between men and women.

A variety of explanations of these gender differences have been proposed, although research has yet to confirm the causal validity of these possibilities. Biological views focus on hormonal explanations, genetic factors, and biological stress reactivity. Hormonal explanations, for example, note that many women experience mood disorders at times of peak hormonal change, such as puberty, the premenstrual phase of the menstrual cycle, and the postpartum period. Some psychological theories focus on greater interpersonal orientation; research suggests that women tend to be socialized and to be more likely than men to look excessively to others for reassurance. Another psychological variable, *rumination* (a persistent and obsessive thought about a certain topic) has been suggested to propel women into a cycle of negative affect that eventuates into a depressive state. Social explanations have also been proposed and focus on the greater likelihood that women experience from traumatic events (abuse) or chronic negative events (such as poverty or sexual harassment). Each of these is plausible, and it seems likely that gender differences will eventually be best explained by a model that integrates biological, psychological, and social explanations.

Age

Depression has an average age of onset in early adulthood, typically in the early to mid-20s, although some individuals experience depression at a later age. However, depression rates vary with age and gender. Not surprisingly, depression is more common in younger than older adults, with rates being highest for individuals from 18 to 45. Men have the highest rates among those aged 18–29, with a large decline in incidence for those aged 45 and older. For women, the incidence of major depression is highest for ages 30 through 44 and with declines in incidence not dropping substantially until age 65. For both genders, rates of first onsets are considerably lower for individuals over 65 years old. There are also differences in symptom patterns in different age groups, particularly at the extremes of these groups. Children who are depressed, for instance, tend to express symptoms of irritability rather than sadness and they may also fail to make expected weight gains rather than lose weight, which is more frequently seen in adulthood. On the other end of the age continuum, older adults are more likely to experience loss of appetite, loss of interest, and thoughts of death.

Culture

Despite the numerous studies on culture and depression that have appeared in the literature, Chentsova-Dutton and Tsai note that “it is sobering to realize how little we know about depression across cultures” (p. 378). It is thus not possible to do justice to all the issues involved in understanding depression across cultures, but we do address several different issues. It seems clear that although humans are more alike than different, those differences that are cultural in nature play an important role in depression. Culture can be broken down within countries, so that in the United States, for example, Latino, African-American, Asian-American, Native American,

and Caucasian groups may share a national identity but also share experiences that are common to these cultural and ethnic identities.

One important issue when considering depression and culture is the nature of the depression idea itself and how it might vary across cultures. That is, in some cultures, what might reflect depression is not expressed in ways that are in line with current diagnostic definitions. Hence, in some non-Western cultures, there may be a dominance of the somatic aspects of depression and a relative absence of the psychological components of the disorder. Physiological and psychological responses to stress may also differ for different groups. Clearly, cultural variables are important in understanding depression, but at this point, theory and research is far away from specifying these variables in their conceptual, empirical, and practical complexity.

Social and Environmental Correlates of Depression

These correlates refer to factors such as employment status, socioeconomic status, and marital status. Consider findings from the ECA study which found that people who were separated or divorced had higher 1-year prevalence rates of major depression (6.3%) than those who were currently married (2.1%). The 1-year prevalence rate of major depression was also higher for the unemployed versus those who were employed (3.4% vs. 2.2%). Additionally, the ECA study found higher rates of major depression among white-collar workers and those with at least 12 years of education.

Although all of these variables are important, consider marital status. According to the EPA study: “When current marital status, regardless of past history is considered . . . separated and divorced men and women have the highest rates” of depression. Why is this the case? There are several possible explanations, each of which may be true to at least some degree. One possibility is that marriage provides a protective effect against the stresses and strains that can precipitate depression; having a confidant may help people deal more effectively with the problems in their lives. Another possibility is that people who are prone to depression may lack the stability to successfully navigate the vicissitudes of courtship and then marriage. In this case, marriage may not have a causal relationship with depression but may instead simply reflect a correlation between two variables.

Theories of Depression

Stress and Depression

A variety of different theories of the causes of depression have been proposed. Before examining these theories, it is important to consider the role of stress in depression. Indeed, the link between stress and depression has been recognized for centuries. Research examining this link consistently finds a strong relationship between the experience of stressful life events and the onset of depression. Even though the link between stress and depression is well documented, the precise nature of this link is complex. As noted by Monroe and Hadjiyannakis, although most models emphasize the role of stress in the etiology of depression, it is also important to ask if stress

plays a role in the course of depression (e.g., degree and duration of symptoms). Another question concerns the nature of the stress that is associated with depression; sometimes, depression is associated with a major life event or several major events; sometimes, it is associated with chronic minor life events. Stress can consist of events that independently 'happen' to people, but data have also shown that depressed individuals may play a role in generating stress that prolongs depression and that may predispose to future depression.

However, not all individuals who experience significant stress develop depression, nor do all individuals who develop depression experience significant stress. *Diathesis-stress* ideas can account for these facts. Diathesis refers to a predisposition to an illness, and although not all models of depression emphasize a diathesis, most contemporary theories do make use of the idea to some degree. Stress and diathesis processes may be closely intertwined in that depression, and depression vulnerability, may affect stress responsivity; that is, psychological or biological predispositions to depression may affect how stress is perceived. Individuals who might have a predisposition to depression might therefore also have a predisposition to either perceive or experience stress in an exaggerated way. Furthermore, some approaches suggest an inverse relationship between stress and diatheses, such that as the degree or severity of the diathesis increases, less stress is necessary to initiate depression. Alternatively, both severe stress and a strong diathesis may be necessary to provoke depression.

Psychological Theories of Depression

Cognitive approaches

Cognitive theories of depression are among the most widely studied theories in the etiology of depression. One of the most influential of these theories was proposed by Aaron Beck in 1967. Beck's model argues that depression results from the activation of depressive *self-schemas*. These schemas refer to organized mental structures that, in the case of depression, are negatively toned representations of self-referent knowledge. Moreover, schemas guide appraisals and interact with information to influence selective attention, memory, and cognition. Although all persons evidence schemas, the schemas of depressed individuals are dysfunctional because they lead to negative perspectives about oneself, the world, and the future, or what Beck has termed, the *negative cognitive triad*.

An important aspect of Beck's model is that depressive schemas lay dormant until activated by relevant stimuli: "Whether he will ever become depressed depends on whether the necessary conditions are present at a given time to activate the depressive constellation." Thus, stressful life events are necessary to activate negative schemas, and once activated, schemas provide access to a complex system of negative personal themes that give rise to a corresponding pattern of negative information processing that eventuates in depression.

Learned helplessness and hopelessness theory

The helplessness theory of depression represents a cognitive theory that evolved from an earlier emphasis on learned helplessness in depression. This work began with Seligman who observed that animals which were unable to control negative events often developed behavior that resembled depressive

symptoms. Based on these observations, Seligman developed a theory of depression that focused on depressed individuals' expectations that they were helpless to control aversive outcomes. Even though much of the research on learned helplessness was supportive of the basic tenants of the theory (e.g., that depressed people tended to display more features of helplessness than nondepressed people), other research highlighted substantial shortcomings. In response to these shortcomings, the theory was later reformulated as an *attributional theory* which focused on how attributions about the causes of events were linked to depression. In 1989, Abramson, Metalsky, and Alloy further refined this theory into the *hopelessness theory* of depression to suggest that hopelessness depression represented a specific subtype of depression caused by the expectation that highly desired outcomes will not occur, or that highly aversive outcomes will occur, and the perception that no response can change the likelihood of these outcomes. Both Beck's cognitive model and the hopelessness model have received considerable empirical support.

Interpersonal approaches

Interpersonal approaches to depression focus on the interplay between a depressed person and his or her relations with others. The underlying theoretical idea is that depression is maintained by a vicious cycle that is caused by disruptions in interpersonal interactions. For instance, many depressed individuals understandably seek out social support from others, and initially, others are supportive. However, such support does not alleviate the negative feelings for long, or at all, and further support is sought. Rather than culling additional support, this intensified support seeking has the paradoxical effect of pushing away those who have been supportive. That is, as individuals begin to feel that their support capacity has been exhausted, they pull back from the depressed person, leading to an even further intensification of social support seeking, and the further distancing of potentially supportive people.

Biologically Based Approaches to Depression

Although related in important ways, genetic approaches to depression, biological approaches, and neuroscience perspectives and data are examined here individually. More broadly, both biological function and genetics are intricately tied to brain structure and functioning. To facilitate understanding, we discuss these variables separately, but it is important to keep in mind that these, and other, variables are closely intertwined. Additionally, given their central emphasis in much of the literature, norepinephrine and serotonin are highlighted here, but it is important to note that other biological variables (e.g., neuropeptides and cortisol) may also play a role in depression.

Genetic approaches

Genetic models propose that some of the variance in the onset of depression, at least in some cases of depression, is linked to genetic factors. Genetic models are generally informed by family studies, twin studies, and adoption studies. Family studies are based on the observation that depression runs in families. However, because families share both genes and environments, such studies cannot separate genetic factors from environmental factors. Twin studies, on the other hand, compare

concordance rates for *monozygotic* twins, who are genetically identical, to *dizygotic* twins whose genes are similar but not identical. Research shows that concordance rates for twins are, depending on the study, approximately twice as high concordance rates for dizygotic twins, thus suggesting a genetic component to depression. Adoption studies are a rarely used but powerful method for examining genetic effects. Adopted children are genetically quite similar to their biological parents, and hence evidence for a genetic role in depression is found when adopted children with a biological family history of depression are also more likely to experience a mood disorder.

Taken together, these types of studies have provided some estimates of the degree to which depression is influenced by genes. In general, the heritability of milder forms of depression ranges anywhere from 20% to 45%, with estimates for more severe cases of depression likely to touch as high as 70%. Heritability for recurrent or chronic cases of depression may also be higher than those for single episodes. Therefore, depending on the severity and type of depression, data suggest that heritability of depression is anywhere from moderate to high.

Neurotransmitters

Norepinephrine and serotonin

Data have shown that both catecholamine norepinephrine (NE) and indoleamine serotonin (5-HT) are involved in depression, and research shows that several possible areas of pathophysiological processes in depression are linked to 5-HT and NE. For example, low levels of a metabolite for NE have been found for some patients, while low levels of a metabolite for 5-HT have been found in some subgroups of depressed individuals. One important source of data for the role of 5-HT in depression comes from tryptophan depletion studies. Tryptophan is a precursor to 5-HT and, when depleted, diminishes the availability of 5-HT. Studies have shown that depressed individuals who respond well to selective serotonin reuptake inhibitors (SSRIs) are more likely to experience a return of symptoms with tryptophan depletion. However, tryptophan depletion for depressed patients not taking SSRIs does not appear to cause a worsening of symptoms.

Research clearly shows evidence of biological dysregulation in depression, but several qualifications are important. For example, although a variety of biological processes are disturbed in depression, these processes do not characterize all cases of depression, nor are they necessarily specific to depression. Some biological processes appear to be stable in some depressions, such as decreased 5-HT, but other processes appear to be more characteristic of the depressed state and tend to normalize in recovery. Moreover, there is evidence that the subgroup of individuals who show evidence of biological disturbances tend to be older and more severely depressed. Moreover, rather than a cause of depression, it may be that disrupted neurotransmitters serve as risk factors for depression rather than as primary causes. Hence, one way to think about disrupted biological function is within a diathesis–stress framework, in that these variables may be necessary for the onset of depression but are not sufficient to bring about the disorder until they are triggered by stress.

Neuroscience approaches

Neuroscience focuses on the neural processes that are linked to cognition and emotion. Although neuroscience uses a variety of methods, the use of imaging techniques such as functional magnetic resonance imaging (fMRI) has become increasingly common. fMRI assesses the role and function of brain structures and regions during various tasks by creating images caused by the oxygen in the blood flow to brain areas that are active during these tasks. As such, fMRI can help to map the brain circuitry that may be involved in depression.

Neuroscience approaches have tended to focus most attention on the prefrontal cortex, the anterior cingulate cortex, the hippocampus, and the amygdala. Even though these anatomical structures serve numerous functions and are interconnected in complex ways, several functions that may be particularly involved in depression are highlighted. For example, depressed individuals have been found to evidence left-side activation deficits prefrontal; such deficits may reflect the disruption of goal-directed activities that frequently characterize depression. Some studies have also found that the children of depressed mothers exhibit a similar left-side hypoactivation, suggesting the possibility of a genetic link to this brain abnormality. Like the prefrontal cortex, decreases in the activation of the anterior cingulate cortex have also been found in some depressed individuals and are thought to be linked to social withdrawal and anhedonia that is sometimes seen in depression. Other data have shown reduced hippocampal volume in depressed patients, suggesting the possibility of atrophy because the hippocampus contains high levels of cortisol receptors; cortisol, which is neurotoxic, leads to cell loss. This idea is in line with some data showing that hippocampal atrophy is correlated with the duration of depression.

The amygdala, which is another brain region that has been linked to depression, has been shown to be hyperactivated in depressed individuals, and has been hypothesized by some investigators to be responsible for the maintenance of sad mood states. Moreover, not only is the amygdala linked to the preservation of sad mood, amygdala hyperactivation may result from the failure of the prefrontal cortex to inhibit this region. Hence, failure of the prefrontal cortex to inhibit the amygdala may precipitate the maintenance of emotional information processing in depression that perpetuates sad mood and interferes with adaptive functioning.

Certainly, other areas of the brain are involved in depression, but the prefrontal cortex, anterior cingulate cortex, hippocampus, and amygdala circuit appear to play a key role in at least some forms of depression. It is important to note, however, that much is still unknown about the neural circuitry of depression. For example, it is unclear if deficits in these areas are linked to the cause of depression, might co-occur with depression, or might arise as a result of depression. Moreover, because these brain regions are densely connected, it is difficult to determine whether one region is primarily linked to depression, while other regions are more secondary. Additionally, some researchers hold out hope that patterns of brain abnormality may themselves lead to different subtypes of depression.

Depth Perception

M R Watson and J T Enns, University of British Columbia, Vancouver, BC, Canada

© 2012 Elsevier Inc. All rights reserved.

Glossary

Cue The signal or information in a two-dimensional image that can be used to infer or reconstruct the spatial relations in a three-dimensional scene.

Depth Refers to the distance between a viewer and an object as well to the distance between two objects that extend away from a viewer. This is the missing dimension when depicting a three-dimensional scene in a two-dimensional image, whether the image be a picture or the pattern of light projected onto the retina at the back of the eye.

Fovea An area of the retina in the center of each eye in humans (as well as in the eyes of many other sighted animals) containing the most densely packed array of light-sensitive neurons. High-resolution vision is only possible when light from an object falls onto the fovea.

Heuristic A method for solving a problem that begins by first making certain assumptions (e.g., a gradation of shading in an image that runs vertically from light to dark corresponds to a surface with convex curvature, but only on the assumption that light is shining from above the surface and the viewer).

Image A two-dimensional projection of a three-dimensional scene from a specific viewpoint.

Retina(e) The array of light-sensitive neurons at the back of the eye. Light rays passing through the cornea and lens of the eye are focused on the retina and these retinal neurons convert the light into electrochemical signals.

Retinal image The array of light projected onto the retina through the cornea and lens of the eye.

Introduction

Depth perception is the ability of humans and other sighted animals to see objects as having volume (as opposed to seeing flat silhouettes) and to see the relative position of objects in a three-dimensional environment (as opposed to in a two-dimensional picture). This ability is crucial for everyday action. Pushing an elevator button requires information about the button's location relative to our eyes, which acquire the information, and relative to our hand, which must make contact with the button. Picking up a coffee mug requires knowledge of the volume of the handle relative to the cup and to our hand. Thus, depth perception enables interaction with our immediate surroundings. It also grants us information about objects and surfaces that are more distant from us, enabling us to consider future actions. In this article, we review how scientists from several interrelated fields currently understand the problem of depth perception, concentrating on how it is accomplished by humans.

Depth perception is complex and still not completely understood. It begins with the two-dimensional patterns of light that are projected onto the retina, the array of light-sensitive neurons at the back of each eye. When considered in this way – as the problem of recovering the third dimension from a two-dimensional image – depth perception is what scientists refer to as an ill-formed problem. That is, there are infinitely many arrangements of three-dimensional objects that could lead to the two-dimensional array of light that is projected onto the retina. To break this impasse, the visual system uses a wide range of heuristics that are applied to the depth cues that it considers. None of these problem-solving techniques is perfect, but used in combination, they are able to hone in on the likely three-dimensional source of the retinal images.

This article divides depth cues into two broad categories: those cues that are only useful in determining depth for objects

relatively near the eyes and those that are reliable over a wide range of distance, both near and far from the eyes. This is an important distinction because humans have evolved a specialized set of mechanisms for near distance vision, capitalizing on the fact that some of the biological apparatus for seeing can alter the nature of the image before it reaches the retina. This includes changing the shape of the lens at the front of the eye to selectively focus the retinal image (accommodation), changing the relative gaze direction of the two eyes to select one of many possible depth planes for sharp focus (vergence), and integrating different images from the two eyes to form a composite binocular image in the brain (stereovision). It is probably not an accident that these structural cues are useful when objects are a short distance from our bodies, enabling us to use these cues when acting rapidly to intercept or avoid objects. Among the cues that are more generally useful, for both near and far vision, we have further distinguished between those that are based on changes in the retinal image that occur over time (depth from motion) and the so-called pictorial or monocular cues (here referred to as static cues to depth).

Specialized Mechanisms for Near Distance

The depth cues that are restricted in their range of distance to within about 3 m (10 ft) from the viewer are known as structural cues, because they involve alterations to the images on the retina by physical changes occurring in a single eye or in the anatomical relations between the two eyes.

Accommodation

The cornea and the lens at the front of each eye are both curved, so as to focus rays of light on the retinal surface at the

back of the eye. In order to form a sharp image at a given distance, the curvature of the eye's lens is adjusted through contraction of ciliary muscles that surround the lens, with greater curvature for near objects and reduced curvature for distant ones. This process is called accommodation.

In healthy humans between the ages of 2 months and 45 years, the eye's lens is maximally curved when focusing on objects about 20 cm away (8 in.), and is flattest when focusing on objects at a distance of 3 m or more (10 ft). Neural feedback from the ciliary muscles signals the degree of curvature of the lens, which is one indication of the current focal distance of the eye, and hence of the distance of the object the eye is currently focused on, which enables accommodation to be used as a depth cue.

The lenses of newborns are curved to focus on objects about 20 cm (8 in.) away and cannot accommodate for objects at other distances. However, by about 2 months, full accommodation is possible. The material of the lens begins to become more rigid by the age of 20 years and by the time most people enter their mid-40s, the accommodative range of the lens has been sharply reduced. This condition is called presbyopia and is the cause of the widespread use of reading glasses and graduated spectacles in people over the age of 45.

There is some controversy over the utility of this cue in everyday situations because changes in accommodation are rather slow and the neural signal from the ciliary muscles is limited in its resolution. A more likely way in which accommodation contributes to the determination of distance is through the amount of blur that is caused in the image when objects are out of focus. Indeed, observers in controlled experiments are able to judge the relative distance of two spots of light in a completely dark room using only one eye, presumably because when one of the spots of light is in focus, the other spot is slightly blurred.

Vergence

The retina contains a small region of tightly packed receptors at the center known as the fovea. In order to see an object at high resolution, the eye needs to be pointed directly at the object such that light reflected from the object falls on the fovea. This is known as fixating the object. Humans typically make three to five fixations every second, moving their eyes to a new location in order to sample up-to-date, high-quality information about the scene they are viewing. Because the left and right eyes are at different locations in the head, separated by 5–6 cm in an adult, each eye must move differently to fixate the same object.

When the eyes move from fixating a distant object to a closer one, they rotate slightly toward each other (convergence). This increases the angle of convergence between the two eyes, measured as the angle formed at the meeting of two imaginary lines projecting from the pupil of each eye. When the eyes move from fixating a close object to a more distant one, they do the opposite, turning away from each other (divergence). The overall degree of vergence (referring to both convergence and divergence) can be estimated by feedback from the extraocular muscles that control the position of the two eyes, and as such, vergence is a potential cue for determining the absolute distance between the object currently being fixated and the viewer.

The utility of vergence as a general cue to depth is limited, however, by several factors. First, the eyes are already maximally diverged for objects more than 6 m from the viewer, making it potentially useful only as a near distance cue. Second, fairly common eye conditions such as strabismus and amblyopia render vergence ineffective. Third, the signal from the extraocular muscles is quite coarse. Yet, like all the other depth cues, when vergence information is combined with that from other cues, the precision of depth perception improves in a synergistic way. Notably, vergence and accommodation in concert yield more accurate judgments of the distance from the viewer to a single point of light than either cue does alone. Vergence can even be seen working in concert with other depth cues when it is technically unnecessary. For example, research has documented that viewers change their vergence angle when merely viewing pictures. That is, even though all objects in a picture are the same actual distance from the viewer, viewers display greater convergence when looking at objects depicted as closer in the scene than when viewing objects depicted as farther away.

Stereovision

Because our eyes are 5–6 cm apart, the images projected onto each retina are slightly different. This difference in images is a cue to depth called binocular disparity, which enables the experience of depth through the process of stereovision. This process combines corresponding features in each retinal image into a single representation that includes information about distance from the viewer.

We are not normally aware that our eyes contain different images of the same scene, but this can be easily demonstrated. Hold the index finger of each hand in an upright position directly in front of your nose, with one finger about 20 cm away (9 in.) and the other finger about 40 cm away (18 in.). Now focus your eyes on the more distant finger and take turns closing and opening each eye. As you do this, the nearer finger will seem to jump from one side of the farther finger to the other. If you now open both eyes together you should see that there are actually two images of the nearer finger. This is binocular disparity, which enables an accurate perception of depth. The greater the horizontal distance between the corresponding images of the same object in the two eyes (the two images of the closer finger in this demonstration), the greater will be its perceived distance from the object that is currently at the center of the fovea in both eyes (the farther finger).

The positions of an object in the two retinal images are systematically related to the distance of that object from the object that is currently at the center of the two images in each eye. In comparison to the rays of light that project from the fixated object to the center of each retina, light from an object that is closer to the viewer will fall slightly to the right of center in the left eye, and to the left of center in the right eye (this is called crossed disparity). Light from an object that is farther away from the fixated object will do the opposite, falling slightly to the left of center in the left eye, and to the right of center in the right eye (uncrossed disparity). For any object that is fixated, there is an imaginary region of space encircling the viewer at the same distance, called Panum's area. Objects at this distance have no binocular disparity,

meaning that the rays of light projecting from them fall an identical distance from the center of the retina in each eye. As such, these objects also appear to be at the same distance from the viewer as the object currently fixated. Objects outside this region will appear to be nearer or farther, depending on whether they produce crossed disparity (for nearer objects) or uncrossed disparity (for farther objects) in the two eyes. Moreover, the size of the disparity corresponds to an object's relative distance from the fixated object. The process of stereovision, therefore, allows the brain to infer the relative distance of objects on the basis of both the sign (crossed or uncrossed) and the magnitude (size) of the image disparities in the two eyes.

Stereovision can be exploited to create illusions of three-dimensionality, such as seen in Victorian-era stereoscopes, the popular twentieth century Viewmaster series of children's toys, and the glasses worn by audience members at modern three-dimensional films. Though the pictures used in such devices always include depth cues other than binocular disparity, such as occlusion, relative size, and shading (see section on Static Image Cues), it is possible to create a compelling illusion of depth using only changes in disparity, which means that stereovision is a more powerful depth cue than the other structural cues. Bela Julesz invented random dot stereograms at Bell Laboratories in the 1960s to demonstrate this. More recently, the concepts used in making random dot stereograms have been employed to generate the fascinating images known popularly as autostereograms or Magic Eye™ images.

As the name implies, a random dot stereogram appears initially as nothing but a group of dots in a chaotic pattern. However, some of the dots have actually been horizontally displaced relative to one another, such that verging the eyes either in front of or behind the depth of the picture allows an illusion of depth to pop out. When the eyes are focused to the correct distance, each eye's image of the dots is roughly the same, yet some of the corresponding dots in each image are displaced relative to each other. This binocular disparity generates the experience that a subset of the dot pattern has popped into the foreground relative to other regions of the dot pattern that now appear to be in the background.

In addition to demonstrating that stereovision can function independently of other depth cues, random dot stereograms also point to the complexity of the brain's stereovision mechanisms. This is because in order to perceive depth in the pattern of random dots, the brain must somehow know in advance which dots in one retinal image correspond to the same dots in the other retinal image. This is known as the correspondence problem, and like many problems in human vision, it is paradoxically both an ill-formed problem and yet one that the brain seems to solve effortlessly. The fact that it is ill-formed means that in the absence of any information other than that contained in the dot patterns, there are an infinite number of possible ways to align any two retinal images. The fact that the brain solves the problem without effort is interpreted to mean that the brain must be using a priori assumptions about regularities in the environment to solve the problem. A major challenge for vision researchers is to determine what those a priori assumptions are. What is already clear is that the process of stereovision comes to a conclusion more rapidly and more reliably when it is informed by other depth cues, including the monocular cues to depth reviewed later in this entry.

Human infants do not appear to possess functional stereovision at birth, but it develops quite quickly. By the time infants are 6 months of age, most will display stereovision at essentially adult levels. Like the other physiological cues (accommodation and vergence), stereovision is only effectively useful within distances of about 3 m (10 ft) from the viewer. Also, for some of the same reasons mentioned in the discussion of vergence (e.g., conditions of strabismus, amblyopia), between 5 and 10% of the general population does not have usable stereovision because of imbalances in the nature and quality of the information contained in the two eyes.

General Mechanisms for Near and Far Distance

Most of the cues for human depth perception are useful across a wide range of distances. Among these are the cues that derive from motion of objects in the scene and from motion of the viewer, as well as the cues that derive from features in an image seen only by one eye. Here we refer to these single-image cues as static cues, in order to contrast them with the cues available from analyzing motion, but readers should note that they are also called monocular or pictorial cues, since they do not require two eyes and are often used by visual artists.

Depth from Motion

The world is often in motion, giving rise to several rich sources of depth information. For example, when a stationary viewer sees an object in motion, there are systematic changes in what is visible over time. At the leading edge of an object in motion, features of the background that were previously visible will suddenly vanish as the moving object occludes their view (called surface deletion), while at the same time, other features of the background that were previously invisible will suddenly appear (surface accretion). The features of the moving object will remain constantly visible during this time, unless the object is rotating, in which case the systematic deletion and accretion of its features can be used as cues to its three-dimensional shape. Surface deletion and accretion from motion are therefore powerful cues for segregating objects from backgrounds and for determining object volume. These two cues alone are likely the most powerful contributors to the compelling nature of motion pictures, which are not able to benefit from any of the structural cues to depth we have already reviewed, simply because all the information in a motion picture is displayed at the same actual distance from the viewer.

When a viewer moves relative to stationary objects in a scene, and the viewer's eye remains fixated on one object, there are a number of cues to help indicate the relative distance of the various objects in the scene from the viewer. These are collectively referred to as the depth cues from motion parallax. Relative to the object that is at the point of fixation, objects nearer to the observer will move across the retina in the same direction as the observer, while objects further away than the fixated object will move in the opposite direction. Furthermore, the closer an object is to the observer, the faster will its movement be across the retinal image. These changes in the direction and speed of the images of objects across the retina are very effective guides to the relative positions of objects, although less effective for judging the absolute distance of objects.

Motion parallax is not only useful when a viewer is actively and intentionally moving, such as when walking or selectively moving one's head and eyes, but can also be used to accurately judge the relative distance of objects when the viewer is moving passively, as when sitting in a train or in a car watching the world move relative to oneself. However, there are important differences between motion parallax caused by active and passive motion. Most importantly, passive viewers do not generate any muscular feedback from their voluntary actions to refine their passive reception of motion, so the judgments of distance made in such cases are less accurate than when motion is self-generated.

When an object rotates with respect to both its background and a stationary viewer, there is a systematic pattern in the motion of its various parts across the retinal image. These motion patterns contain rich cues for determining the volume of the object. For example, when a car turns toward us, the regions of the retinal image associated with its various parts will move at different speeds, with, for example, the headlight farthest away from us moving at a faster rate than the closer headlight. These differential rates of motion provide the brain with rich information about the relative distance between various object features, thereby allowing the perception of three-dimensional shape to emerge from an analysis of motion patterns alone. This object-relative motion cue was called kinetic depth by Hans Wallach, who first systematically studied the perception of three-dimensional shape that occurs when viewing the shadows of moving objects on a screen, and more recently has been referred to as structure-from-motion by researchers studying the computational complexity of the problem.

When an object moves toward or away from an observer, the size of the region it occupies on the retinal image also increases and decreases proportionately, which is a depth cue from motion known as looming. A particularly important aspect of this depth cue is how symmetrical the changes on each side of the image of the object are. Specifically, a looming image that is expanding symmetrically and rapidly is consistent with an object that will soon hit the viewer on the head. In contrast, a looming image that is expanding asymmetrically is consistent with an object that will move past the viewer without a collision. Human vision is extremely sensitive to looming cues, likely for good evolutionary reasons, and these processes occur largely without awareness.

Research on the development of sensitivity to the entire class of motion cues to depth indicates that these are among the most primary. Newborn infants show sensitivity to the surface accretion and deletion cues of relative motion, to motion parallax, to structure-from-motion, and to looming. Indeed, the newborn startle response to a looming image includes eye blinking, cardiac slowing, and neck and limb stiffening, as though humans are innately programmed to avoid collisions with other objects.

Static Image Cues

Many of the static cues to depth available in static images can be illustrated by considering the beach scene shown in [Figure 1](#).

Researchers have noted that one of the first simplifying assumptions humans make when viewing such a scene is to

Figure 1 This beach scene from Santa Monica California depicts many of the static cues to depth, including edge intersections, attached and cast shadows, familiar size texture gradients, proximity to the horizon, and aerial perspective. Specific examples of each cue depicted are given in the text.

ignore unlikely possible arrangements of the world. One such unlikely possibility in [Figure 1](#) is that the beach umbrellas are really very different sizes, and have been carefully cut out and positioned into a mosaic pattern, such that they are all at the same distance from the viewer. The visual system ignores this possibility in favor of the more likely interpretation that the umbrellas are all more or less the same size and shape, and that they are positioned at various distances, so that the nearer ones occupy a larger retinal size and occlude our view of parts of the umbrellas that are farther away. This is known as the generic viewpoint assumption, because we assume that the image would not change drastically if our viewpoint on the image were to change slightly. Note, in contrast, that even a small change in viewpoint on this scene would quickly confirm or deny the unlikely mosaic interpretation of the umbrellas. So, in the absence of any evidence to the contrary, humans tend to view scenes, including flat pictures, under the assumption that a small change in viewpoint will not alter the spatial layout of the scene. The generic viewpoint assumption is the basis of a compelling and surprising form of visual art known as anamorphic sidewalk or pavement drawings.

The static depth cues that must be considered in conjunction with the generic viewpoint assumption will be presented here, for convenience, along a continuum from local to global. By local, we mean that a cue can be considered quite reliably in

isolation from other regions of the image; by global, we mean that a cue is based on information distributed over a large region of the image.

At the extreme local end of this continuum are the junctions that occur when edges intersect with one another in an image. Edge junctions contain some of the most reliable cues to relative depth in an image. For example, in [Figure 1](#), the edges of the large orange umbrella near the center terminate where they meet the edges of the two umbrellas in front of it, forming T-junctions. T-junctions are formed whenever one edge occludes the view of a more distant edge. The edge in front is continuous, whereas the occluded edge terminates at the intersection, making this a reliable local cue to depth. T-junctions are generally considered to be a local cue for what is classically known as the depth cue of occlusion or interposition.

L-junctions are also quite reliable cues to surface relationships in the scene, but must be used in conjunction with a convexity assumption, which is the assumption that, in the absence of any other information, surfaces in the world are more often convex (bulging out) than concave (indented). The convexity assumption applied to L-junctions suggests that the side of the L with the smaller angle belongs to the surface that is nearer to the viewer than the side of the L with the larger angle. L-junctions can be seen in all of the umbrellas in [Figure 1](#), and invariably they occur when an umbrella lies in front of a surface that is further away from the viewer than the umbrella in question.

A second important class of local depth cues concerns the three-edge intersections (i.e., Y- and arrow-junctions) that occur when surfaces are joined together at corners. Corners are extremely useful pieces of information about the three-dimensional shape of objects, and tend to be interpreted in the absence of other information as being convex rather than concave. Note in [Figure 1](#) how the three-dimensional shape of the orange umbrella is revealed by the intersection of its ribs. These edge intersections are ambiguous with regard to convexity–concavity when considered in isolation, but in conjunction with the convexity assumption, they provide rich information about the umbrella shape.

Shadows also convey information about depth. Researchers have found it important to distinguish between attached and cast shadows. In general, the region of a uniformly colored object that is relatively darker than other regions is said to be an attached shadow, so called because this region of the object is being blocked from receiving direct light by other parts of the same object. Attached shadows are particularly useful for determining the three-dimensional shape of objects. For example, in [Figure 1](#), the shadows on the white T-shirt of the young man standing near the front of the picture reveal the shape of his torso. One critical ambiguity that must be resolved in order to use this information to determine the three-dimensional shape of the surfaces is the direction of the light source. All things being equal, the visual system usually assumes that the light in the scene is assumed to be shining from above, which means that if the object has a convex surface, the region of attached shadow lies toward its bottom. However, if the light was actually shining from below, then the same pattern of image shading would indicate a concavity, and the assumption of light shining from above would lead us into error. The interrelatedness of these assumptions in human depth perception can be vigorously exercised by viewing the hollow mask

illusion, which occurs when our assumptions of convexity, light generally coming from above, and the familiar shape of faces come into conflict with one another.

Cast shadows help resolve this problem. This can be seen in [Figure 1](#), where the shadows cast by the umbrellas indicate that the sun is almost overhead. Cast shadows provide less information than attached shadows do about the three-dimensional shape of the object casting the shadow, because the shape of the shadow is dependent on both the position of the light source and the shape of the surface they are cast upon. However, they do provide a high-fidelity source of information about the relative positions of the objects in the scene with respect to the light source. The position of the inferred light source can then be used to more accurately judge the shape of objects on the basis of their attached shadows.

Cast shadows are also a rich source of information with regard to relative object position. For example, if a cast shadow borders directly on the object that is casting it, then the casting object is very likely resting on the shadowed surface. On the other hand, if there is a gap between the cast shadow and its casting object, then the casting object must be farther from the surface. The distance between an object and its cast shadow is therefore a cue for their relative positions in space. If this cue is combined with motion, it can be used to create powerful illusions.

Another, somewhat more global, static cue to depth can be derived from comparing the relative retinal size of the images cast by similar objects. In general, it is safe to assume that when two objects of a similar actual size differ in their distance from the viewer, the nearer object will project a larger retinal image. But note that the constraint of objects being of similar actual size rests on its own assumption, namely that the viewer is familiar with the objects and therefore knows that their sizes are similar. When this assumption of familiar size is met, as it is for our perception of the people in [Figure 1](#), then we can reliably see the people of smaller retinal size being farther away in the depicted scene. When some of these interrelated assumptions are violated, as occurs when two objects of similar size are depicted in different apparent locations from the viewer, then even familiar people can appear to vary greatly in their perceived size, as occurs in the Ames Room illusion.

An even more global version of the familiar size cue to depth occurs when linear perspective is used to infer relative distance in a scene. Just as objects of the same size will have smaller retinal sizes as they move further away from the observer, so too will parallel edges in a scene converge toward the horizon as their distance from the viewer is increased. The point at which these lines converge, either within the frame of an image or outside of it, is known as the vanishing point, and corresponds to infinity as far as depth perception is concerned. Note that these lines may be explicit, as occurs when depicting architectural drawings, or they may be implicit, as occurs if we look down a road bordered by trees of a similar height. Here the imaginary lines connecting the tops of the trees converge with the imaginary lines connecting the trunks to the ground at the vanishing point. Linear perspective is the depth cue developed most vigorously in Western art made since the time of the Renaissance until the invention of photography. It is especially effective when used to depict the depth relations among carpentered objects, presumably because these objects tend to have

many parallel edges to calibrate the interpretation of depth. When straight lines cannot be assumed in a carpentered scene, then our tendency to interpret the scene as containing linear perspective can go awry, leading to tantalizing ambiguities and even outright impossibilities, as in the art of M. C. Escher.

When the depth cue of linear perspective is combined with the depth cue of the relative retinal size of familiar objects, it leads to a global depth cue called the texture gradient. A texture refers to any collection of objects in an image, and a texture gradient refers to the pattern of changes in the relative size and spacing of these objects. For example, the beach umbrellas depicted in [Figure 1](#) form a semiregular pattern, becoming smaller and closer together in the retinal image as they correspond to actual umbrellas that are more distant from the viewer.

Texture gradients inform the viewer about depth through gradual changes in image size and spacing, as seen in the beach umbrellas in [Figure 1](#), and the discontinuities in the gradient are themselves informative because they indicate a sudden change in the orientation of a surface relative to the observer. For example, if we are in a room that has been tiled consistently on the floor and wall, we can use discontinuities in the texture gradients to determine changes in surface orientation. These occur where the floor meets the wall and where one wall meets another wall. In the famous study of human infant's sensitivity to a visual cliff by Eleanor Gibson and Richard Walk, only a texture gradient was used to signal to the infants that the surface beneath the glass floor they were crawling on consisted of surfaces at two different distances.

At the most global end of the continuum are several static depth cues that require a comparative analysis of almost the entire visual field. Proximity to the horizon (also known as relative height or height in the plane) refers to the observation that objects that are nearer to the horizon are generally seen as being farther away from the viewer than are objects that are farther away from the horizon. This means that below the skyline, more distant objects tend to be higher in the retinal image. Thus, in [Figure 1](#), the people in the water are seen as more distant than the man in the white T-shirt. Above the horizon, these relationships are reversed, with nearer objects in the scene being higher and more distant objects being closer.

Finally, aerial perspective is a global depth cue that is based on relative differences in contrast and color rather than on size or spatial position. When light travels through the air, it is either scattered or absorbed by various particles. This means that the light from distant objects travels through more air before reaching our eyes than the light reflected from nearby objects, with the consequence that less of a distant object's reflected light reaches the eye. As such, distant objects will tend to be more blurred than nearby objects (relative contrast), and they will tend to be darker (relative brightness). They will also have a bluish tinge (relative hue), because air molecules scatter shortwave blue light to a greater extent than light of longer wavelengths, and some of the blue light from the sun is scattered toward the viewer. This can be seen in the hills at the top of [Figure 1](#).

Not surprisingly, given the complexity and interrelatedness of the static cues for depth, these cues tend to appear more slowly in human development than the structural and motion-based cues. Sensitivity to edge intersections develops relatively early in life, with research suggesting that by 3–4 months infants are responding to T-junctions in an adult-like manner.

However, it is not until 6–7 months that most infants can respond reliably to linear perspective, texture gradients, familiar size, or shading. The reliable use of cast shadows may not be fully developed until 3 or more years of age.

Depth Perception in the Brain

There is currently much scientific interest in understanding how the various cues for depth are processed and combined by the neurons of the brain. The cue that has been studied most thoroughly in this regard is binocular disparity, which, as discussed in an earlier section, is critical for the computation of stereovision. Neurons that are tuned to specific binocular disparities have been found in numerous regions of the visually sensitive cortex of primates (including humans). Roughly speaking, the further removed these neurons are from the eye (by virtue of the number of synapses that must be crossed for information to reach them), the more accurate and refined is the stereovision they exhibit. Neurons in area V1, the first stage of cortical visual processing, are sensitive to stimuli in the two eyes that satisfy very loose criteria of similar disparity. Neurons in the next cortical region, area V2, function under stricter criteria, implying that more of the correspondence problem has been solved at this point. In keeping with this trend of increasing sophistication of processing as we move away from the eyes, neurons in higher cortical regions are also specialized to different *kinds* of disparity. For example, one class of neurons may respond only to abrupt changes in depth, whereas other neurons may register more continuously graded changes.

Conclusion

This review of depth perception in humans has emphasized what is currently known about the way various physical factors – both in the structures of the eye(s) and in features of the image – are used by the brain to achieve the experience of depth perception. The review organized depth cues into two broad categories: those specialized for depth at near distances, where direct bodily interaction with other objects is most likely, and those cues that work at any distance from the eyes. The near cues included changing the shape of the eye's lens (accommodation), changing the relative gaze direction of the two eyes (vergence), and integrating disparate images in the two eyes (stereovision). Among the cues more generally useful for both near and far vision, the review further distinguished between those that involve changes in the retinal image over time (depth from motion) and those that are effective when they appear in a picture (static image cues).

Glossary

Behavioral genetics A methodology for establishing the genetic and environmental bases of individual differences in observable behaviors or traits.

Equifinality Phenomenon in which different pathways may lead to similar expressions of pathology, that is, different initial states can lead to similar end states.

Etiology The causal processes and mechanisms underlying the development of a behavior or trait.

Heterotypic continuity Process when underlying mechanisms remain constant while the actual type or form of the manifested behavior changes with development.

Homotypic continuity Process when an observable behavior remains constant while the underlying mechanism causing the behavior changes with development.

Mediation Statistical model that seeks to explain the relationship between an independent and a dependent variable with the inclusion of a third explanatory (or mediating) variable.

Molecular genetics Study of association and linkage between DNA variants and observable behaviors and traits.

Multifinality Phenomenon in which similar initial pathways may result in different forms of dysfunction; that is, similar initial states lead to multiple possible end states.

Phenomenology Study of individuals' subjective experiences of an event, that is, an individual's unique experience of a psychological disorder.

Psychiatric comorbidity The co-occurrence of two or more diagnosable psychological disorders within one individual.

Psychopathology Atypical and/or maladaptive behaviors and mental/emotional processes.

Introduction

Psychopathology and its associated interpersonal, emotional, and financial costs impact society at multiple levels and across a variety of domains. Research investigating the causes, course, and outcome of psychopathology has the potential to provide enormous benefits to afflicted individuals, their families, and society in general by informing innovative and specialized prevention and treatment strategies for a variety of different disorders. Developmental psychopathology has emerged as a leading scientific framework for identifying the dynamic exchange processes that influence both adaptive and maladaptive behavior.

The developmental psychopathology perspective represents an integration of several distinct scientific disciplines, including genetics, neuroscience, and psychiatry, as well as experimental, clinical, and developmental psychology. Scientists working within this framework aim to use these multiple levels of analysis in order to uncover the mechanisms that give rise to and maintain psychological disorders. This work is anchored on the perspective that the processes underlying typical and atypical development are mutually informative. That is, the continuity between normality and pathology (or adaptive and maladaptive behavior) as well continuity among the underlying causal mechanisms is emphasized.

This article aims to provide an introduction to the developmental psychopathology framework, including discussion of its key concepts and principles, as well as potential challenges to psychopathology research. Antisocial behavior is then discussed as an example, in order to further illustrate the ways in which developmental psychopathology research is advancing knowledge regarding the phenomenology, etiology, and treatment of psychiatric disorders.

Key Concepts, Principles, and Challenges

The principles of developmental psychopathology have become main stream in both the larger fields of psychiatry and clinical psychology. At its core, developmental psychopathology is the broad study of the processes involved in the emergence and course of maladaptive behaviors. While there are many features encompassing the developmental psychopathology perspective, the key concepts and principles involve (1) the approach to the study of causation; (2) the heterogeneity of cause, course, and outcome; and (3) the emphasis on the trajectories and continuity between typical and atypical development.

Causal Processes

Unlocking the etiological factors that give rise to psychopathology undoubtedly offers great potential for advancing treatment and prevention. Recognition of the influence of genetic factors on psychological disorders and the innovation of behavioral genetics has greatly contributed to these efforts. Behavioral genetics, which relies on differences in genetic and environmental relatedness among family members to estimate genetic and environmental effects on a given condition, has been able to quantify the magnitude of genetic and environmental influences on virtually all forms of psychopathology. Advances in molecular genetics, specifically the mapping of the human genome, has inspired work seeking to identify specific DNA variants that may contribute to psychopathology. Importantly, for both behavioral and molecular genetics, influences from genetic and biological factors are typically conceptualized as *probabilistic* (rather than deterministic).

Consistent with the latter perspective, psychosocial and environmental risk factors are also thought to be essential to the development, course, and outcome of psychopathology. These include main effects related to prenatal development, the family environment, as well as neighborhood, community, ecological, and sociocultural elements. In addition, there is growing interest in understanding the exchanges between biological and environmental factors that confer risk and/or protection for psychopathology via studies of gene–environment interplay. Examination of this interplay has been pursued specifically via studies of gene–environment correlation (rGE) and gene x environment (GxE) interaction processes – two related but distinct mechanisms by which genetic and environmental factors influence one another. rGE refers to the extent to which an individual's genetic makeup influences their exposure to particular environmental factors. Alternatively, GxE interaction describes genetic differences in sensitivity to environmental exposures, such that certain environments only contribute to psychopathology for individuals with particular genetic variations. Work examining both rGE and GxE effects for psychopathology has surged in recent years and positive findings have effectively demonstrated that genetic and environmental factors do not operate in isolation from one another. This work has also has reframed the nature–nurture debate in psychology and behavioral sciences by adding weight to a growing consensus that both genetic and environmental factors are important in human development.

Heterogeneity

Two essential concepts, *multifinality* and *equifinality*, are key to the principle of heterogeneity in developmental psychopathology as it relates to causal mechanisms. *Multifinality* refers to the notion that a single risk (or protective) factor can result in multiple outcomes, whereas *equifinality* refers to the idea that a single behavioral dimension or category of psychopathology is influenced by multiple risk factors. Put another way, it is unlikely that a single risk or protective factor will be the sole necessary cause of one specific type of behavior or psychopathology. This greatly complicates the task of researchers attempting to understand the causes of psychopathology, and yet it is critically important for untangling the various causal pathways which can result in disorder across individuals.

In addition to heterogeneity in causal mechanisms, it is also important to consider heterogeneity in terms of behavioral presentation. The types of behavioral symptoms present at any one time, as well as the onset, course, and responses to treatment, often differ even within similar behavioral dimensions and/or diagnostic categories. Thus, subtyping forms of psychopathology in terms of symptom profile, onset, and course has become one particularly common and useful method for focusing on more etiologically homogenous subgroups within more multifaceted or multidimensional forms of psychopathology.

Developmental Continuity and Discontinuity

The developmental psychopathology perspective also highlights issues of continuity and discontinuity between normality and pathology. That is, developmental psychopathology is

focused upon understanding the dimensional aspects of behavior (i.e., the mean and the extremes), as well as the mechanisms that contribute to the etiology of behavioral continua. The primary notion here is that atypical or maladaptive behavior cannot be understood outside of the context of typical development and that each is mutually informative. The study of typical development has served to refine our understanding of psychopathology across many domains. For example, the emergence of theory of mind (i.e., the ability to attribute mental states to oneself and others) has been shown to be an important milestone of cognitive development in early childhood. Deficits in the development of theory of mind are now widely recognized as one core feature of autism spectrum disorders. In short, we cannot identify particular behaviors as psychopathological if we are not yet clear on which behaviors are normative at a given age. Importantly however, while the underlying liability for psychopathology may be conceptualized as dimensional, categorical decisions are often required for clinical and practical purposes (e.g., diagnosis and treatment).

In addition, the developmental context for behavior is an important consideration for the examination of psychopathology. The relative frequency or commonality of behaviors often changes with the developmental stage and what is typical at one stage may be atypical (or maladaptive) at another. Identifying specific trajectories of behavioral development (both common and atypical) may then also aid in making distinctions between normality and psychopathology. This distinction is critical for identifying maladaptive behavior itself, as well as for identifying the individuals that may be at risk for the development of further problems versus those whose atypical or problematic behavior may be more likely to remit with age and development.

Challenges

While the developmental psychopathology framework has provided numerous advantages for the examination of maladaptive behavior, multiple challenges (both theoretical and practical) remain. Put another way, the developmental psychopathology framework has also aided researchers in identifying specific issues that may introduce potential confounds or may complicate the interpretation of findings within the field.

Measurement

Developmental psychopathology research often relies on informant-based approaches on various measures (e.g., questionnaires, interviews, etc.) and is often limited by the extent to which individuals are reliable reporters of their own and others' behavior. The measurement of these behaviors is also sensitive to the informant's own expectations and the understanding of 'problematic behavior,' as well as their exposure to or familiarity with specific behaviors within a particular developmental context.

Heterotypic and homotypic continuity

Heterotypic continuity refers to the notion that the underlying mechanisms or processes that contribute to psychopathology may stay constant whereas the behavioral manifestation of that liability may change with development. By contrast,

homotypic continuity indicates that the behavioral manifestation may stay constant whereas the underlying mechanisms and processes may change with development. Longitudinal work that considers the developmental context and trajectories of maladaptive behavior across time and development is thus necessary for attempting to disentangle these processes. Such work is difficult for researchers to conduct, however, and thus heterotypic and homotypic continuity remain challenges for developmental psychopathology research and theory.

Comorbidity

In addition to issues with causal continuity, the co-occurrence or overlap between various (and presumably independent) forms of psychopathology remains an important issue for developmental psychopathology researchers. Maladaptive behavioral dimensions tend to be correlated with one another and may represent different manifestations of the same underlying liability. Alternately, there may be specific types of comorbidity patterns that represent etiologically distinct forms of psychopathology. In fact, comorbidity among psychiatric disorders is often the rule and not the exception and thus remains an important consideration. Indeed, by complicating the clinical picture, the presence of comorbidity can make it more difficult to identify the etiology, course trajectory, and specific impairments associated with any one particular disorder.

Sex differences

One final challenge related to developmental psychopathology work involves sex differences in frequency and behavioral expression. For example, autism and developmental delays tend to be more common among males whereas depression and anxiety tend to be more common among females. Similarly, the behavioral expression of aggression looks quite different across sex: whereas as boys are more likely to engage in physical aggression, girls are more likely to engage in social aggression (e.g., gossip, name-calling). Questions remain regarding whether these differences are due to sex or gender differences in terms of behavioral expectations and developmental context, sex differences in biological, cognitive, or social development, or potential sex-specific etiological mechanisms or pathways operating for various forms of psychopathology.

Onset versus course

Central to identification of the specific mechanisms involved in psychopathology are some additional principles regarding the potential ways in which causal processes are operating. Among these is the notion that the biological and/or environmental risk processes involved in the *onset* of a particular set of behaviors may be distinct or partially distinct from those contributing to the *course* or maintenance of maladaptive behaviors. Additionally, determination of the direction of environmental/socialization effects remains the key (i.e., the extent to which children influence their environments and vice versa). Longitudinal designs are particularly useful for examining these various distinctions and remain a popular and fruitful investigative tool.

In all, these principles and challenges remain at the core of developmental psychopathology research. We next turn to an exemplar case – antisocial behavior – to highlight the strengths of the developmental psychopathology approach.

Applied Example: Antisocial Behavior

Antisocial behavior represents one behavioral domain in which the developmental psychopathology approach has proven extremely useful. Antisocial behavior refers to a cluster of problematic and disruptive aggressive and rule-breaking behaviors, the core of which involves persistent violations of societal norms and the rights of others (e.g., bullying, stealing).

Causal Processes

It is now well-established that there are significant genetic influences on antisocial behavior, accounting for approximately 50–60% of the variance in the population. Genes may also influence the types of environments individuals seek out as they mature (e.g., antisocial adolescents may actively seek out and chose to associate with delinquent peers, i.e., an example of active rGE). Molecular genetics has also recently begun to identify specific genetic variants that increase the likelihood of developing antisocial behavior. To date, there are several promising genes of interest, mainly related to dopamine and serotonin neural transmission.

Additionally, research has also focused upon identifying the ways in which an individual's genetic make-up may influence their sensitivity to environmental risk factors, referred to as a GxE interaction. Indeed, one of the first and most influential studies of GxE focused upon examining these processes in relation to antisocial behavior. Here, the effects of childhood maltreatment on the development of antisocial behavior varied, depending upon the form of a gene (specifically a gene involved in dopamine neural transmission). That is, for children with the low activity gene, the relationship between maltreatment and antisocial behavior was strong. However, for those with the high-activity form of the gene, the relationship between maltreatment and antisocial behavior was significantly attenuated. Thus, mistreatment may effectively act to 'turn on' genes of risk.

Researchers are also aware that environmental influences are not necessarily independent of genetic risk. Indeed, yet another line of work has focused upon identifying rGE processes, where by genes exert their influence via nonrandom exposure to particular environmental experiences. In the case of antisocial behavior, biological parents both pass on any genes of risk for the behaviors and may also create an aversive environment through their own antisocial acts (i.e., a passive rGE). In contrast, children who engage in antisocial behaviors tend to evoke harsh, rejecting, and inconsistent parenting practices (even when these parents are not biologically related and thus do not share the genes for antisocial behavior, referred to as an evocative rGE).

In sum, genetic and environmental risk and protective factors are thought to influence the onset, development, and maintenance of antisocial behavior through a variety of complex and dynamic processes. These processes include both environmental mediation of genetic risk (as illustrated above) as well as genetic mediation of environmental influences. Work exploring this complex interplay between genetic and environmental risk factors for antisocial behavior will likely remain an active area of research in the years to come.

Heterogeneity

Researchers have identified many demographic, personological, and psychosocial factors that are associated with antisocial behavior. Child sex emerges as a particularly salient risk factor, as boys and men are much more likely to display antisocial behavior than are girls and women. Moreover, children who are impulsive and sensation seeking, and who exhibit low levels of prosocial behavior and high levels of emotional instability, are at greater risk for developing antisocial behavior. A number of environmental factors have also been related to antisocial behavior, including prenatal complications, low birth weight, maternal substance use during pregnancy, low socioeconomic status, association with delinquent peers, and certain family and neighborhood characteristics. Importantly, intervention studies have also emerged as an important tool for examining the etiological role of various environmental factors, as possible causal mechanisms can be extrapolated from successful treatment strategies (e.g., interventions which target the parent-child relationship have been shown to be successful in treating children with disruptive behavior problems). The multitude of both genetic and environmental risk factors associated with antisocial behavior can be interpreted as consistent with the concept of equifinality – that different factors all contribute to the same outcome.

That said, multifinality is also present, in that many of these same factors are also predictive of other psychopathological outcomes. For example, identified family and parenting characteristics including discordant marital relationships, inadequate parental supervision, punitive disciplining strategies, physical or sexual abuse, and neglect as well as neighborhood risk factors (e.g., living in a high-crime area) are all predictive of antisocial behavior as well as depression, anxiety, and inattention and hyperactivity. In addition, antisocial behavior rarely occurs independently of these other psychological problems, and is commonly comorbid with inattention and hyperactivity.

Heterogeneity is also operating in terms of the types of processes underpinning the development of antisocial behavior. For example, some studies suggest that the impact of the familial and contextual environment on the development of antisocial behavior may be greater (and that of genetic influences lessened), when living in a poor, high-crime neighborhood. In sum, research in antisocial behavior has shown heterogeneity not only in terms of the types of risk factors but also with the types of mechanisms that may underlie its development.

Developmental Continuity and Discontinuity, Challenges, and Future Directions

Like many other forms of psychopathology, understanding the nature of antisocial behavior and its causes is dependent upon both its relation to typical behavior and developmental context. For example, physically aggressive behaviors are quite common among toddlers and preschool children (more than 50% of toddlers bite, kick, or hit). However, the behavior becomes less developmentally appropriate as children age, and thus behaviors we consider essentially normative (if unpleasant) in

3-year-olds would be markedly atypical in adolescents. By contrast, the less severe rule-breaking behaviors within the broader construct of antisocial behavior (e.g., shoplifting, vandalism, lying) occur relatively frequently among adolescents (and particularly adolescent males), but are rare during childhood. Future research on antisocial behavior needs to consider these issues of continuity and discontinuity.

Measurement of antisocial behavior is complicated by many contextual factors. Often researchers rely upon parent or teacher reports of a child's behavior, or self-report measures. These measurement techniques are prone to many sources of potential bias, including limited parental knowledge of typical versus atypical child behavior, as well as influences of informant personality and/or psychopathology, and their psychological state at the time they fill out the report. For their part, children may struggle to accurately reflect on their own behavior, and respondents of all ages may not wish to disclose antisocial acts (even when guaranteed anonymity). In an attempt to circumvent some of these difficulties, researchers often obtain data from multiple informants, including observer ratings of videotaped behavior.

Regardless of the informant, however, questions also arise regarding the demarcation between typical and atypical or maladaptive behavior, as well as changes in the manifestation of antisocial behavior with age. The context in which the behavior occurs as well as the developmental timing of the behavior is critical for making these distinctions (see above example of physical aggression in 3-year-olds as compared to adolescents). Furthermore, mechanisms underlying antisocial behavior may stay constant, while the behavioral forms (e.g., physical aggression, rule-breaking behaviors) may change with development, an example of heterotypic continuity. Alternately, there may be homotypic continuity operating, such that the types of behavior may stay relatively constant throughout the lifespan, however, the processes and pathways influencing these behaviors may change. In line with this, the processes that influence the onset of antisocial behavior (i.e., those that influence aggression in toddlerhood) may be distinct or partially separable from those that contribute to the continuation or maintenance of these behaviors across development. These issues still need to be resolved, and research in antisocial behavior is increasingly relying upon longitudinal designs to capture and examine these developmental complexities.

In all, the integration of a broad range of scientific disciplines within the developmental psychopathology framework has aided in identifying the complex exchange processes that contribute to both typical development as well as psychopathology. The heterogeneity of causal processes and outcomes, the multifinality and equifinality of risk and protective factors involved in psychopathology, as well as comorbidity and measurement issues create many challenges for the study of antisocial behavior (and for psychopathology more broadly). Yet, the recognition of these complexities has been critical to many advances in our understanding of the onset and course of maladaptive behavior. While much work remains to be done, the developmental psychopathology perspective provides a useful framework for both identifying causal mechanisms as well as for applying this knowledge toward to the development of effective prevention and treatment strategies.

Glossary

Construct A hypothetical entity in brains that is assumed to exist because of a regular pattern of activation and behavioral response to particular cues.

Disgust A system in animal brains that orchestrates behavior that serves to avoid infection.

Hygiene Behavior that serves to avoid sources of infection.

Parasite An organism living on or in another, dependent on it for at least a part of its life cycle and causing damage to the host.

Pathogen A microorganism living on or in another, dependent on it for at least a part of its life cycle and causing damage to the host.

Introduction

Most people have had experience with disgust. Confronted with feces, vomit, dead animals, or bad-smelling food, we react aversively, removing ourselves from contact with the offending object, turning up our noses, saying 'Yuck!' and experiencing unpleasant feelings akin to nausea. But what sort of a thing is disgust? In common with many psychological phenomena, disgust is a construct: a black box we assume to exist in brains because encountering particular cues occasions a regular pattern of response. However, disgust is a slippery construct; the events and objects that occasion it are extremely diverse, ranging from certain organic objects, animals, and people, to unhygienic, transgressive, and immoral behavior. The response is also highly diverse; it includes physiological changes such as lowered heartbeat and galvanic skin response, activation of the basal ganglia and insula, and a variety of facial expressions. It also includes diverse behavioral responses, including laughter, pointing out the object to others, distancing oneself from the object, or approaching so as to remove or clean up the object of revulsion. To a lay person, the one constant factor that is diagnostic of disgust is its accompanying affect – without the feeling of disgust the disgust construct is not activated.

Disgust is thus something of a puzzle. Why should such a wide variety of stimuli occasion this variety of responses and such strong feelings? Though disgust has never been a particularly popular area of scientific study, a variety of psychologists, philosophers, and social scientists have tried to come up with coherent explanations for this phenomenon. In this article, I argue that these attempts at explanation fail, or are at best incomplete, when they do not take into account the evolved function of the disgust system. Taking a biological perspective, I show how animals of all taxa, including humans, have had to solve the problem of parasites: organisms smaller than themselves that attempt to make a living on, or in, their hosts. Animals have evolved a variety of systems to reduce the fitness costs of infection, including coherent self-repairing skin and complex immune systems. They have also evolved behavioral defenses to parasites, avoiding encountering and incorporating them. This behavior is produced by the disgust system, which serves to detect cues that parasites may be present, and to orchestrate relevant protective behavior. Here I describe a selection of disease-avoidance behaviors in animals, and show the

continuity with human parasite-avoidance behavior. I also explore the areas where human disgust has diverged from that of other animals; where its use extends into the moral domain. I argue that the current burgeoning of scientific work on disgust would be more successful if it took better account of disgust's evolutionary purposes.

Attempts at Explanation

Humans report that they are disgusted by a bewildering array of objects and events. These include spoilt or unfamiliar foods, bodily wastes, body contents, dead bodies, poor hygiene, certain sexual activities, certain animals and insects, sick, deformed, or poor people and those seen as outsiders, as well as dirty environments. Actions that imply certain sorts of immorality, including transgression, hypocrisy, and cruelty, are also commonly reported as disgusting.

There have been many attempts at understanding why all of these things should be disgusting. Prescientific explanations made disgusting things offences against God. Later attempts at explanation in the philosophical, anthropological, humanities, and psychological literatures have been almost as unscientific. They made disgust part of the psychodynamics of the repression of desire, or a product of the ordering of society, or of magical folk thinking. Darwin began the scientific exploration of disgust but sent scientists down a number of blind alleys. The current standard approach in psychology explains disgust using a complex composite of these approaches. Recent evolutionary approaches offer a more rational basis for the study of disgust, as I shall argue.

Ancient societies considered disgusting matter and behavior as offenses against the divine. Early religious texts include lists of the unclean such as the 12 impurities of the body ('Oily exudations, semen, blood, the fatty substance of the brain, urine, feces, the mucus of the nose, ear-wax, phlegm, tears, the rheum of the eyes, and sweat ...') in the laws of Manu, one of the sacred texts of Hinduism dating from about 200 BCE. Ancient Greek texts describe the pollutions of childbirth, death, sex, and murder. The abominations of Leviticus include body wastes and deviant sexual practices. Purification rituals were codified to return the offender to a state of purity, thus reducing their threat to society and to the divine order.

Charles Darwin provided one of the earliest discussions of the function of disgust. From linguistic evidence, he proposed that disgust's original purpose was the avoidance of things offensive to the taste. He asked leading questions of his correspondents around the world and from this concluded that the facial expression of disgust was universal in humans. He also related anecdotes about disgusted turkeys and baboons.

Whilst Darwin emphasized the universality of the emotion, Herbert Spencer was one of the earliest of a long line of anthropologists to insist on the differences between what different cultures found disgusting:

Here human flesh is abhorred, and there regarded as the greatest delicacy; in this country roots are allowed to putrefy before they are eaten, and in that the taint of decay produces disgust; the whale's blubber which one race devours with avidity will in another by its very odor produce nausea.

The social anthropologist Mary Douglas did most to entrench the view that disgust is a product of culture. She tackled the much-puzzled-over topic of the different food taboos of different religions and from this extracted a broad theory of culture. Following Durkheim and Mauss's idea that classification is inherent in the organization of social life, she decided that dirt is a by-product of order. Accordingly, anomalous objects and events that do not fit the local cosmology have to be rejected, and classed as dirty or impure, as otherwise they would pose a threat to the social order. The caste system in India is Douglas's paradigm case. Human wastes are anomalous materials, neither alive nor dead, both belonging to, but rejected by, the person. Hence wastes such as feces are dirty and polluting. Humans who deal in wastes become symbolically impure and the rejects of the social system: the castes that henceforth have to be kept apart for fear of social disorder [3]. Douglas' approach is widely cited in anthropological and cultural studies.

Freud had disgust serving a purpose different from that proposed by Douglas. For him, disgust served the psychodynamics of the repression of desire, defending the brain against its baser tendencies. Children are taught to repress their urges, keeping their animal *id* in check by learning to be disgusted. Learning disgust of feces during toilet training represses any temptation to want to contact or eat them. Disgust of the bodies of others reduces the temptation to give in to lust at every opportunity.

In 1927, Aurel Kolnai wrote the first scholarly work entirely devoted to the subject of disgust. Using the phenomenological approach current at that time, he provided a careful account of the experienced emotion, painting a near complete picture of disgust's domains. For him, biological disgusts include putrefaction, excreta, secreta, dirt, animals, and insects – especially crawling ones – certain foods, the human body in too close contact, exaggerated fertility, disease, and deformity. His moral disgusts include excess and satiety, lies, deceit and corruption, moral weakness, and sentimentality. But Kolnai's explanation was in the Freudian tradition. For him, disgust served a balancing function, in encouraging the avoidance of excess, surfeit, and a desire toward death.

As a practicing psychiatrist, Andres Angyal puzzled over the things his patients found disgusting. He found a pattern of disgust objects being "base or mean, capable of permanently

permeating anything they have contacted, leaving a lingering, unpleasant after-sensation, even after washing the hands." For Angyal, disgust objects often had a sense of the uncanny – they may be cold or clammy and imply death. From a few anthropological accounts he concluded that disgust is more universal than culturally specific, and that it operates independent of any knowledge about disease or microbes. However, the nearest he came to an explanation of the patterns he described is that wastes belong outside and it would be a perversion of nature for them to be taken back in.

Today the most cited source for explanations about disgust is the work of Paul Rozin and Jon Haidt. These authors use a composite approach mixing Darwinian, cultural, and Freudian ideas with folk magic. For them core disgust is centered on all animals and their products, as potential foods. In their most recent summary (in the *Handbook of Emotions*, 2008) they suggest that disgust evolved out of distaste, and then expanded to include reminders of our animal nature, certain types of interpersonal contact, and moral violations. They suggest that this core is based on a widespread fear of oral incorporation of substances that might change one's nature, based on the magical folk belief that 'you are what you eat.' They explain the rejection of contaminated foodstuffs that have come into contact with offensive objects or persons with the law of sympathetic magic: 'once in contact, always in contact,' and the law of similarity: when objects that look like something disgusting then they are disgusting. For Rozin and Haidt, cultural dietary and food preparation rules serve to separate foods from their animal nature and help us not to think too hard about the process that brought them to our plate. Otherwise we would not be able to consume them.

These authors suggest that the fear of oral incorporation of animal products has since spread beyond the mouth to the rest of the body. Hence inappropriate sexual acts, poor hygiene, death, and violations of the ideal body 'envelope' or exterior form (e.g., gore, deformity, obesity) are also found disgusting. However, now the concern is Freudian in origin, where disgust represses a drive toward death. They postulate that humans have to deal with the existential terror of knowing that they are animals and, as such, are condemned to die. Disgust develops to repress thoughts of mortality. Hence certain sexual acts and envelope violations remind us of our animal nature, and poor hygiene places us below the level of humanity. Disgust thus protects both the body and the soul from pollution. They describe a further category of interpersonal disgust as a response to strangeness, disease, misfortune, and moral taint. They also set out evidence that disgust may be elicited by certain moral violations, especially in the domain of purity and sanctity, and maintain the view that disgust is unique to humans.

A number of writers in the humanities have also explored the phenomenon of disgust. William Ian Miller continues the Freudian concern with mental balancing, concluding that "ultimately the basis for all disgust is us – that we live and die and that the process is a messy one emitting substances and odors that make us doubt ourselves and fear our neighbours." He also concurs with Kolnai that we are disgusted by that which is too much alive. Robert Rawdon-Wilson explored disgust in all its facets, and found it has many positive uses, for example in humor that ridicules immorality, and in marking where social boundaries can and cannot be transcended.

However, he ultimately labeled it ‘the Hydra’ because he found it too complex to explain.

None of these approaches provide a satisfying scientific solution for the puzzle of disgust. None can explain why such a wide variety of objects and actions cue disgust, or why they produce typical behavioral reactions of disgust. If we are to understand disgust we need to look elsewhere; we need to make reference to the process that designed brains and behavior – evolution. We need to ask what adaptive purpose is served by the disgust system in the brain.

A small, but increasing number of scientists, including Dan Fessler, Debra Lieberman, Mark Schaller, Richard Stevenson, and my group, are exploring disgust from an evolutionary perspective. For us, there is a simple and parsimonious solution to the puzzle of disgust: disgust systems evolved to defend animals from attack by parasites, the tiny, usually invisible, predators that attack by stealth and eat their hosts alive. It orchestrates behavior that encourages animals to avoid the sources of pathogens – whether in the environment, in other animals, or the parasites themselves. That disgust in humans is a product of evolution does not, of course, mean that it does not vary from individual to individual, or from culture to culture. Indeed evolution has designed such systems to be responsive to local conditions. Individuals inherit differing propensities to disgust and individuals tune their disgust responses over their lifetime according to experience and local cultural rules. This is one of the reasons why previous work has found disgust to be a hydra, having multifarious forms in multiple settings. But disgust does have a single basic function: it evolved to orchestrate the avoidance of parasites.

The Problem of Parasites

Parasites are everywhere. Viruses, bacteria, plasmodia, rickettsia, and multiple species of worms and ectoparasites swarm throughout, and over, all animals. The total biomass of parasites on planet earth is greater than that of predators. Parasites cause damage to their hosts by consuming resources, releasing toxins, manipulating their behavior, and spreading to kin and community. Parasites thus exert a selection pressure on their hosts – encouraging them to develop systems to minimize the damage they suffer to their evolutionary fitness. All taxa have immune systems that serve to track down, immobilize or kill pathogenic parasites. All taxa that have been studied also display behavior that serves to minimize contact with parasites, before they can infect the host. This has been dubbed ‘the behavioral immune system.’ In humans (and, debatably, in other animals), this pathogen-avoidance behavior is orchestrated by the disgust system.

The disgust system has a difficult task; it has to recognize a possible risk of infection without being able to detect tiny or invisible parasites directly. One way of doing this is to avoid close contact with conspecifics, especially those that show signs of sickness. Another is to avoid other animals that may be carrying parasites, or indeed, anything that looks like a parasite. A third way is to avoid environments and objects where parasites might be lurking.

Pathogen/parasite-avoidance behavior has been found in the animal kingdom wherever it has been studied. Many

animals avoid others that show signs of sickness. So, for example, the sociable Caribbean spiny lobster *Panulirus argus*, refuses to share a den with other lobsters who are infected with the lethal PaV1 virus, which is transmitted by physical contact. Bullfrogs, *Rana catesbeiana*, suffer from a yeast infection that reduces their mobility and can kill them. Given the choice, healthy tadpoles avoid going anywhere near those that have the infection. Similarly, when experimenters injected Killifish, *Fundulus diaphanous*, with black inkspots to mimic the effects of a common parasite, other killifish avoided shoaling with them. Social primate species will generally only accept a new member into the troop after a long period of quarantine, which includes stressful attacks to expose the state of health of the candidate member. Candidates showing signs of sickness remain marginalized.

Like the animals that avoid sick conspecifics, humans also avoid others that show signs of sickness, and we also find signs of sickness in others disgusting. **Figure 1** shows a photograph of a man’s face which we manipulated to look ill by painting on spots, and mimicking signs of fever. This was scored as twice as disgusting as the same individual in a healthy state by over 40 000 respondents in a web survey. **Figure 2** shows an infected wound, which was scored as 27% more disgusting as a clean burn in the same experiment. **Figure 3** shows that an empty underground train was scored as much less disgusting than one that was full of people. Few humans are prepared to come into close contact with and share bodily fluids with others, whether they are healthy or not, except in particular overriding circumstances, such as for pair bonding or child

Figure 1 Average disgust score of two facial images.

Figure 2 Average disgust score of two wounds.

Figure 3 Average disgust score of two images of an underground train.

care. In a more recent wide-ranging web survey, we found that signs of infection on genitals and poor genital hygiene were amongst the strongest elicitors of disgust.

Animals can, in some cases, detect and avoid or remove parasites directly. *C. elegans*, the tiny and much-studied nematode worm which has only 302 neurons to its name, can tell the difference between pathogenic bacteria, from which it flees, and prey bacteria, on which it feeds. Fish detect and swim away from the cercariae of eye flukes that can cause blindness. Animals also expend a lot of precious energy on removing damaging ectoparasites. Cattle swish their tails to drive away biting tsetse flies, fish scrape themselves to remove fish lice, vampire bats scratch to remove batflies, and impala use their teeth as tick combs. If impala or doves are experimentally prevented from grooming themselves, lice and ticks multiply. Over 250 species of bird are known to 'ant'; rubbing crushed insects such as ants or millipedes over their plumage. This behavior distributes compounds such as formic acid that protect from parasitic bacteria, fungi, and arthropods. Chimpanzees have been seen engaged in penile hygiene-wiping themselves off with leaves after mating. Some animals will pay highly for a groom to rid themselves of parasites; cleaner fish remove ectoparasites but also bite off bits of healthy flesh, and a study of long-tailed Macaques, *Macaca fascicularis*, revealed a biological market system where males paid for sex at the going rate in the currency of time spent grooming.

Humans also expend considerable effort and funds in grooming themselves and others to remove ectoparasites such as lice and scabies mites. Figure 4 shows a head louse, which was found significantly more disgusting than a wasp in the photographic comparison. Humans recognize and avoid parasitic species of worm and find them disgusting. Figure 5 shows *Ascaris* worms which were scored as more disgusting than caterpillars. Humans are further disgusted by species of animals that can vector parasites such as flies, cockroaches, rats, bats, snails, and pigs.

Animals also have to be careful not to come into contact with places where parasites might be lurking. When *Daphnia* are forced by fear of predation to swim near the muddy bottom

of a tank, they acquire more parasites. Ants avoid making nests in the vicinity of ant carcasses; birds abandon nests that are infested with parasites. Many insects have tricks such as 'frass-flinging' or 'turd-hurling' to keep their environment free of feces, penguins eject projectile poo, and tapirs, badgers, and blind mole rats use latrine sites. Sheep avoid feeding on pasture that is heavily dunged, and it has been suggested that the reason why many herbivores, such as reindeer and caribou, migrate is to avoid parasite build-up in calving grounds. Anecdotal evidence suggests that human nomads also move on when camping grounds get too insanitary.

Like other animals, humans avoid substances in the environment that might harbor parasites. In our web survey, urine and excrement, as well as sticky door handles and filthy buses, were rated highly disgusting. Figure 6 shows that a plate of food looking like bodily wastes scored more highly than a plate of what looked like inorganic matter.

Humans have a further ability, that it seems is not found in other animals: to track contamination. When an object of disgust comes into contact with a previously nondisgusting object, the second object can become disgusting. So for example tooth brushes, eating implements, or bedclothes known to have been used by strangers tend to be rejected. This response is what Steven Pinker has called 'instinctive microbiology.' Objects that harbor microbes can deposit microbes on the surface of other objects; hence these others become as disgusting as the original source.

Since the problem of parasites is common to all animals, including humans, it is not surprising to find that the basic avoidance behavior of humans is similar to that of other animals. Like other animals, humans avoid close contact with most others of the same species, especially if they are sick; they avoid other species that are parasites or parasite vectors; and they avoid environments and objects where parasites and pathogens are likely to be encountered. This gives us a parsimonious explanation for why humans should have a disgust system. From this perspective, then, disgust is the construct in the brain that takes cues of potential parasite presence and then orchestrates the behavior that serves to avoid them.

Parasite detection and avoidance was a hard problem to solve for a number of reasons. Apart from the problem posed by their size, there is also the problem of their indirect effect. While animals can learn from painful experience with predators, sickness does not usually immediately follow pathogen contact, so it is hard to learn what to avoid from experience of what has caused illness. A further problem animals have to solve is that it can be costly to avoid parasites. Refusing to consume rotten food may cause one to miss an opportunity for a scarce meal, and avoiding a sick person may cause one to miss a mating opportunity, for example. Over evolutionary

Figure 4 Average disgust score of two insect images.

Figure 5 Average disgust score of worms and caterpillar images.

Figure 6 Average disgust score of two plates of 'food'.

history, the genes of those animals which, on average, did best at solving these parasite-posed problems did better at passing on their genes.

Have we now solved the puzzle of disgust by invoking the disease avoidance function? Well, not quite. It is easy to see why the main disgust elicitors should be avoided: spoiled foods, bodily wastes, body contents, dead bodies, poor hygiene, certain sexual activities, certain animals and insects, sick, deformed, or poor people and those seen as outsiders, as well as dirty environments can all harbor pathogens and hence pose a risk of infectious disease. Objects that have contacted any of the above may have also been contaminated with microbes; hence the disgust associated with contagion. Questions, however, remain about why unfamiliar foods should elicit disgust and also about the evolutionary purposes of moral disgust.

Disgust of Unfamiliar Food

Humans are omnivores who live in a huge range of ecological zones. In principle, humans could eat almost any living thing; however, given the potential for foods, especially those of animal origin, to contain pathogens and parasites, it makes sense to be neophobic. Since the current social group is still alive, it is probably a good rule of thumb to eat what others in the current environment are eating. This is, in fact, what happens in humans (similar patterns are observed in another omnivore, the rat). Children are prepared to eat a huge variety of foods that are fed to them by their family until the age of about 2 years. Then an extreme reluctance to try new foods sets in. This helps explain why food rules differ between cultures and why disgust is often evinced by people offered unfamiliar types of food, especially those of animal origin. Though disgust's core concern with infection prevention is constant, the way in which it is expressed in individuals is developmentally, and adaptively, tuned.

The final piece of the disgust puzzle is why certain sorts of immorality – including transgression, hypocrisy, and cruelty – are also commonly reported as disgusting.

Moral Disgust

We recently asked 77 UK-based adolescents to list what they found morally disgusting. Top ten on their lists came rape, racism, murder, torture, bullying, pedophilia, discrimination, necrophilia, genocide, and exploitation. High on the list also came stealing, abuse of trust, and corruption. Two concerns can be distinguished here. One is moral outrage concerning taking unfair advantage, especially in the maltreatment of the weak. Some of these outrages also involve exposure to bodily fluids and so are doubly disgusting. While the latter concern has already been explained, why is it that unfairness, cruelty, and exploitation are found to be morally disgusting?

One explanation that has been offered is that the word disgust is being used as a metaphorical sense. The disgust of moral offenses is like that felt for infective organic material but is not the same. People use the word disgust for a feeling of revulsion for moral violations. But this is not, in fact disgust; it is more akin to anger. However, a recent series of fMRI studies

have suggested that there is considerable similarity in the activation patterns of moral and organic disgust. People offered unfair deals in an ultimatum game, for example, show activity in the anterior insula, a locus that is characteristic of disgust. The same facial muscles are involved in the expression of both moral and organic disgust. More recently, a series of studies have shown interactions between the two; priming with an organic disgust, or sitting beside a smelly waste bin makes moral judgment more severe, while hand washing can assuage feelings of moral guilt.

It thus seems likely that while the proper domain of disgust is the avoidance of the likely sources of infection, it has evolved an extended domain in humans that causes aversion to morally reprehensible behavior. One explanation may be that instead of responding to the likely presence of a parasitic organism that threatens bodily resources, the brain is responding to cues that an individual is behaving like a parasite, using unfair means to take more than his or her fair share of social resources. Racists gain unfair advantage by denigrating others; pedophiles, rapists, and bullies take advantage of the weak, while necrophiliacs abuse bodies that cannot defend themselves. Revulsion from such parasitic behavior leads to shunning of the perpetrators, and their exclusion from the benefits of social life. The threat of punishment by exclusion is a powerful one, and one that helps keep individuals behaving cooperatively. Disgust thus serves to police the boundaries of society, keeping social parasites out, in a way that is functionally equivalent to the purpose it serves in keeping parasitic organisms out of the host body.

While this explanation fits the pattern of moral disgusts, by what mechanism could disgust of the organic sources of infection have been exapted to extend to revulsion for the social parasite? Here we can turn again to animal models for some insight. While few animals are as ultrasocial as humans, the eusocial insects including ants, termites, wasps, and bees live colonial and cooperative lives. Like humans, insects have to deal with threats from parasitic species, which threaten them as individuals and as a colony. Ants, for example, clean food of parasitic fungal spores; bees remove sick individuals from the nest and prevent sick individuals entering; termites warn of parasites through a special dance. Further, individuals of the same species can act as parasites. In the social Hymenoptera, including most ants, Apis honeybees, Meliponinae stingless bees, and Vespinae wasps, workers retain ovaries even though they cannot mate. These workers can lay unfertilized, male-destined eggs and thereby challenge the reproductive primacy of the queen. However, other conspecifics do not tolerate this selfish behavior and eat the eggs of the rebel. Another example is caste fate policing. In many bee species, individuals that do not accept their fate to become a worker and try to develop into a supernumerary queen are discriminated against or killed by conspecifics.

The punishment of cheaters is one of the mechanisms that allow societies to keep cooperating. In humans, punishment by disgust – the avoidance and shunning of social cheaters – is a powerful disincentive to selfish behavior. Social parasites such as rapists and thieves are subjected to public disgust and revulsion when they are exposed. Indeed, such public contempt is not always required. We humans police ourselves to great extent, being disgusted with ourselves for selfish behavior. We fear the embarrassment and shame we may feel if we behave badly,

for example subjecting others to our own disgusting bodily emanations, or subjecting others to our own dishonest or greedy parasitic tendencies. Having the human ability to imagine the disgust of others leads to plans being made to behave cooperatively, so as to avoid shame and embarrassment at all costs.

Explaining Disgust

I have argued in this article that the explanation for the construct of disgust in the human brain is the evolutionary need to avoid damage from parasitic infection. This need is something we have in common with all animals. I have also argued that, beyond its proper domain of parasite avoidance, humans have extended the function of disgust to apply to moral revulsion at social parasitism.

This Darwinian explanation differs from those offered previously by anthropologists, psychoanalysts, and psychologists. It is even somewhat at odds with Darwin himself.

While Darwin was surely right that the expression of disgust is near universal in humans and that disgust can be observed in animals, he was incorrect to suggest that disgust originated in distaste. Parasites have many routes of access to the resources of a host body and humans, like all of their animal ancestors, must police those portals of entry, by removing ectoparasites from the skin, avoiding contact with diseased sexual organs, or avoiding breathing in the exhaled droplets of diseased conspecifics. Avoiding consuming spoilt or contaminated food is only one amongst many of the strategies animals use to avoid parasites. Humans must have inherited all of these multiple aversions from their animal ancestors. It is thus highly unlikely that human disgust originated in human distaste, which then later diverged into a variety of other aversions, as Rozin and Haidt, following Darwin, have argued.

However, does it make any sense to suggest that animals can be disgusted, as Darwin proposed and Rozin and Haidt refute? The answer to this question depends entirely on how one defines disgust. If it is defined, as I propose, as a system in brains that recognizes cues to infectious diseases and orchestrates appropriate avoidance responses, then disgust is ubiquitous in the animal kingdom. The nematode worm, *C. elegans*, fleeing parasitic microbes in its petri-dish, is exhibiting disgust-driven behavior. However, if we define disgust as an emotion and if having an emotion depends on being able to report its characteristic qualia of feelings, then disgust must be confined to humans, since only they can report feelings. In my view, it is more helpful to see feelings as an epiphenomenon of such motivation systems. Feelings are used in the theatre of the conscious brain to learn the consequences of behavior and to imagine its future consequences. Knowing that one is likely to feel disgusted by rotten food tomorrow encourages one to store it correctly today. Knowing that one may step in feces tomorrow encourages one to save to build a latrine next year. Knowing that one might meet, and be disgusted by, sick people helps to encourage one to stay at home in times of plague. While the feeling of disgust is probably confined to the small number of higher animals with conscious imaginations, all animals have disgust systems.

For Rozin and Haidt, the paradigmatic source of core disgust in humans is the consumption of animals and their

products. From an evolutionary perspective, however, animals are just one likely source of parasites, amongst others. Other humans harbor more human pathogens and hence should be more central to the disgust system than other animals (cannibalism is especially disgusting, for example). Animals should be disgusting inasmuch as they pose a risk of transmitting infection. So pigs share more parasites with humans than herbivores such as sheep, and hence pig meat is more likely to be treated with disgust than lamb, for example. Animal products such as fish and meat are more risky to consume than vegetable matter, especially if spoilt. Interestingly, it has been hypothesized that microbes may have evolved to exploit our aversion to rotten meat by producing large amounts of volatile warning chemicals. These heighten our disgust, thus allowing the smell-emitting microbes to feast on the nutrient-rich material that we have rejected. Our disgust systems may thus be being fooled into overreacting to gone-off animal foods. The avoidance of animal materials as one source of pathogens provides a more parsimonious explanation for their rejection than Rozin's invocation of magical thinking such as 'you are what you eat.' Indeed it is clear that 'animal nature' is not a key issue since not all animals disgust us and humans will sometimes compare animals favorably with themselves. Further, Rozin and Haidt's suggestion that people distance themselves from meat preparation so as not to be too disgusted to eat it may be true for modern American societies but does not hold in most developing countries, and was probably untrue for most of recorded history, where families had no choice but to butcher their own produce.

Rozin and Haidt propose a magical 'law of similarity' for why children will refuse to eat fudge shaped like feces, despite the children knowing that it was fudge. Here, again, no magical thinking is needed to explain this phenomenon; in the environments in which our brains evolved, things looking like feces simply were feces. The instinctive reaction cannot simply be overridden by the experimenter's reassurance as to edibility. Similarly the law of contagion – 'once in contact, always in contact' – is better explained by 'instinctive microbiology' than magical beliefs. Disgusting objects are disgusting because they may contain invisible pathogens. These microbes can be transferred by simple contact. Hence, it is not surprising that those of our ancestors who took note of objects with a recent history of contact with disgusting objects thrived better than those who did not. Though the same argument should apply to animal behavior, we know of no experiments that have tried to ascertain whether animals record, remember, and avoid objects that have become contaminated in this way.

Freud argued, as do Rozin and Haidt, that disgust is part of an internal psychodynamic regulation system, where the dysfunction of one part of the brain is relieved by the functioning of another. For Freud inappropriate appetites and maladaptive lust after sex are countered by learning to be disgusted by bodily wastes such as feces and sexual fluids. Evolutionary psychologists recognize that there are conflicts internal to brains but do not make one system regulate another. They rather recognize such internal conflicts as trade-offs. Animals have to constantly balance a range of evolutionary needs. People who are hungry, for example, have to balance their need for food with the danger of eating unsafe foods, and will lower their disgust thresholds to expand the range of what they can eat.

Rozin and Haidt follow Freud in positing a psychodynamic use for disgust in controlling our own reactions to the fact of our mortality. For Rozin and Haidt, disgust helps to keep us from dwelling on the terrifying truth of our own animality and of our future annihilation. Fessler and Navarette have challenged their use of the so-called Terror Management Theory (TMT), showing that death disgust is negatively correlated with age, when TMT predicts the opposite, and that priming thoughts of mortality do not increase disgust. They argue, as do we, that disgust is better seen as an adaptation for disease avoidance.

The approach to disgust in the social sciences tends to follow the work of Mary Douglas, who held that we categorize items as disgusting when they are 'out of place,' when they are anomalous and do not fit the local cosmological system, as we saw. For Douglas, societies came first, and disgust is one of their products. Yet it cannot be true that disgust is a human cultural production, since as we have seen, disgust predates humans and certainly predates societies. Douglas does, however, point us toward some of the symbolic uses of disgust in society where, for example, the caste system is extrapolated from the principle that those with contaminating jobs should be kept apart from the rest. Street sweeping, house cleaning, and waste collection remain low-status jobs in most countries today. Douglas's work on the symbolic and ritual uses of disgust in making social separations between pure and polluted, in group and out group remains deeply insightful. However, from the Darwinian perspective, disgust is not purely a product of culture but a factor that shapes culture – disgust came first. Cultures may have elaborate rules about purity and pollution, but these tend to be based on our organic disgusts.

I have argued that the work of Darwin, Freud, Douglas, Rozin and Haidt, and their followers have sent disgust studies down a number of blind alleys. Disgust is not unique to humans, it does not originate in distaste, it is not a product of magical thinking, nor of the cultural constructions of societies, neither did it arise to psychodynamically balance inappropriate appetites or fears of death. There is one simple explanation for why humans and all animals avoid others, certain other animals, and contaminated environments, and that is the threat of infectious disease. Humans have extended the domain of disgust, using it to police and punish social parasites, hence reinforcing the cooperative behavior that makes social life possible. This explanation for disgust should be preferred on grounds of parsimony; it provides a simple, single explanation for all of the diversity of disgust-related phenomena we have been considering.

Disgust and Its Uses

Does it matter in the end whether disgust is an adaptation to the threat of parasites as I contend? Since disgust has tentacles that go deeply into the human psyche, influencing our everyday hygiene and our everyday aversions, as well as being one of the sources of both prejudice and moral behavior, understanding it fully must be an important task for life scientists. Further, disgust may hold the key to improving our ability to fight infectious disease on a planet where infections still kill over 13 million children every year.

There is still controversy in neuroscience over the exact parts of the brain that are activated in the case of disgust. One reason

for this may be that neuroscientists still tend to take disgust stimuli off the shelf, rather than selecting them in a principled manner from the stimuli that should be disgusting according to evolutionary theory; that is, those containing a threat of infection or social parasitism. Until they do this, it will be impossible to develop a detailed and replicable picture of the mechanics of disgust and its component parts using brain scanning.

Beyond better science, there are practical benefits to adopting an adaptive view of disgust. Those who have to deal with disgusting material as part of their job would benefit from a recognition that disgust is a part of human nature. Those who have to deal with wastes, care for the sick, or groom others have to do emotional labor in overcoming disgust and would benefit if this fact were acknowledged and increased support provided. Tendencies to marginalize such individuals can also be recognized and counteracted, in the same way that societies have increasingly come to reject racism or other types of prejudice.

In the domain of public health, it would be helpful to recognize that evolved responses to infection avoidance may not be a good guide to the best way to avoid disease in our modern environments. For example, quarantine and the avoidance of physical contact were intuitive, but not useful responses in the HIV/AIDS pandemic. Recent campaigns have successfully harnessed the power of disgust to get people to wash their hands with soap in a variety of settings to avoid diarrheal and influenza pathogens. Regular panics about the contamination of food are costly for companies and countries and might be avoided if we understood more of the operation of intuitive disgust.

In the moral domain politicians have a sorry history of making capital by exploiting a tendency to xenophobia – disgust of the outsider, as an aid to entrench their own power. The more such behavior is recognized and is generally understood, the less effective it will become.

Probably our most important scientific task in the domain of disgust is to tease apart the story of the role that disgust plays in the evolution of human morality. This is the frontier to watch where exciting discoveries are going to be made in the next decade.

Dissociative Disorders

E Cardena, Lund University, Lund, Sweden

© 2012 Elsevier Inc. All rights reserved.

Glossary

Depersonalization disorder Persistent and recurrent episodes of feeling estranged from the self and/or the environment.

Dissociation Experienced loss of information or control over mental processes that, under normal circumstances, would be available to conscious awareness, self-attribution, or control.

Dissociative amnesia A dissociative disorder characterized by a nonmedically caused loss of personally significant memories.

Dissociative fugue A type of psychogenic amnesia that also includes sudden wandering away from one's residence or job alongside with other alterations of consciousness.

Dissociative identity disorder The most severe of the dissociative disorders, characterized by a lack of integration and control among different psychophysiological states or identities, and a number of other symptoms.

Spirit possession The experience, often accompanied by amnesia, in which one's identity is substituted by that of another being. It most often occurs as part of religious practices that do not involve any psychopathology.

Trance An alteration of consciousness featuring apparent lack of awareness or unresponsiveness to the surroundings, sometimes accompanied by automatic movements.

Dissociation

At the same time that Aristotle was explaining learning as a conjoining or association of different psychological elements, Greek sibyls in the Delphi and other oracles had episodes in which they seemed to have their ordinary identity substituted by that of Apollo or other Gods. All throughout history, there have been descriptions in which ordinary processes such as memory and personal identity seemed to be in abeyance, or parallel psychological strands vied for the person's cognition and behavior. Those phenomena are currently being studied under the rubric of dissociation, a complex term encompassing a broad domain of psychological processes and experiences. In contrast with *association*, the assembling of different processes or parts, *dissociation* implies either that processes that were conjoined were split asunder or that they did not become integrated or associated in the first place as would be expected. Before focusing on the dissociative disorders (DD) per se, it is important to understand what is meant by dissociation, including its pathological manifestations.

Dissociation is a term used in various disciplines (e.g., dissociation of chemical processes). In psychology, it generally refers to a discrepancy between indexes of information (e.g., variations between implicit and explicit perception or memory). In the areas of clinical and personality psychology and neurology, this idea can be subdivided into (1) the apparent absence of conscious awareness of impinging stimuli or ongoing behaviors (e.g., becoming unresponsive to or unaware of the surroundings as a consequence of a ritually induced altered state of consciousness or an epileptic seizure), (2) the seeming coexistence of separate mental systems or identities that are not integrated with the self (e.g., instances of dissociative identity disorder (DID) and spirit possession or, in neurology, cases of 'alien hand'), and (3) ongoing behaviors or perceptions inconsistent with an honest introspective verbal report (e.g., the 'blindsight' phenomenon in which an individual with damage

in the striatal cortex reports being blind in a hemifield while behaviorally showing awareness of occurrences in that hemifield, or a similar uncoupling of reports and behavior in a patient with a conversion – or pseudoneurological – disorder). In order to differentiate *dissociation* from the more general concepts of nonconscious processes, a requirement is that these events are not just part of ordinary processes such as overlearning.

Another descriptive notion of *dissociation* is that of consciousness alterations characterized by experiential disconnection with all or parts of the self (e.g., depersonalization, out-of-body experiences) or the environment (e.g., derealization, a sense of unreality of the environment and other beings). Some authors use dissociation to refer to any alteration in the state of consciousness, but this is inappropriate; mystical states, for instance, produce a sense of enhanced connectedness rather than the opposite.

Dissociation has also been used as an explanatory theoretical construct. In this sense, based on psychodynamic theory, the assumption is that dissociation is an intentional mechanism with the goal to experientially and/or cognitively distance oneself from traumatic or other material that is threatening. Naturally, it is perfectly reasonable to postulate that dissociative processes may at times be consciously controlled or even unconsciously intentional, whereas at other times, they may not have any specific purpose and just be epiphenomena of attentional or other cognitive changes.

Figure 1 is a bidimensional heuristic to characterize dissociative phenomena. Axis x indexes whether the processes causing the phenomena are mostly biological (e.g., neuroendocrine processes) or psychological (e.g., psychological trauma, hypnotic suggestions) processes, whereas axis y groups them as to whether they can be considered pathological or innocuous. The remaining of this article focuses on the upper right-hand quadrant, that is, pathologies whose etiology is mostly psychological (naturally, this does not mean that there are no biological

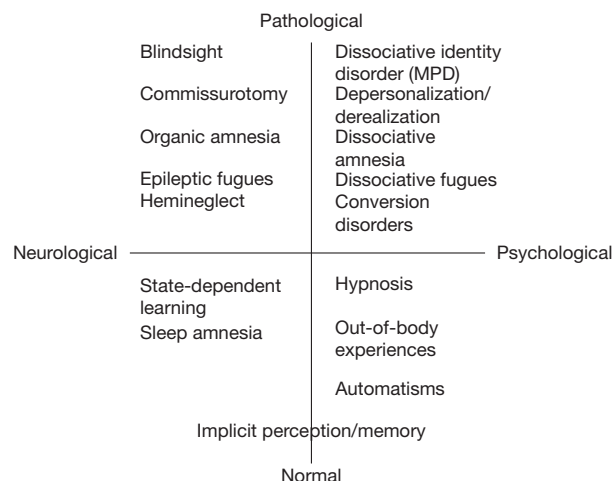

Figure 1 The domain of dissociation. Modified with permission from Cardeña E (1994) The domain of dissociation. In Lynn SJ and Rhue J (eds.) *Dissociation. Clinical and Theoretical Perspectives*, pp. 15–31. New York: Guilford.

correlates of these experiences, but that psychological processes such as exposure to trauma play the major role). With the exception of DID, which does not have a clear parallel among neurological disorders, the latter should be considered as differential diagnoses for all of the other DD, as they may have, at least superficially, similar presentations.

I would like to emphasize that dissociation should be considered a particular form of psychobiological functioning rather than something necessarily pathological. For instance, a number of dissociative alterations in consciousness and identity can be part of ritual or religious activities, are not necessarily associated with pathology, and can even foster creative endeavors as in the case of some instances of automatic writing or drawing. The clinician should look at other factors such as how controllable, organized, desired, and culturally appropriate the dissociative experience is to determine whether it is pathological.

A comprehensive definition of pathological dissociation is an experienced loss of information or control over mental processes that, under normal circumstances and for the age and developmental level of the person, would be available to conscious awareness, self-attribution, or control. These phenomena are characterized by (a) involuntary and unwanted intrusions into awareness or behavior of memories or experiences, with an accompanying loss of continuity in subjective experience (so-called 'positive' dissociation); and/or (b) an inability to access information or control mental functions, manifested in symptoms such as gaps in awareness, memory, or self-identification, that are normally amenable to such access/control (so-called 'negative' dissociation), and/or (c) a sense of experiential disconnectedness, which may include perceptual distortions, about the self or the environment.

With respect to distal and proximal variables associated with the propensity to dissociate, there is evidence for both genetic and nonshared environmental contributions. With regard to the former, studies have found that the propensity to dissociate has a heritability component and that the COMT

gene is likely to be implicated. As far as early environmental contributions are concerned, there is a body of literature showing that disorganized attachment and related factors such as dissociative behaviors from the caretakers (e.g., suddenly 'freezing,' acting as if they were someone else, or their inability to have affective control of their inner states) are strong predictors of the adult dissociation of their children. With regard to proximal factors, there is abundant evidence that traumatic events are closely related to acute and chronic dissociation. If the traumatic events are not very severe and chronic, such as the possible consequences of short-term natural disasters, most people experience just short-lived dissociative episodes. In contrast, particularly virulent events such as early abuse or being a victim of prolonged brutalization can give rise to chronic dissociative phenomena. Although a few authors have argued against a trauma-dissociation link proposing that dissociative individuals just fantasize traumas that never occurred, a voluminous body of literature with retrospective and prospective studies on clinical and nonclinical samples does not support their case.

Dissociation in general, and the DD in particular, can be evaluated in a number of ways, including behavioral observations in attachment tests (e.g., stopping all behavior or 'freezing') or in the clinical situation (e.g., suddenly seeming to become a very different person without an obvious reason), and a number of valid and reliable instruments, including standardized and semistandardized interview and questionnaires, many of them translated into various languages. Research on measures of neuroendocrine dynamics may also be able to serve as reliable indicators of dissociation in the future.

The Dissociative Disorders

The fairly universal phenomenon of spirit possession was partly replaced in the West by mesmeric/hypnotic and spiritualist/channeling phenomena. Although these phenomena were mostly manifestations of experiences and beliefs that did not bring about serious distress or dysfunction, there have always been cases that were pathological even within the cultural standards of the time. At the inception of psychology as a science at the end of the nineteenth century, many of the foremost theoreticians and clinicians in Europe (e.g., J. M. Charcot, F. W. H. Myers, Pierre Janet, Sigmund Freud) and the United States (e.g., William James, Morton Prince) sought to explain and treat such unusual phenomena as patients presenting with strange paralyses, or behaviors or reservoirs of knowledge for which they claimed no conscious knowledge or control but which were psychologically meaningful and did not have a medical basis. When these manifestations were associated with dysfunction or distress, they were subsumed under the rubric of *hysteria*, a sexist term referring to the uterus, and later became known as the dissociative and some somatoform disorders (mainly pseudoneurological or conversion symptoms) in the Diagnostic and Statistical Manual (DSM) taxonomy. However, the International Classification of Diseases (ICD) did not split asunder the DD from conversion. The rationale for the DSM was that pseudoneurological symptoms seem to be medical, the same as other symptoms such as hypochondriasis. On the other hand, it has been shown that the disorders covered in the following sections have high positive correlations with

pseudoneurological and similar symptoms, and both have strong associations with a history of trauma and seem to share underlying psychological processes. Conversion and somatoform disorders in general will not be further considered here, but it is worth pointing out that the earlier observation of a relation between hypnotic suggestion and conversion symptoms has been supported by brain imaging and other research procedures. It has also been proposed that self-suggestion processes underlie at least some types of conversion, mediated by changes in the frontal lobe affecting the cingulate cortex. In a related fashion, research has shown that individuals with DD and posttraumatic disorder are more hypnotizable than other psychiatric groups, so hypnotic susceptibility may very well be a predisposing factor in the inception of various dissociative phenomena.

The initial interest in dissociative processes and disorders during the late nineteenth and early twentieth centuries was short-lived. The focus on alterations in consciousness and cognitive processes were replaced by an emphasis on behavior in academia and on unconscious processes in clinical psychology. It was not until the latter part of the twentieth century, when a number of cultural and intellectual forces came together, that research on consciousness at large, and dissociation in particular, reemerged. I can mention the development of parallel-processing cognitive and neurodevelopmental models consistent with dissociative processes, as well as the increasing realization that traumata (e.g., war, accidents, early abuse) are far more common than realized earlier and that these events are clearly related to acute and chronic dissociative phenomena. With regard to the DD, the last years have witnessed increasingly careful and sophisticated treatment, development of valid and reliable measures, and research which has most recently included brain imaging techniques.

A word now about the denial by some authors of the validity and prevalence of DD, especially DID (erstwhile known as *multiple personality disorder*), which they claim to be iatrogenic and/or culturally created, mostly produced by therapists' leading suggestions and circumscribed almost exclusively to Anglo-Saxon countries. The critiques have been based almost exclusively on a reconsideration of the literature rather than on new research and are contradicted by various studies showing that these disorders are found across the globe, although with some variations (e.g., the experience of being chronically possessed by an external agency rather than having alter identities), and that hypnosis is not a tool used for diagnostic purposes, but for therapy. Furthermore, if therapists' suggestions were the main cause of symptom presentation, considering that many if not most DID patients have received earlier diagnoses, they should continue to manifest the initially diagnosed condition, rather than providing refractory to treatment until dissociative processes are considered (there is now budding research on the efficacy of therapy for DD). There are also both cognitive and neurophysiological studies that are inconsistent with the theory that DD are forms of malingering or mere role-playing. Naturally, these studies do not eliminate the influence of culture in the shaping of a syndrome nor the possibility of iatrogenic factors in a few diagnoses, but the same could be said for any psychiatric condition. Of especial value in this controversy have been a number of longitudinal studies showing that dissociative phenomena in adulthood are

strongly predicted by such earlier variables as traumata (e.g., abuse, loss, anatomical malformation requiring painful and intrusive medical procedures), and disturbances in attachment to the early caretaker.

With regard to the prevalence of the DD, although it has been at times stated that *hysteria* was circumscribed to the Victorian times, epidemiological research in various countries has shown that patients in outpatient and inpatient units could receive a primary or secondary DD diagnosis within a range of 10–45%, depending on their history of trauma and other serious adversities. In the general population, it has been reported that up to about 11% might fulfill the criteria for DD, although this figure probably would vary considerably across cultures with different levels of exposure to trauma and different criteria for dysfunction. In the following sections, the DD according to the DSM-IV are described.

Before this, I should mention, albeit briefly, pathological dissociation among children. There has not been nearly as much research with children and teens as there has been with adults for a number of reasons, including the difficulty of differentiating what may be age-appropriate manifestations (e.g., not having a sense of self across time in early childhood) from actual pathological manifestations, the lack until relatively recently of valid measures for this group, and the differing presentations of pathological dissociation of children and adults. Regarding the last point, an expert has written that *trance* (i.e., seeming unresponsiveness to the surroundings) may be the most prevalent form of dissociation among children, a phenomenon that does not seem to be quite as central in the DD of adults. Also, rather than the multiplication of identities found among adults, dissociative children seem to fail to reflect on, or mentalize, their own psychological processes and those of others, besides having uncontrolled alterations of consciousness.

Dissociative Amnesia

The definition of this disorder by the DSM-IV centers on one or more instances of amnesia for important personal information, which cannot be explained by a medical condition, ordinary forgetfulness, or the developmental amnesia for the first years of life. This diagnosis is given when the amnesia is the only or central symptom, rather than just being part of a syndrome as is the case in acute stress disorder (ASD) and posttraumatic stress disorder (PTSD), or in more complex forms of DD such as fugue and DID.

The material that is forgotten is typically related to intense stress or trauma (e.g., a very painful divorce, a war battle) and can adopt different forms. Amnesia can be *localized* in time, either to a previous event such as the loss of a close person, or to a period of time such as not remembering some years of life during which chronic abuse occurred. Amnesia can be *selective* in the sense that certain aspects of a trauma that would be expected to be remembered cannot be accessed (e.g., not recalling how a brawl concluded in the person shooting someone else). *Systematized* amnesia is characterized by a theme connected to trauma or stress, for instance, not recalling the various visits of a perpetrator during the holidays or events having to do with an impeding marriage. Lastly, in the rarely encountered *generalized* or *global* amnesia, the person forgets much or most episodic memory, not being able to remember even one's name or other basic

personal information. The great majority of amnesia episodes are not generalized or global, and the material that is inaccessible at some point may become accessible later on, as the basic mechanism of memory would predict, notwithstanding some pronouncements about the impossibility of 'recovered memories.' Besides these symptom presentations, it is worth stating that a history of trauma and dissociation have also been associated with impaired working memory. Currently, the mechanisms through which dissociative amnesia occur are far from clear, but there is some evidence that both failures to store memories and inability to retrieve memories may be implicated.

This disorder, the same as other DD, is commonly associated with other symptoms, including depression and anxiety, and typically manifests early in life up to early adult years. There are various medical conditions (e.g., concussions, vascular problems, dementia) that also produce amnesia, but the memory problems in these cases are not so clearly related to severe stress or trauma and may include such memory problems as antero-grade amnesia, or inability to learn, that is not a typical feature of dissociative amnesia.

Dissociative Fugue

This disorder is characterized by generalized amnesia, confusion about one's identity and sudden wandering away from home or place of residence. Sometimes, the confusion/amnesia about one's identity may give place to an alternate identity. Because of the nature of the disorder, these individuals may first be encountered by law agencies or acute care hospital units, become homeless, or be taken advantage of by other individuals (there is some evidence that prostitutes and exotic dancers dissociate more than average, although it is not clear whether this symptom preceded their profession, may result from it, or both). During the fugue episode, the person may seem partially or totally unresponsive to the external environment and flees away from a source of stress or trauma (e.g., an upcoming wedding that produces strong conflict, or a violent household).

In a differential diagnosis, the clinician should consider the postictal episodes of wandering known as epileptic poriomania, and psychotic episodes in which, for instance, voices may tell the person to flee. The pattern of symptoms of these other conditions and the close association with stress or trauma in the case of fugue help with the differential diagnosis. Currently, there is a suggestion for the DSM-5 that dissociative fugue should be considered a special case of dissociative amnesia, which I have also advocated for earlier.

Depersonalization Disorder

The DSM-IV defines depersonalization disorder as persistent and recurrent experiences of feeling separated from one's body or psychological processes, but with intact reality testing. During a depersonalization episode, individuals may feel disconnected from sensations, feelings, or thoughts, or as if they were not quite real or were dreaming. Also commonly found are sensory alterations such as a strange quality to colors or sounds. Technically, *depersonalization* refers to this experience as it relates to the self, whereas *derealization* relates to the surrounding environment or to other people, for instance,

'feeling' that others are not quite real. These experiences commonly co-occur.

Depersonalization *disorder*, in which these experiences are recurrent, chronic, and the central aspect of the person's suffering or dysfunction, must be distinguished from depersonalization *episodes*, which may be isolated and innocuous, or be part of a larger syndrome such as in DID or panic disorder in which great fear is often associated with depersonalization. With respect to reality testing, whereas in psychosis, the person may, for instance, *believe* that he/she is dead, in depersonalization, the person does know that he/she is not dead but *feels* that way.

Depersonalization episodes can happen in connection with a seizure disorder, may be triggered by great anxiety or exposure to trauma, or be the by-product of ingestion of psychoactive drugs or of mental techniques such as meditation and hypnosis. Although depersonalization episodes may have appeared initially as part of a mood or an anxiety disorder, they may remain after the other symptoms have cleared, thus becoming a unique disorder.

Recent studies on depersonalization disorder have shown that a frequent etiological factor is early emotional abuse (rather than, say, physical and/or sexual abuse as in the case of DID, see below) and, more proximally, severe stress or trauma. The disorder is associated with memory and attention problems, functional abnormalities in brain areas related to sensory integration and body schema, blunted neuroendocrine response, and hypothalamic-pituitary-adrenal dysregulation.

Because depersonalization and derealization episodes often happen in tandem or may alternate and there are no clinical reasons to differentiate them, it has been recommended that the DSM-5 expand its definition of depersonalization disorder to also include derealization episodes, which are currently diagnosed as DDNOS (DD not otherwise specified).

Dissociative identity disorder

The phenomena subsumed under DID have been previously called double or multiple personality, but the DSM-IV changed the name to underline that the core of the condition is *not* the presence of many personalities, but the failure to integrate various aspects of the individual into a single personality. This terminological change has the important implication that a unified personality is an achievement rather than a given. Thus, the current therapeutic goal in the treatment of DID is to integrate different aspects or states of the person so that the person can partake of a common memory, self-attribution, and control, rather than trying to find the *real* personality, as was the goal earlier on.

DID is defined by the DSM-IV as the presence of two or more distinct identities or personality states (or alters), with characteristic patterns of perceiving and behaving, and which recurrently take control of the individual. Another diagnostic requirement is psychogenic amnesia, which in the case of DID can take an additional form besides the ones described earlier, namely that one identity may remember what another one did but not vice versa. DID is the most severe of the DD and typically subsumes a number of other symptoms, including depersonalization, anxiety, depression, and affective lability (including attempts at self-injury), chronic anxiety, various phobias, conversion and other somatization problems, and

substance abuse, eating, sexual, and personality disorders (especially avoidant and borderline disorders within the last category). This multiplicity of symptoms has led some authors to propose that the lack of identity integration is not as important as the multiplicity of symptoms, which helps explain why patients with DID have a history of many previous diagnoses, often of a mood disorder or schizophrenia, before receiving the DID one. It has also been observed that the severity and patterning of symptoms can vary across individuals and times. There are DID patients who can function quite well and may even go undetected by those around them, whereas other patients may at times become frankly psychotic.

Other authors have remarked that the presentation of distinct identities is not easy to detect (contrary to the popular stereotype DID patients are socially avoidant rather than histrionic) and instead propose as diagnostic criteria simpler dissociative symptoms, including hearing voices that are not attributed to the self and may, at times, exert control on it, amnesias, pseudoneurological or other somatization symptoms, depersonalization/derealization, becoming unresponsive to the surroundings, and experiencing various alterations in the sense of self. At this point, it is seems that the DSM-5 will maintain a minimalistic approach to DID rather than have many symptoms as part of its definition.

As mentioned earlier, some authors have questioned the validity of this diagnosis but have failed to provide empirical support for an iatrogenic hypothesis. On the other hand, a study found that the validity and reliability of the DID diagnosis was comparable to that of some noncontroversial diagnoses, and memory and neuroimaging studies have been consistent with the DID patients' reports that they experience alternate, not consciously integrated psychophysiological states.

Regarding etiological factors, in a number of studies, the vast majority of DID patients have reported severe and chronic forms of early abuse. Some critics have countered that such reports, coming from highly hypnotizable individuals are suspect, but other studies have shown that the search for some type of independent corroboration, which may be very difficult after many years have elapsed, has been substantially consistent with the patients' reports. Nonetheless, it is clear that the vast majority of children who suffer severe abuse or neglect do not develop DID, thus other factors have to be involved. A genetic predisposition to dissociate interacting with some form of disorganized or disrupted attachment seems to also be important etiological factors. I should underline that traumas are important particularly if they occur early in life, when a sense of an integrated self is being developed and is thus vulnerable to disruptions.

Pathological Spirit Possession and Trance

In the DSM-IV, *dissociative trance disorder* (DTD) was defined as 'worthy of further study,' although still lacking enough evidence to consider it a DD on its own rather than just being an example of DDNOS. DTD includes *trance*, namely marked alterations of consciousness or loss of the usual sense of identity characterized by a lack of or unusually narrow awareness of the surroundings and stereotyped behaviors or movement, but without replacement by another identity. DTD also includes *possession trance*, a temporary alteration of

consciousness defined by the replacement of the usual sense of identity by another one (which may be recognized as an ancestor or a spiritual force), stereotyped behaviors attributed to the possessing entity, and typically full or partial amnesia for the possession episode.

The alterations of consciousness just described are usually not pathological and are associated with religious or other rituals, following a cultural syntax for such events. Research shows that most experiences, under these circumstances, evidence good psychological adjustment. Nonetheless, in a few cases in both industrialized and nonindustrialized societies, they may occur outside of cultural norms, be dysfunctional, and produce distress, thus becoming pathological. A case can be made that pathological spirit possession is the nonWestern version of DID (and, with logical equivalence, that DID is a Western version of pathological spirit possession). Although this formulation has been made without much empirical grounding, a recent study in Uganda found that pathological spirit possession sufferers reported greater traumatic events and various types of dissociative symptoms than a comparison group, a pattern similar to that of DID patients in the West.

Both for conceptual and now for empirical reasons, it has been recommended that the DSM-5 criteria for DID include an expansion of the phrasing to cover pathological spirit possession. An obvious advantage of this change would be to have a more specific diagnosis than the vague DDNOS. DTD would remain, however, one of the examples of the DDNOS.

DD Not Otherwise Specified

Studies in both Western and non-Western cultures have found that the catch-all bag diagnosis of DDNOS is the most prevalent DD diagnosis, which suggests that the DSM classification is incomplete in some important ways. The proposed changes to the DSM-5, if accepted, will partly ameliorate the problem by having derealization without depersonalization being included within depersonalization disorder, and pathological spirit possession within DID. Nonetheless, it is very likely that some presentations will still remain outside of the main diagnostic entities. One example is likely to be individuals who are mostly unable to regulate their states of consciousness, especially when dealing with even minor stresses, which may be experienced by them as severe stresses or even traumas. They may then have mixed episodes of 'blacking out' (i.e., seemingly becoming unaware or unresponsive to the environment), either because they do not seem to have conscious experiences at that time or they are absorbed in some distressing memory or fantasy, alongside with bouts of depersonalization, amnesia, feeling that they cannot control different aspects of their selves, and so on.

Currently, the DSM-IV provides the following examples of DDNOS: cases similar to DID that do not fulfill all of its criteria (for instance, experiencing multiple identities without amnesia); derealization without depersonalization; dissociative states in those subjected to coercive persuasion; DTD (including both the pathological possession and trance manifestations described earlier); loss of consciousness, stupor, or coma not attributable to a medical condition; and Ganser's syndrome or the giving of approximate answers to questions (when it is associated with alterations of consciousness and is not the

product of ignorance or temporary confusion). Two further examples of DDNOS are being proposed for the DSM-5: acute dissociative reactions to stressful events and acute states characterized by mixed dissociative and psychotic (e.g., hallucinations, delusion) symptoms.

I would like to comment further on two of the current or proposed examples.

The first one refers to nonmedical loss of consciousness, stupor, or coma. This is a case in which the frontier between dissociative and conversion symptoms is so blurred as to have no meaning. For instance, how can one really distinguish between a pseudoneurological petit mal or absence seizure from stupor or loss of consciousness? Another important issue is that even though there is a common assumption that psychological disorders are typically individual, the literature on mass unexplained medical illness shows that such symptoms as fainting or hallucinations can spread within a group of susceptible individuals in both Western and non-Western countries.

The second point is that at least as currently phrased, the proposed example of 'acute dissociative reactions to stressful events' has a great overlap with ASD, an entity listed under the Anxiety Disorders and defined as an acute posttraumatic reaction that includes dissociative and PTSD (i.e., reexperiencing, avoidance, or hyperarousal) symptoms.

Worthy of mention also are a number of culture-bound syndromes (e.g., latah, amok) that include dissociative phenomena and are not covered by the DDNOS examples provided. Thus, a clinician is well advised to consider that dissociation can occur in all major areas of functioning (self-image, volition, memory, identity, perception, emotion) above and beyond the descriptions provided by psychiatric taxonomies. Whether these phenomena are pathological or not requires not only consideration of the concept of dissociation in general, but of the semantic networks of diseases, values, and ethnoepistemologies present in every culture, along with such aspects as the ability to control and organize the experience.

In sum, after a hiatus of a few decades, the interest in the research, evaluation, and treatment of the DD has been rekindled. We have barely begun to investigate and try to understand what dissociation can reveal to us about how humans achieve epistemological and phenomenological integration and what produces its willed and unwilled disruptions. Wherever these studies may lead, there is good evidence now that DD are not nearly as rare or exotic as clinicians used to think even some years ago. The founder of the most important psychopathology journal, Morton Prince, may have had the last word when he wrote in 1906–1907 that dissociative phenomena in their mild forms are 'an almost every-day clinical affair.'

Divorce

S Stack, Wayne State University, Detroit, MI, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Agreeableness A tendency to be warmhearted, a team player, supportive, trusting, and generous; one of the five principal dimensions of personality in the five-factor model.

Crude divorce rate The number of divorces per 1000 persons in the general population.

Divorce A dissolution of a marriage.

Five-factor model of personality A model of personality orientations based on five principal dimensions of personality including openness, conscientiousness, extroversion, agreeableness, and neuroticism.

Mania A psychiatric disorder marked by long-term tendencies toward abnormally elevated expansive or irritable moods, and supplemented by such characteristics as grandiosity, racing thoughts, and pressure to keep talking.

Social integration The strength of the bonds between the individual and the social order, including the number of shared beliefs and practices.

Suicide The act of taking one's own life knowingly and intentionally.

Over the last half century, the percentage of the population that reported that "having a good marriage and family life is extremely important" has remained relatively constant at 70–85%. Nevertheless, given the rising number of divorce cases, fewer people realize this cultural value.

Divorce is a significant indicator of the quality of marriages and, more generally, of the quality of life. Divorce often breeds feelings of rejection, loss, and failure. On scales of traumatic life events, divorce is second only to the death of a spouse. For adults, divorce increases the odds of many social problems, including financial strain, depression, a sense of disorientation, and suicide. Divorce is also associated with lower well-being for children both in the short term on such indicators as school performance and psychological distress, and in the long term on indicators such as social mobility, psychological problems, and divorce as an adult. As divorce becomes more prevalent, it can interfere with the production of the next generation of appropriately socialized and trained persons for society.

While divorce is associated with many stress-producing consequences, approximately a million couples continue to obtain divorces every year. Recent national survey data indicate that 43% of first marriages end in divorce within 15 years. At least half of the persons currently getting married will ultimately have their marriages end in divorce. Divorce is becoming part of the normal 'life course' or socialization experience of people. Most people will ultimately and eagerly seek a divorce at some point in their lives. It is not clear, however, if the benefits of ending an unhappy marriage are, in fact, greater than the costs of a divorce.

The Extent of Divorce

Descriptive Data and Trends

The United States

Currently, there are 23 million divorced adults in the United States and an even larger number of remarried, formerly divorced persons (four of ten marriages involve a bride and/or a groom who were previously divorced). The number of

children of divorced parents is approaching the number of children from intact homes.

Divorce rates measure the flow of marital breakdown. They refer to divorces per 1000 general population in a particular year. Rates vary across geographic space. The rates for the South and West tend to be higher than those for the Midwest and Northeast. These differentials have been narrowing over time. In 2007, states with the highest rates of divorce were Nevada (6.5) and Arkansas (5.9) and states with the lowest rates were Massachusetts (2.3) and Rhode Island (2.8), states with a high proportion of Catholics.

A second measure of the incidence of divorce is the stock of divorced persons (the percentage currently divorced or the percentage ever divorced). The percentage of the population that has ever been divorced varies little across regions. This stock measure is lower in the Northeast at 19% compared to 26–27% elsewhere.

Gender is related to the odds for remaining divorced. Females, being somewhat less likely to remarry than males, are more apt to be divorced than males. Using a stock measure for 2008, for example, 8.5% of males over 15 were divorced compared to 11.1% of females over 15.

The risk of being divorced varies over the life course. [Table 1](#) provides data for the percentage of nine gender/age groups who were divorced in 2008. The percentage of males who are currently divorced increases with age and peaks at 15.0% for males aged 50–54. For females, there is a similar age gradient, but the peak is at 55–64. In all age ranges, the percentage of females who are currently divorced is higher than that for males. Divorced males opt to remarry at a higher rate, and sooner, than do divorced females.

As the proportion of persons in society who opt to marry decreases, it is increasingly important to conceptualize divorce in the context of the population at risk: the married population. This is especially important in describing the incidence of divorce between Caucasian and African-Americans.

For example, in 2008, 10.5% of Caucasians were divorced and 57.7% were married, the ratio being approximately one divorced white for every six married ones. In 2008, 12.1% of

Table 1 Percentage of selected age groups who are currently divorced by gender, 2008, United States

Age group	Percentage of males divorced	Percentage of females divorced
20–24	0.8	1.4
25–29	3.0	4.6
30–34	6.4	8.1
35–39	9.1	11.4
40–44	11.9	15.2
45–49	14.2	17.5
50–54	15.0	17.6
55–64	14.0	18.7
65–74	9.5	13.9

Table 2 The percent divorced and married by race, 1990–2008

	1990	2000	2008
Caucasians % divorced	8.1	9.8	10.5
Caucasians % married	64.0	62.0	57.7
Blacks % divorced	10.6	11.5	12.1
Blacks % married	45.8	42.1	35.1

Source: US Bureau of the Census (2009) Statistical Abstract of the US, 2009.
Washington: US Government Printing Office.

blacks were divorced, but only 35.1% were married, the ratio being approximately one divorced black for every three that were married. **Table 2** presents trend data on the marital status of whites and blacks indicating that the ratio of the stock of divorced persons to the stock of married persons has increased over the two decades for both races. It is also noted that in 2008, among adults, four of ten blacks and two in ten whites fell into the category 'never married.'

As the proportion of married persons in society dwindles, the divorce rate (divorces per 1000 general population) would be expected to go down since the population at risk of divorce is smaller. This is what has been happening in the last two decades in the United States and many other industrialized nations.

There is some inequality in who initiates divorce. Wives initiate approximately six out of every ten divorces, while men initiate about three in ten. Joint actions constitute the remainder of the filings. When children are present, wives initiate nearly the same percentage of filings.

Half of all divorces involve at least one child under the age of 18. The average number of children per divorce has been falling since 1964, a reflection of a decline in overall family size. The median duration of marriages that end in divorce has held relatively steady since 1970: 7 years.

Prior to the twentieth century, the custody of children was uniformly given to the father who was legally responsible for providing for his children. Given the spread of Freudian ideas on child development, this pattern totally reversed in the twentieth century, with the courts uniformly awarding custody to mothers. Today, while fathers are increasingly awarded joint (or shared) *legal* (decision-making) custody, it is still unusual for fathers to obtain *physical* (residential) custody of their children. However, joint physical custody is becoming more common.

Trends

The incidence of divorce has increased substantially over the last century and a half. The earliest data on the estimated percentage of marriages that ultimately ended in divorce are for 1867. Ultimately, 5.3% of the persons who married in 1867 became divorced. This figure doubled to 12.0% for those married in 1900. Currently, most marriages will ultimately end in divorce.

Between 1921 and 1965, the divorce rate had been rising very slowly in the United States. The two noticeable departures from this pattern were a drop in the depths of the Great Depression and a short-term substantial upswing in the aftermath of WW II. As the postwar baby boomers began to wed, the divorce rate nearly doubled between 1965 and 1975. It reached a record high of 5.3 in 1981. Since that time it first leveled off and has been declining since 1992. Currently, the American divorce rate is 3.7. The decline is associated with the aging of a large cohort, the 'baby boomers,' who are now well past their divorce-prone years. In addition, marriage rates, generating a population at risk for divorce, have fallen. The population of persons living together without marriage has increased more than tenfold in a space of a generation, thus further decreasing the stock of persons at risk for divorce.

Comparative perspectives: other nations

The United States has one of the highest divorce rates in the world. This has been true for over a century. In 1869, the rate was 1.2, a rate higher than some industrialized nations in the 1990s.

Table 1 presents data on divorces per 1000 population for selected nations of the world. Nations with a high proportion of Catholics (e.g., Ireland, Italy) tend to have a low divorce rate; Ireland had no legal provision for divorce until 1997.

Norms against divorce are especially strong among Catholics and loosen with economic development. The Russian Federation has surpassed the United States and now has the highest divorce rate of this group, with the United States in second place.

It has not been fully understood why the rate of divorce in the United States is so high. One possibility is the high level of individualism, a quest after the maximization of individual goals and pleasures. The country is relatively low in 'collectivism.' For example, the proportion of the labor force that belongs to unions, a collective form of organization, is the lowest in the industrialized world. If the costs of a marriage outweigh its benefits, Americans are apparently more likely than the members of most other nations to seek a divorce.

Between 1990 and 2007, the divorce rate decreased in 7 nations, in 14, it increased, and in 4, it remained relatively constant. In four nations, the increase was 100% or more, including Ireland where divorce was legalized in 1997 (**Table 3**).

The Causes of Divorce

Macrosociological Explanations

Changes in divorce legislation

In colonial America, there were no divorce courts and divorces were rare events. Divorces were a *legislative* matter, and each and every divorce was debated in the colonial congress!

Table 3 Divorces per 1000 population circa 1990, and circa 2007 selected nations, and trend (if > 10% change)

<i>Nation</i>	<i>Divorce rate 1990</i>	<i>Divorce rate 2007</i>	<i>Trend</i>

Notes: up+ = more than a 100% change.

Further, one alternative to marriage, living alone, was either banned or heavily taxed. With the development of judicial divorce, more lenient divorce legislation, female labor force participation, and other changes, divorce was more common by the late nineteenth century.

An analysis of 17 industrial nations found that the degree of liberality in the divorce law was the variable most closely associated with the variance in divorce rates; it was more important than economic conditions and female labor force participation. However, the liberality of divorce legislation was largely determined, in turn, by the strength of Catholicism. Divorce law itself may be a reflection of the status of religion in society.

Economic factors

Two conflicting theories link the business cycle to the divorce rate. In the first view, economic prosperity should increase the divorce rate since divorce is less costly in prosperous times. Prosperity provides unhappy couples the financial means for a divorce. Proponents of this first view often note the sizable drop in the divorce rate during the worst years of the Great Depression. According to the second view, economic prosperity should decrease the divorce rate since it reduces stress on families. In this perspective, it is economic depression that increases the divorce rate. Financial strain adds tensions to family life that in turn increase the probability of divorce.

While surprisingly little rigorous empirical testing has been done on these opposed perspectives, the weight of the evidence, from the post-WW II era, suggests that economic prosperity (e.g., low unemployment) has a slightly negative effect on divorce. The size of this effect is typically less than that of the age structure and the extent of female labor force participation.

Women's increased labor force participation is perhaps the most frequently cited factor underlying the increase in the divorce rate since World War II. As economic opportunities for women have increased, more women have obtained an independent financial base. They are less dependent on marriage for monetary support and more apt to seek a divorce from an unhappy marriage. Increased female labor force participation has often been the leading determinant of shifts in the incidence of divorce. However, other nations have even higher rates of employed women than the United States and such nations as Sweden often have lower divorce rates. There is more to the divorce equation, then, than this factor.

The age structure of the population can affect divorce through influencing economic opportunities for different age cohorts. As the proportion of young people in society expands, this sets in motion certain rigidities in the supply of labor. An oversupply of labor results in more competition for employment. An abundance of young workers results in the fall of their incomes, more financial strain on their marriages, and, hence, a higher incidence of divorce.

Social integration

Factors such as religiosity, migration, urbanism, and war can affect the strength of the bond between the individual and society. The extent of shared beliefs and practices can be affected by these conditions; when bonds to social institutions like religion and neighborhoods are weakened, life can become less meaningful. Urban life can promote a sense of anonymity undermining integration and increasing tolerance for divorce. In such contexts, the probability of divorce increases.

A study of divorce rates in 3000 counties found that indicators of social integration were more important than socio-economic variables in explaining the variation in divorce rates. In particular, the higher the incidence of church membership, the lower the rate of divorce. Also, the higher the rate of population growth, the higher the rate of divorce. Finally, the higher the urban percentage, the higher the incidence of divorce.

As divorce becomes more commonplace, the normative climate surrounding divorce is liberalized. The stigma associated with divorce may decline, resulting in an increase in divorce; divorced persons can provide role models and encourage others to follow suit. Overtime data for the United States confirm a positive association between divorce and the previous level of divorce. This suggests some support for a cultural perspective.

Individual-Level Explanations

Personality, psychiatric disorders, dissimilarities

According to the selection hypothesis, persons who succeed in long-term marriage are a select group. Such persons have solid personalities before and during marriage, which help their

marriages to be satisfying and rewarding. Thirteen studies are available that measure personality in large samples of married persons and then keep track of who gets divorced as time goes by. A recent meta-analysis reviewed all 13 over time studies, which measured personality using the dominant 5-factor model. Three of the five major dimensions of basic personality orientation were predictive of divorce. The best predictor was agreeableness (a tendency to be warm, a team player, supportive, trusting, and generous). Agreeable persons were significantly less apt to become divorced. The second best predictor was neuroticism. Neurotic persons (e.g., chronically depressed, overanxious) were considerably more apt than nonneurotic persons to eventually divorce. Finally, conscientious persons (tendency to be well organized, industrious, efficient, enterprising) were less apt to become divorced. Importantly, these understudied personality dimensions were at the same level of importance in predicting divorce as more traditional major predictors, including socioeconomic status. The risk of divorce also has a heritable component, perhaps operating through personality constructs.

One of the best predictors of divorce is age at first marriage: the higher the age, the lower the odds of divorce. For example, in the United States, marrying at over 25 years of age lowers the risk of divorce by 24% (compared to marrying under 18). Age at first marriage predicts the risk of divorce across 17 nations for which data are available. However, to the extent that age captures maturity, it may be, in part, a proxy for aspects of the conscientious and agreeable personality types.

While there is little systematic, overtime research, evidence suggests that long-standing, serious psychiatric problems increase the odds of divorce. Analyses using the national comorbidity surveys determined that 11 of the 14 psychiatric disorders investigated were associated with an elevated risk of divorce over time. The manic disorder (marked by abnormally and persistently elevated, expansive, or irritable moods and supplemented by such considerations as grandiosity, racing thoughts, pressure to keep talking, requiring <3 h sleep) was the best predictor of divorce. It elevated the odds of divorce by 3.2 times. Persons diagnosed with major depression had an enhanced risk of divorce 1.7 times that of the general population. The greater the number of psychiatric disorders, the greater the risk of divorce.

Studies tend to find that the greater the differences in status between spouses, the higher the odds of marital disruption. This is especially true for dissimilarities in religious preference, but also extends to differences in age, education, and race. Communication between the spouses is a function, in part, of similarities on these characteristics. The associated value conflicts can increase divorce risk.

Social integration

Social isolation increases risk of divorce. Measured in terms of the number of ties to friends and community organizations, the greater the 'integration' the lower the probability of divorce. This is mainly for the first 7 years of marriage. Stronger results are found for 'normative integration' or the number of close relatives and friends who have experienced a divorce. In an 8-year panel study of 2000 married couples, the probability of divorce was only 9% among those with no significant others divorced, whereas the probability of divorce

was 16% among those who had both a friend and relative who had divorced. As normative standards permit or encourage divorce in one's social networks, the likelihood of divorce increases.

One particularly strong predictor of divorce is low religious integration. Catholics have a lower incidence of divorce than Protestants, given the stronger norms against such in the former. From national survey data, being a member of any religious group versus not having a religious affiliation lowers the risk of divorce by 13%.

Economic factors

The occupational status, education level, and income of the husband lower the risk of divorce. Having some college education lowers the chances for a divorce by 13%. However, only income tends to remain significant if one holds the other variables constant. National survey data in the United States indicate that persons living in households with incomes over \$50 000 were 30% less apt to divorce than their counterparts over the first 10 years of marriage. Financial strains place the family under stress which, in turn, increases the probability of marital dissolution.

Table 5 presents data on the percentage of men who are divorced in each income class. Since age status is confounded with income status (older men tend to make more money than their younger counterparts), the data refer to a particular age range containing the 'baby boomers,' those 55–64 in 2008. While these men in Table 4 are about the same age, the percentage of them who are divorced varies from a low of 8.3 for those with personal incomes of over \$100 000 to a high of 18.5 for those men with the lowest incomes. Importantly, as one goes from the income group of men earning \$40 000–\$75 000 to a group above the median or typical income (\$75 000–\$99 999) for men of this age, the percentage divorced drops from 11.3 to 8.8. That income is associated with the odds of being married is indicated by the ratio of the percentage married to the percentage divorced. This ratio improves from 3.3 for the poorest group to 10.4 for the richest group of men.

Table 4 The odds of divorce for persons diagnosed with selected psychiatric disorders, national comorbidity surveys, United States

<i>Disorder</i>	<i>Increased risk for men</i>	<i>Increased risk of divorce for women</i>	<i>Increased risk of divorce, total population</i>
Mania	3.3×	4.8×	3.2×
Major depression	1.7×	1.7×	1.7×
Generalized anxiety	2.3×	1.4×	1.7×
Drug abuse	1.4×	1.4×	1.4×
Number of disorders			
One disorder	1.3×	1.7×	1.3×
Two disorders	2.3×	1.7×	1.5×
Three disorders	2.5×	2.5×	1.9×

Table 5 The percentage of men, ages 55–64, who are currently divorced, and currently married by personal income range, 2008, United States, current population reports

<i>Income range</i>	<i>Number of males, 55–64</i>	<i>(A) percent married</i>	<i>(B) percent divorced</i>	<i>Ratio of (A)/(B)</i>
\$1–\$5 000	411 000	62.3	18.8	3.31
\$5 000–14 999	888 000	65.5	17.0	3.85
15 000–24 999	1 306 000	71.4	15.1	4.72
25 000–39 999	2 255 000	73.0	15.0	4.87
40 000–74 999	3 998 000	79.9	11.3	7.1
Above median income ranges:				
75 000–99 999	6 567 000	84.3	8.8	9.6
100 000+	1 805 000	86.3	8.3	10.4

Table 6 Top five perceived causes of divorce reported by divorced persons themselves, marital instability over the life course survey, United States

<i>Perceived cause</i>	<i>Total (%)</i>	<i>Males (%)</i>	<i>Females (%)</i>
Infidelity	21.6	15.6	25.2
Incompatibility	19.2	19.5	19.1
Drinking/drugs	10.6	5.2	13.7
Grew apart	9.6	9.1	9.9
Personality problem	9.1	10.4	8.4

Divorced persons' perceptions of causes of divorce

When queried about what caused their divorce, divorced persons tend to give little credence to widely referenced factors in the academic research such as age at first marriage or conflict resolution skills. Infidelity, for example, rates high on the list, a relatively unstudied factor in academic research. **Table 6** provides national data on the top five causes of divorce as reported by divorced persons themselves.

Further insight into the cross-cultural causes of divorce is provided by anthropologists. Betzig reviews contributing factors to divorce as recorded by anthropologists in 186 societies, including the Aztec and Native American tribes such as the Apache, Huron, and Pawnee.

Family dynamics and process

Premarital cohabitation

While premarital cohabitation might be seen as 'preparation' for a successful marriage, persons who cohabit before marriage are at relatively high risk of divorce. This risk factor for divorce is consistent across 17 nations. Both cohabitation and divorce may be indicators of a predisposition to go against normative behavior regarding marital conventions.

Children

On the one hand, children are often thought to decrease the odds of divorce since they can give an unhappy couple 'a reason to stay together,' or perhaps problems concerning

children per se help to prevent a focus on marital problems, thereby lowering the risk of divorce. On the other hand, children can increase stress; children also represent a source of numerous economic and social demands on parents. In a study of over 40 000 marriages across 17 nations, it was determined that the greater the number of children that a married couple has, the lower the risk of divorce.

Esteem for spouse

Spouses in happy marriages tend to hold each other in higher esteem than do divorced persons. The former group is considerably more likely to describe their mate's traits as superior to their own than the latter group. This factor of support for the spouse is related to having an agreeable personality.

Sexuality

A badly neglected variable, sexual adjustment distinguishes happily married couples from divorced spouses. The former report significantly more enjoyment and higher actual/preferred sex frequency ratios than the latter. Sexual incompatibility is one of the more frequent explanations that divorced persons themselves give for the breakdown in their marriages. Further, adultery is a much-cited reason for divorce among divorcees.

Consequences of Divorce

Probably, the best researched area in divorce studies is that of the consequences of divorce. The effects of divorce include psychological, economic, and social consequences. The literature on the effects of divorce is divided first into that discussing effects on children and that discussing effects on adults. For children, effects are further subdivided into short- and long-term impacts. Finally, the sources of variation in the extent to which people are affected by divorce are discussed for both children and adults.

Effects on Children

Short-term consequences

Psychological impacts

Meta-analyses of over 100 relevant studies found that parental divorce increases the risk of psychological maladjustment and low self-esteem in children.

There is some evidence that the children of divorced parents have lower peer popularity at school than the children of intact families. This may be a social consequence of psychological impairment.

School performance. Two meta-analyses of over 100 studies found that parental divorce is associated with decreased school performance. Contributing factors to low-grade point averages included mothers with high levels of depression and low education levels.

The 'task overload' often found in single-parent, divorced families is associated with weaker supervision, increased labor force participation of the custodial parent to offset the loss of the income of their former spouse, and less parental monitoring of school work.

Criminal behavior

Divorce tends to be associated with a higher incidence of criminal behavior. A meta-analysis of 72 studies determined that children from divorced homes have higher rates of felony thefts, crimes against persons, drug abuse, and other offenses than children from intact homes. Divorce reduces the amount of supervision and control of children, both within the family and in neighborhoods with high proportions of single-parent families.

Long-term consequences

Psychological impacts: depression

Life-course approaches to divorce and depression have established a link between parental divorce and the odds for depression among children after they become adults. This association is independent of other marital and socioeconomic life outcomes of the children.

Divorce

A systematic analysis of 40 000 marriages in 17 nations determined that parental divorce increases the risk of divorce among children when they reach adulthood. The children of divorced parents tend to have more favorable attitudes toward divorce than the children of intact families. Divorced parents can constitute a negative role model for their children. Children growing up in families with constant bickering may not adequately learn the interpersonal skills that contribute to successful marriages.

In addition, personality orientations and disorders have genetic components. The intergenerational transmission of divorce may involve the transmission of genes that promote disagreeableness, low conscientiousness, and forms of neuroticism.

Social mobility

The experience of family disruption during childhood substantially increases men's odds of ending up in the lowest occupational stratum. Family disruption also weakens the association between the father's occupational status and the occupational status of the son. These relationships hold for both blacks and whites.

At the macrolevel of analysis, the increase in divorce rates since the 1960s is tied to the weakening of the association between sons' class of origin and class of destination. As more sons have been coming out of divorced homes, fewer of them are achieving the amount of occupational advancement that one would ordinarily expect on the basis of their father's occupation.

Explaining the variation in effects among children

Some children of divorced parents fare better than others in their level of well-being. Amato's review of 180 relevant studies suggests five indicators of well-being: academic achievement, behavior problems, psychological adjustment, self-esteem, and quality of social relations. Evidence-based investigations have reported the most consistent results for two moderating factors: the quality of the custodial parent's mental health and the level of conflict between the former husband and the former wife.

First, the hypothesis that the well-being of the children of divorced parents is positively linked with the postdivorce

psychological adjustment of the custodial parent is supported in nearly all studies. Better-adjusted parents are able to foster higher levels of well-being in their children. Further, the higher the quality of the relationship between the custodial parent and the child, the greater the well-being of the child.

Interparental conflict generally lowers the well-being of the child. Nearly 90% of the relevant studies support the notion that children's well-being is inversely correlated with the level of postdivorce conflict between their parents.

A majority of studies support the notion that the greater the economic well-being of the postdivorce household, the greater the well-being of the child.

The life-stress perspective contends that it is not a single stressor that erodes children's well-being, but a series or accumulation of stressors. Changing schools, moving, financial strain, loss of contact with grandparents, and so on, may ultimately wear down the child and threaten his/her basic well-being. Two-thirds of the relevant investigations confirm this notion that the greater the number of stressful life events, the lower the well-being of the child.

Generally speaking, children of divorced parents are more apt to have better well-being if their custodial parent is in good mental health, interparental conflict is low or absent, and the number of stressful life events is low.

Effects on Adults

Psychological and physical health

Generally, research has found a strong association between divorce and psychological impairment. For example, national survey data find that the divorced have a level of depression that is 40% higher than the national average. Levels of problems such as loneliness, guilt, anger, and anxiety are higher among divorced persons than among married persons. These problems are often attributed to such factors as a deterioration of the standard of living after divorce, a relative lack of confidants, and a deep sense of loss.

Divorced persons have a risk of suicide that is 2–4 times greater than married persons depending on the gender and age group one inspects. For example, divorced males aged 40–44 have a suicide rate of 104.4/100 000, 4.58 times that of married males of the same age (20.3/100 000). At the societal level, the relationship between suicide and divorce rates is like a sociological 'law.'

Turning to physical health, research on both the United States and other nations has tended to find a higher rate of both morbidity and mortality among the divorced than among the married. The increased risk of illness among the divorced has been linked to suppressed immunological functioning, which is especially pronounced among persons who are still attached to their exspouse.

Economic effects

In an egalitarian marriage where both husband and wife earn \$50 000 a year, they may be able to make a \$2000 per month mortgage or rent payment on a large home place in a desirable neighborhood. However, after a divorce, all else being equal, each would half their pooled income. A home place with a \$1000 per month payment might be all each could afford. It would probably be smaller and in a less desirable

neighborhood, probably with poorer schools for their children. On the whole, the custodial parent is faced with an ~30% or more reduction in their income and standard of living. Remarriage is the main avenue for restoring the predivorce standard of living.

Social effects

An immediate target for criminal violence is the exspouse, a person who is often the perceived source of considerable anger. Crimes of violence occur among one-quarter of all divorcing couples. At the aggregate level, the divorce rate is a fairly reliable predictor of the crime rate in cities.

Explaining the variation in effects among adults

Gender differences

Women experience greater negative financial consequences from divorce than do men. The degree of this difference, however, may be changing as the income gap between men and women's predivorce income narrows.

While both men and women experience an increase in depression following divorce, the causes of the depression tend to be somewhat different. For men, loss of emotional support is cited ahead of financial problems. In contrast, for women, financial problems are cited ahead of loss of emotional support.

Economic

The financial consequences of divorce are cushioned by the economic resources, such as skills and degree of labor force participation, of the custodial parent. Custodial parents with higher levels of education and training, and who increase the number of hours worked, fare better than their counterparts.

Support systems/social isolation

A recent meta-analysis of 21 studies determined that the higher the degree of social relationships following divorce, the lower the level of maladjustment. Maladjustment indicators include depression, anxiety, negative affect (e.g., unhappiness, life dissatisfaction), generalized psychological distress, and physical symptoms. Social support involving specific relationships (e.g., one-on-one relationships such as that with a best friend) buffer against maladjustment. Network-based or secondary social support such as that gleaned from membership in groups (e.g., church, circle of friends, neighborhood, and support group) may especially promote positive adjustment. For older divorced persons, relationships

with their adult children, who can now provide support, are often critical to divorce adjustment.

Relations with exspouse

Interspousal hostility and bitterness over the divorce impedes divorce adjustment. Positive attachment, such as dependence, to a former spouse may account for long-term psychological distress in some divorces. A relationship with one's ex marked by indifference may be the healthiest mode. The development of a new intimate relationship with someone of the opposite sex improves divorce adjustment.

Cultural beliefs

A belief in the immorality of divorce is associated with higher levels of psychological stress among divorcing couples. Adherence to liberal gender roles improves divorce adjustment for women.

Sexuality

An important aspect of divorce adjustment is reestablishing an intimate sexual relationship. Research at the national level has found that males were considerably more sexually involved than females, especially at older ages. Persons low in religiosity, high in education, and high in political liberalism were more sexually active than their counterparts.

Conclusions

Divorce in the Context of Rising Cohabitation Rates

While there have been declines in divorce recently in some nations, this trend is associated with parallel declines in marriage rates and upticks in the incidence of cohabitation, a key alternative to marriage. [Table 7](#) provides the essential data for establishing a context for the study of relationship breakdown in the future.

In the space of under 50 years, the number of cohabiting, unmarried American couples increased more than 15-fold from 439 000 in 1960 to over 6 million in 2008. In the same period, the percentage of persons who were divorced rose. Marriage became correspondingly less popular. A total of 88% of males were married in 1960, but only 65.7% were married by 2008. Importantly, the marriage rate, here, the number of marriages for every 1000 unmarried women 15 and over, declined by 50% from 73.5/1000 in 1960 to just 39.9/1000 in 2004.

Table 7 Trends in divorce and associated social indicators, 1960–2004

Year	% divorced males	% divorced female	% married male	% married female	Married rate per 1000 married female	Number of cohabitants (1000s)	% kids with both parents	% births to unmarried mothers
1960	1.8	2.6	88.0	87.4	73.5	439	88	5.3
1970	2.2	3.5	89.3	86.9	76.5	523	85	10.7
1980	4.8	6.6	84.2	81.4	61.4	1589	77	18.4
1990	6.8	8.9	74.1	73.0	54.5	2856	73	28.0
2000	8.3	10.2	69.0	71.6	46.5	4736	69	33.2
2004	8.2	10.9	65.7	67.3	39.9	5080	68	34.6
2008	9.0	11.7	Na	Na	Na	6800	Na	Na

The rise in unwed births and rise in divorce is associated with a substantial drop in the percentage of children under 18 who live with both biological parents: from 88% in 1960 down to 68% in 2004. For African-Americans, this figure is substantially less, with only 35% of children now living with both biological parents.

Importantly, there has been a sevenfold increase in the percentage of children born to unmarried mothers: 5.3% in 1960 rising to 34.6% by 2004. For African-Americans, fully 68% of births are to unwed mothers.

Cross-national research spanning 17 nations has consistently found that cohabitation before marriage raises the odds of divorce after marriage. Far from being a way to reduce the chances of divorce, it apparently backfires and enhances the chances of divorce. In the United States, over half of all first marriages are now preceded by cohabitation.

With so many children being born to unwed mothers, and with the fall in the marriage rate and rise in unmarried cohabitation, future research on divorce needs to include not just the breakups experienced by married couples, but also the breakups of the unions of unmarried couples. In some nations, the proportion of unmarried cohabiting couples is now greater than the proportion of married couples.

It seems unlikely that these trends which began a generation ago are apt to reverse. They are best understood as an expression of a highly individualist culture. Cultural attitudes of young people, the group constituting the future of the family, increasingly support new marriage and family forms. For example, after increasing over the years, a majority of youth in the United States now report that "having a child without being married is experimenting with a worthwhile lifestyle and not affecting anyone else." Academic research needs to respond to these trends and begin the systematic study of union dissolution among cohabitants.

Glossary

Agonist A chemical that binds to a neurotransmitter receptor and mimics the action of an endogenous neurotransmitter.

Antagonist A chemical that binds to a neurotransmitter receptor and has no effect other than to block the action of endogenous neurotransmitters and other receptor agonists.

Drug A chemical that, in small amounts, has significant effects on physiology.

Hallucination Perceptual experiences in the absence of associated external sensory stimuli.

Neurotransmitter A chemical that is released by nerve cells and diffuses extracellularly to bind to receptors on nerve cell membranes, thereby mediating intercellular communication of neural signals.

Neurotransmitter receptor Proteins located in nerve cell membranes that specifically bind neurotransmitters, undergo a resulting conformational change, and thereby mediate changes in cell membrane electric potential or initiate various intracellular biochemical processes.

Synaptic cleft At a synapse, the narrow gap between a neuron and an adjacent neural cell.

Uptake transporter Proteins located in nerve cell membranes that function to remove neurotransmitter from the synaptic cleft and move it into the interior of the cell; often located on the presynaptic axon terminal, thus returning neurotransmitter into the cell from which it was released.

Introduction

Drugs are chemicals that, in small amounts, have significant effects on physiology. Psychoactive drugs are chemicals that have effects on the psyche or mind, presumably by way of their interaction with the nervous system and, in particular, the brain. The human brain is likely the most complex object thus far encountered in the universe. Its complexity is manifest in its ~100 billion neurons interconnected by trillions of synapses. In addition, the human brain contains several hundreds of billions of various kinds of glia cells, some of which are intimately involved in cellular signaling processes. Astrocyte glia cells, for example, play central roles in cell-to-cell signaling at synapses, exhibiting many of the properties formerly considered unique to neurons.

Each and every synapse is the setting for an intricate molecular drama involving release of chemical neurotransmitters, rapid diffusion of neurotransmitter across the narrow gap (cleft) separating the presynaptic from the postsynaptic neuron, binding of neurotransmitter to receptor proteins – located in the membranes of the postsynaptic and presynaptic neurons and of astrocyte glia cells – and resulting conformational changes of the receptor proteins. If the receptor is an ionotropic receptor, the effect will be ion flow across the cell membrane, a change in the membrane voltage, and a resulting change in the excitability of the cell. If the receptor is a metabotropic G-protein-coupled receptor (GPCR), the result will be the modulation of intracellular processes that include ion-channel gating, enzyme activation, and gene transcription. The neuronal signaling process is terminated when the neurotransmitter is taken back up into the neuron that released it, or into other nearby cells, via membrane proteins called uptake transporters, or is enzymatically degraded.

Dozens of different molecules have been identified as neurotransmitters in the human brain. Glutamic acid or glutamate

is the primary excitatory neurotransmitter in the human brain. GABA (γ -amino-butyric acid) is the major inhibitory neurotransmitter. Other neurotransmitters include acetylcholine, serotonin, dopamine, norepinephrine, epinephrine, histamine, glycine, adenosine, anandamide, nitric oxide, and the opioid polypeptides. Additional neurotransmitter molecules no doubt remain to be discovered. The diversity of chemical neurotransmitters and the numerous different receptor proteins – typically, many different types of receptor proteins for each type of neurotransmitter – are another facet of the vast complexity of the brain.

As far as is presently known, psychoactive drugs exert their influence by interacting with the signal transmission process at synapses. There are various ways in which this can happen. A drug can mimic the effect of a neurotransmitter because sufficient similarity in molecular structure allows the drug to bind to and activate a receptor in a manner similar to that of endogenous neurotransmitter. Such a drug is called a receptor agonist. Or it could bind to a receptor and block the receptor, preventing its being activated by endogenous neurotransmitter. Such a drug is called a receptor antagonist. Some drugs enhance neurotransmitter release or leakage from the presynaptic neuron. Others block uptake of neurotransmitter from the synaptic cleft, or interfere with the synthesis or degradation of neurotransmitter, or interact with the chemistry of the brain in ways not yet elucidated.

Psychoactive drugs include the following chemicals: commonly used nonmedical substances such as caffeine, alcohol, and nicotine; medically prescribed substances such as amphetamine, morphine, and benzodiazepines; mind-altering substances that have been excluded from accepted medical use and are declared illegal, such as heroin, cannabis, and psychedelics like lysergic acid diethylamide (LSD) and mescaline; and medications used to treat mental-health conditions, such as antidepressants and antipsychotics. Among these drugs, some

are frequently used for their pleasure-producing effects (alcohol, caffeine, etc.), some are used medicinally (antidepressants, antipsychotics, etc.), some are used for both (amphetamine, opioids, benzodiazepines, cannabis, etc.), and some are more prone to fostering problematic relationships such as addiction (nicotine, alcohol, benzodiazepines, opioids, etc.).

Historically, psychoactive drugs were all natural products, ingested in the form of plants or fungi, or extracts of these organisms. The word 'drug' comes from the Old English word 'drogge' and the Old French word 'drogue,' words that may have earlier had the meaning of 'dry' or 'dried plant.' Beginning in the 1800s, chemists isolated and identified a number of molecules from plants that had psychoactive effects. Morphine, caffeine, nicotine, atropine, cocaine, and mescaline were all identified as psychoactive compounds from plants by nineteenth-century European chemists. Beginning near the end of the nineteenth century and continuing to the present day, medicinal chemists have synthesized previously unknown molecules having psychoactive effects. Some of these new molecules have been marketed by the pharmaceutical industry as drugs for the treatment of various conditions.

In the United States, many psychoactive drugs are classified according to the Controlled Substances Act, a federal law first instituted in 1970 and copied in some form by all of the states. The US Controlled Substances Act classifies psychoactive drugs that have been declared to have potential for abuse (problematic use leading to possible addiction) into five categories or schedules. Schedules II, III, IV, and V are legally available for medical use with an appropriate physician's prescription. Examples are amphetamine, morphine and other opioids, and the benzodiazepines. Schedule I drugs have been declared categorically illegal and are not available for legal medical use. Examples are heroin and the psychedelics. Alcohol and nicotine (or tobacco) are not regulated by the Controlled Substances Act. Some other countries have similar classifications of psychoactive drugs, such as the Misuse of Drugs Act in the United Kingdom. This UK Act classifies drugs having abuse potential into one of three classes: A, B, or C, with Class A drugs considered to be potentially the most harmful. Many countries worldwide have signed on to an international classification of controlled substances: the United Nations Convention on Psychotropic Substances, instituted in 1971.

Abuse and addiction are toxic aspects of certain drugs. Even drugs that have substantial medicinal benefits may also have significant toxic effects. Indeed, as the pioneer pharmacologist Paracelsus (1493–1541) said nearly 500 years ago: "Everything is a poison. The difference between a poison and a medicine depends on the dose."

In terms of both physiology and behavior, the effects of any psychoactive substance may be impacted by both the mental state or set of the user (expectations, prior experience, mood, etc.) and the physical setting of use (alone, social, therapeutic context with a healer, spiritual ritual, etc.). Some drugs are more susceptible to these 'set-and-setting' effects than others. Thus, caffeine may generally have a small set-and-setting effect and alcohol an intermediate one, while for substances such as cannabis and the psychedelics the set-and-setting effect may be very large.

This article will briefly describe the essence of what is currently known about the neurochemical effects of various

psychoactive drugs, as well as something of their effects on behavior. Sometimes knowledge of neurochemical effects can be mechanistically related to behavioral actions, and sometimes there is little understanding as to how the known neurochemistry and a drug's effects on behavior are related. As knowledge about the brain increases, we may find that many of the neurochemical actions of psychoactive drugs are far more complex than are presently understood.

Caffeine

Caffeine (1,3,7-trimethylxanthine) is by far the most widely used psychoactive drug in the world. It is found in a number of plants, the most well-known being coffee (*Coffea arabica*, native to Africa), tea (*Camellia sinensis*, native to China), and cacao (*Theobroma cacao*, native to South and Central America), from which chocolate is made. Other caffeine-containing plants include kola (*Cola acuminata*, native to Africa), guarana (*Paullinia cupana*, native to South America), and yerba mate (*Ilex paraguayensis*, native to South America). Closely related to caffeine are two other methylated xanthines with similar psychoactive effects. These are theophylline (1,3-dimethylxanthine), found in tea, and theobromine (3,7-dimethylxanthine), from cacao. Caffeine is believed to act by antagonizing (blocking) receptors for the inhibitory neurotransmitter adenosine, thereby producing a stimulant effect on brain activity.

Nicotine

Nicotine comes from the tobacco plant – *Nicotiana tabacum*, *Nicotiana rustica*, and related species – native to the Americas. It is generally taken into the body by smoking the dried leaves of the tobacco plant. It may also be absorbed through the nasal mucosa or oral-buccal cavity, using a snuff preparation or chewing tobacco. The major known neurochemical effect of nicotine is to bind as an agonist at the nicotinic-type receptor for the neurotransmitter acetylcholine. This produces complex effects in the brain that are presumably related to the behavioral effects of relaxation, mental stimulation, and focused attention experienced by users of tobacco. Nicotine also stimulates the cardiovascular system, producing an increase in heart rate and blood pressure. Chronic exposure to nicotine can result in cardiovascular disease and increased risk of heart attack and stroke. Tobacco smoking is related to increased risk of lung diseases such as cancer and emphysema, apparently due to irritant and carcinogenic substances in smoke. The carbon monoxide component of smoke produces additional stress to the cardiovascular system and other body organs by decreasing the oxygen-carrying capacity of the blood.

Sedative-Hypnotics

Sedative-hypnotics produce relaxation and sometimes euphoria in low doses, drunkenness and sleep in higher doses, and possible coma and death if the dose is sufficiently large. Alcohol (ethyl alcohol or ethanol) is the most widely used sedative-hypnotic drug. Ethyl alcohol is a natural product of

the fermentative metabolism of carbohydrate by yeasts. As this process occurs easily and naturally in the environment, it is likely that human consumption of alcoholic beverages goes far back in history.

Synthetic pharmaceutical sedative-hypnotics include the benzodiazepines (diazepam (US brand name, Valium), alprazolam (Xanax), lorazepam (Ativan), temazepam (Restoril), etc.), barbiturates (phenobarbital, secobarbital, amobarbital, etc.), and other substances such as chloral hydrate, meprobamate (Miltown), and methaqualone (Quaalude). Pharmaceutical sedative-hypnotics have been prescribed medically as treatments for anxiety (anxiolytic agents), as aids to sleep, as muscle relaxants, and as antiseizure medications. A variety of primarily hypnotic drugs have also been introduced to the marketplace in recent years. There include zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta).

General anesthetics are powerful sedative-hypnotics used to induce loss of conscious awareness and insensitivity to pain during surgical procedures. They are often volatile organic compounds inhaled as part of a gas mixture during surgery. Historically, diethyl ether and chloroform were used in this way. Contemporary examples include halogenated compounds such as desflurane, enflurane, halothane, isoflurane, and sevoflurane.

GHB, γ -hydroxy butyric acid, is a sedative-hypnotic whose chemical structure is similar to that of the neurotransmitters GABA and glutamate. In the United States, GHB has been declared a Schedule I drug because of its use in recreational settings. However, it is also available as a Schedule III pharmaceutical for the treatment of certain sleep disorders.

Kava kava (*Piper methysticum*, native to South Pacific islands), valerian (*Valeriana officinalis*), chamomile (*Matricaria recutita*), lavender (*Lavandula angustifolia*), catnip (*Nepeta cataria*), and hops (*Humulus lupulus*) are examples of plants with sedative-hypnotic properties.

Many sedative-hypnotic substances are believed to exert their effect on the brain by interacting with receptors for the neurotransmitter GABA. While not acting as direct receptor agonists, their effect at these receptors enhances the action of GABA as an inhibitory neurotransmitter and thus results in decreased excitation in the brain. Some (alcohol, for example) may also have actions at glutamate receptors, reducing the action of glutamate, which is the brain's major excitatory neurotransmitter. In addition, GHB may itself have direct inhibitory neurotransmitter action in the brain, with its own distinct receptors. The various plants listed above may contain chemical constituents that act at the GABA receptor. They may well also contain multiple psychoactive molecules that contribute to their overall effects. This is an important distinction between plants and molecules: Although a single molecular species may be associated with the primary medicinal effects of a plant, the plant will always have more complex effects, as the plant contains numerous different chemicals, a number of which may possess physiological activity.

Cocaine

Cocaine comes from the plant *Erythroxylum coca* and several related species, native to South America. Cocaine blocks

reuptake transporter proteins for the neurotransmitters dopamine, norepinephrine, and, to a lesser extent, serotonin. In the brain, this results in the activation of circuits that increase alertness and wakefulness, produce euphoria, and decrease appetite. In the peripheral nervous system, cocaine activates the sympathetic branch of the autonomic nervous system, with resultant increased heart rate, blood pressure, pupil size, and bronchial airway size. The leaves of the coca plant have been used by indigenous peoples of South America for centuries (and possibly millennia) as a stimulant and for other medicinal qualities. Cocaine, extracted and purified from the coca plant, has far more intense effects on the body than does coca leaf. Sympathomimetic effects may damage the cardiovascular system and may be acutely toxic by precipitating a heart attack or stroke. Excessive stimulation of the central nervous system (CNS) may result in stimulant psychosis (paranoia, other delusions, hallucinations) and seizures.

Amphetamine

Amphetamine and its close chemical relative, methamphetamine, are synthetic substances that cause the neurotransmitters dopamine, norepinephrine, and serotonin to leak out of the presynaptic nerve terminal into the synaptic cleft. The leakage occurs not via the usual process of synaptic-vesicle fusion and exocytosis of neurotransmitter, but by way of the reuptake transporter protein somehow passing neurotransmitter from the interior of the axon to the exterior. This results in activation of the same brain and peripheral nervous system circuits as with cocaine and substantially similar behavioral effects. There are a number of pharmaceutically manufactured substances that can be considered molecular relatives of amphetamine and that work in similar ways. They have been prescribed as CNS stimulants for the treatment of narcolepsy, as appetite suppressants, and as treatment for attention deficit hyperactivity disorder (ADHD). Ephedrine and pseudoephedrine (from plants of the genus *Ephedra*, found worldwide), cathinone (from the khat plant, *Catha edulis*, native to northeast Africa and Yemen), and the synthetic compounds methylphenidate (Ritalin) and phenylpropanolamine are examples of other related molecules with both central and sympathetic nervous system stimulant effects resulting from cellular actions similar to those of amphetamine.

Opioids

Opioids (or opiates) are a group of naturally occurring and synthetic chemicals that act on the nervous system like opium, the gummy secretion from the unripe seedpod of the opium poppy, *Papaver somniferum*, native to central Europe and the region around the Mediterranean Sea, and now grown throughout the world. Natural opium contains morphine and codeine. The discovery of morphine by Friedrich Wilhelm Sertürner (1783–1841) in the early years of the nineteenth century (the reported date of discovery ranges from 1803 to 1817) was a landmark event in the history of science. It was the first time a chemical was isolated and purified from a plant and shown to account for some aspect of the medicinal properties of the

plant. This became a defining event for organic natural-products chemistry and contributed to the perspective that purified chemicals were a more valuable basis for understanding the actions of medicinal substances than whole plants.

Opioids act on opioid receptors in the brain to reduce the perception of pain (analgesia), suppress cough, constrict pupils, and slow respiration. They may also produce relaxation, euphoria, and a dreamy state of consciousness. Medicinally, opioids are invaluable as analgesics and cough suppressants. Acting at opioid receptors in the digestive system, opioids slow intestinal motility and thus are valuable treatments for diarrhea. The most significant potentially toxic aspects of opioids include the risk of dependence and addiction, and the acute depression of respiration, which can lead to death.

A number of opioids are either chemical derivatives of morphine, codeine, or other related molecules in opium, or are synthesized from nonopioid precursors. Heroin (diacetylmorphine) is a simple chemical derivative of morphine that allows it to cross the blood-brain barrier about 3 times more efficiently than morphine. It was first introduced in 1898 as a pharmaceutical medicine for the treatment of pain and cough by the Bayer company. Hydromorphone (Dilaudid), oxycodone (Percodan, OxyContin), and hydrocodone (Vicodin) are all derived from opium precursors. Methadone, meperidine (Demerol), and propoxyphene (Darvon) are examples of synthetic opioids, not derived from opium-based precursors. The synthetic opioids fentanyl, sufentanil, and carfentanil range from being about 100 times to nearly 10 000 times more potent than morphine.

The known opioid receptors are widely distributed in the brain and spinal cord, and are also found in the digestive system and elsewhere in the body. Receptors are GPCRs and are generally characterized as one of three subtypes: mu, delta, or kappa. The neurotransmitters acting at opioid receptors are a class of small peptide molecules collectively called endogenous opioid polypeptides or endorphins (from 'endogenous morphine'). These range in size from the 5-amino-acid-long leu-enkephalin and met-enkephalin to the 31-amino-acid-long β -endorphin. The endorphins are derived from the post-translational processing by specific enzymes of three larger polypeptide products of gene transcription and translation: pro-opiomelanocortin, pro-enkephalin, and pro-dynorphin.

Cannabinoids

The cannabinoids are a class of chemical substances found in the *Cannabis* plant, the source of marijuana (dried buds and leaves) and hashish (concentrated resinous exudate from the buds and leaves). The primary psychoactive cannabinoid in cannabis is delta-9-tetrahydrocannabinol, often referred to simply as THC. The cannabis plant is one of the most ancient human cultivars, with medicinal use documented in Chinese medical texts from more than 3000 years ago. Some botanists recognize distinct species of *Cannabis sativa*, *Cannabis indica*, and *Cannabis ruderalis*, while others believe cannabis has been cultivated by humans for so long that no distinct wild-type species remain. Whether they are considered different species or not, certainly different varieties exist. The plant is believed

to have originated in central Asia and now grows throughout the world.

The psychoactive effects of cannabis may include relaxation, sedation, intensification of thoughts and feelings, alterations of perception, and increased appetite. Medicinally, cannabis has been used as an analgesic, an anti-inflammatory, a treatment for migraine headache, an antiemetic (to decrease nausea), an anticonvulsant, a muscle relaxant, a treatment for glaucoma, and an appetite stimulant. It was widely used as a medicine prior to the initiation, in 1937, of repressive legislation by the US government. Recent years have witnessed a resurgence of interest in the medicinal properties of cannabis and consideration of new laws allowing resumption of legal medical use and clinical research.

For many years, the neurochemical mechanism of action of THC remained obscure. The last decade of the twentieth century saw the discovery of specialized receptors responding to THC (cannabinoid receptors). Cannabinoid receptors are widespread in the human brain, as well as elsewhere in the body, such as in the immune and endocrine systems. Thus far, at least two endogenous compounds have been implicated as neurotransmitters for the cannabinoid system. These are anandamide and 2-arachidonyl glycerol (2-AG), both of which are long-chain, polyunsaturated compounds derived from membrane lipids. The function of the cannabinoid signaling system remains largely unknown, although it is likely to be involved in things such as appetite, memory, and the perception of pain.

A very exciting aspect of endocannabinoid neurochemistry is the notion that cannabinoid signaling at synapses is involved in the modification of synaptic strength. These effects are mediated by way of a novel mechanism that has been termed retrograde signaling. In locations where this occurs – and these locations appear to be pervasive throughout the brain – conventional neurotransmission via the abundant excitatory neurotransmitter glutamate may trigger the postsynaptic on-site synthesis of endocannabinoids. These then diffuse into the synaptic cleft and carry signal information in a retrograde fashion back to the presynaptic neuron or to other nearby neurons and glia cells. The effects of these endocannabinoid transmitters at cannabinoid receptors may then alter the properties of the presynaptic neuron as well as other nearby cells.

Psychedelics or Hallucinogens

The psychedelics are among the most interesting and poorly understood of all the psychoactive drugs. They produce a variety of complex effects on the brain and mind, including intensification of thoughts and feelings, alterations of sensory perception, and loosening of psychological defenses. Reported effects range from euphoria, therapeutic insight, and mystical experiences, to anxiety and panic. The effects of psychedelic drugs on behavior and mental experience, to a greater degree than is the case for other drugs, are significantly influenced by the mental state and the physical setting of the user.

As their properties came under investigation by twentieth-century biomedical science, many of these compounds were initially called psychotomimetics, because it was believed their effects were much like the symptoms of psychosis. This term was eventually eclipsed in favor of hallucinogen, highlighting

that effects may include alterations of perception, including hallucinations. In 1956, the psychiatrist Humphry Osmond (1917–2004), in correspondence with the author Aldous Huxley (1894–1963), proposed the word ‘psychedelic’ (from the Greek roots ‘mind manifesting’) to describe the unique effects of these compounds on consciousness. In their plant forms, psychedelics have been used by cultures around the world for thousands of years to facilitate states of consciousness conducive to mystical experiences. This has led to the use of the word ‘entheogen’ (generating god within) to emphasize their ritual use in spiritual settings.

Although it has not been found as a natural product in plants or fungi and its profound psychoactive properties were not known until it was synthesized and tested by Albert Hofmann (1906–2008) in 1943, LSD is perhaps the most widely known psychedelic chemical. It is one of the most potent psychoactive substances known, active in quantities of a few micrograms. Psychedelics identified from plants and fungi include lysergic acid amide from morning glories (family Convolvulaceae), psilocybin and psilocin from a variety of mushrooms (many from the genus *Psilocybe*), dimethyltryptamine (DMT) from a variety of plant species found throughout the world, and mescaline from several species of cacti, one of which is peyote (*Lophophora williamsii*). Numerous chemical relatives of the compounds named above have been synthesized, tested, and found to have psychedelic effects in humans. This broad category of substances is sometimes additionally delineated as the ‘classical’ psychedelics or hallucinogens, to distinguish them from other substances discussed later that also possess psychedelic and hallucinogenic effects.

The therapeutic utility of psychedelic plants and fungi has been appreciated for centuries in cultures where shamanic practitioners provided medical and psychotherapeutic care. And prior to their being declared illegal in the United States, these compounds were researched and utilized for their psychotherapeutic properties. Clinical research during the 1950s–1960s found them to be of value in the treatment of alcoholism and in psychotherapeutic work addressing death in terminally ill patients. There is ample reason to believe that when used with therapeutic intent in carefully controlled settings, they can be of extraordinary value. Such use may exclude some individuals having preexisting mental illness, as their powerful effects on the brain and mind may exacerbate preexisting symptoms or tendencies toward psychopathology.

Neurochemically, psychedelics have been found to bind as agonists to various serotonin receptor subtypes, especially type-2A serotonin receptors. Psychedelics also bind to other neurotransmitter receptors, including those for dopamine and norepinephrine. The connection between their neurochemical effects and their profound effects on mental function remains largely obscure.

Methylenedioxymethamphetamine

Methylenedioxymethamphetamine (MDMA), popularly known by the street name ‘ecstasy,’ and its close chemical relative methylenedioxyamphetamine (MDA), are often considered together with the psychedelic drugs. While MDMA does have some of the mind-manifesting characteristics of the

psychedelics, its overall properties are distinct enough to warrant a separate category. Chemically related to methamphetamine, MDMA produces CNS stimulation, euphoria, and sympathetic nervous system stimulation. The methylenedioxy moiety confers upon the molecule additional psychoactivity that is psychedelic-like, characterized by intensification of thoughts and feelings and enhanced feelings of connection with others. For many individuals, there is a reduction in anxiety and an enhanced ability to verbalize feelings. These qualities led to the use of MDMA as an adjunct to psychotherapy prior to its being declared an illegal Schedule I substance in 1985, an act that followed media attention to its use as a recreational drug in dance clubs. Though illegal, MDMA continues to be used for both its psychotherapeutic and recreational properties by some individuals. Recently it has been the subject of clinical research for the treatment of posttraumatic-stress disorder.

While MDMA has been found to interact with a number of CNS neurochemical systems, the primary neurochemical effect of MDMA appears to be the release of serotonin and dopamine from nerve terminals into the synapse. Release is not via the usual process of storage vesicle fusion with the cell membrane, as occurs with a nerve impulse, but is by way of leakage of neurotransmitter out of the cell through the reuptake transporter. Animal studies have indicated that MDMA may result in oxidative damage to serotonin nerve terminals. The implications of these findings for human use remain to be determined.

Nitrous Oxide

Nitrous oxide (N₂O) is a gas (sometimes called ‘laughing gas’) widely used in medicine and dentistry for its anesthetic and analgesic properties. It is used by dentists as a sole anesthetic agent and is a component of the inhalation anesthesia (together with potent volatile sedative-hypnotic general anesthetics) for major surgeries. In addition, in subanesthetic doses it can produce a powerful psychedelic-like state of consciousness. Its various psychoactive properties were documented in 1800 by the British chemist Humphry Davy (1778–1829). Davy’s work, published as a book of more than 300 pages in length when he was only 21 years old, represented the first detailed study of the effects of a defined chemical substance on the human mind. Although nitrous oxide has been found to interact as an antagonist at the *N*-methyl-D-aspartate (NMDA)-type of glutamate receptor (a variety of ionotropic glutamate receptor occurring throughout the brain), the mechanism of its psychoactive effects remains obscure.

Dissociative Anesthetics

This class of psychoactive drugs consists of ketamine and PCP (phenyl cyclohexyl piperidine or phencyclidine). These are synthetic compounds introduced into medicine to produce an anesthetic loss of bodily sensation without depressing the vital functions of respiration and cardiovascular action, as do the general anesthetics. While PCP is no longer used medically, ketamine is used in both human and veterinary surgical

procedures. For human surgeries, it is perhaps used most often in infants, the elderly, and in trauma cases, where depressing vital functions may be particularly dangerous. At subanesthetic doses in humans, ketamine catalyzes a change of consciousness having some hallucinogenic and psychedelic characteristics and may be accompanied by a loss of body awareness. Recent research has suggested that subanesthetic doses of ketamine may have prolonged antidepressant effects, that is, elevation of mood in persons suffering from clinical depression. The primary neurochemical effect thus far discovered for these drugs is antagonist action at the NMDA-type glutamate receptor.

Anticholinergics

These substances act as antagonists at muscarinic-type receptors for the neurotransmitter acetylcholine. Such receptors are found in the brain and in the parasympathetic branch of the autonomic nervous system. Psychoactive effects can range from feelings of disorientation to dreamlike alterations of consciousness to powerful hallucinations. Effects on the autonomic nervous system produce a cluster of symptoms that include dry mouth, difficulty urinating, constipation, blurry vision, and orthostatic hypotension. Hyoscyamine (named after henbane), atropine (a mixture of D and L stereoisomers of hyoscyamine, and named after *Atropa belladonna*), and scopolamine (named after *Scopolia*) are anticholinergics found in a number of species of plants from the family Solanaceae. These include *A. belladonna* (deadly nightshade), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Scopolia*, *Brugmansia*, *Datura*, and *Brunfelsia*.

Atropine, scopolamine, and tincture of belladonna are used to treat intestinal motility problems such as diarrhea and irritable bowel syndrome. Several synthetic anticholinergic drugs are used as adjunctive treatments for Parkinson's disease. Several of the phenothiazine antipsychotics and tricyclic antidepressants (TCAs) described below have anticholinergic effects in the brain and autonomic nervous system.

Salvia divinorum

This plant is put into a class of its own, as there are no other substances that are known to have its peculiar effects on mental experience. A member of the mint family, its Latin name literally means 'sage of divination,' and it has been used for centuries by shamanic healers in southern Mexico (its only known indigenous location) for ritual spiritual purposes. It was introduced to the modern world when the shaman Maria Sabina (1888–1985) told Gordon Wasson (1898–1986) about it in the 1950s. Its effects are powerful and of a hallucinatory nature, although of a very different sort from the classical psychedelics or the anticholinergics. The historical use of the plant was by way of chewing the leaves in a ritual context with a shaman. This plant was unknown outside of a relatively narrow ritual context and likely would have remained so without the aid of the Internet. Contemporary use includes smoking of the dried leaves or of concentrated psychoactive extracts.

The primary psychoactive molecular component has been identified as salvinorin A, a terpenoid compound acting in the brain as an agonist at kappa-opioid receptors.

Antipsychotics

In Indian ayurvedic medicine, from ancient times to the present, extracts of the snakeroot plant, *Rauwolfia serpentina*, have been used to treat symptoms of psychosis (troubling hallucinations and delusions). In the mid-twentieth century, the chemical reserpine was isolated and identified from *Rauwolfia serpentina* and found to cause decreases in the activity of monoaminergic neurons using the neurotransmitters dopamine, norepinephrine, and serotonin.

The first pharmaceutical antipsychotics were the phenothiazines such as chlorpromazine (Thorazine), introduced in the 1950s. Other phenothiazine antipsychotic drugs include perphenazine, thioridazine, trifluoperazine, and pimozide. Non-phenothiazine antipsychotics introduced in the 1960s and 1970s include haloperidol (Haldol) and thiothixene (Navane).

The primary neurochemical effect of all these compounds is to block various types of dopamine receptors. This is believed to lead to a reduction of psychotic symptoms and also to the production of various motor side effects, such as Parkinsonian-like symptoms and movement dyskinesias.

More recently, several antipsychotic medications have been introduced that have fewer motor side effects. These so-called 'atypical' antipsychotics include clozapine (Clozaril), risperidone (Risperdal), paliperidone (Invega), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), and aripiprazole (Abilify). In addition to being antagonists at dopamine receptors, these drugs are also antagonists at type-2 serotonin receptors. The serotonin-receptor antagonism is believed to compensate for some of the dopamine-blocking effects in the motor circuitry of the brain, thereby reducing problematic movement symptoms. Many of the atypical antipsychotics have been associated with endocrine-system effects related to problematic weight gain and increased risk of diabetes.

Antidepressants

Extracts of the plant Saint John's Wort, *Hypericum perforatum*, have been used for centuries in Europe for its antidepressant effects. This plant also facilitates wound healing when preparations are used topically. Its healing properties were mentioned in the ancient medical texts of Hippocrates, Pliny, and Galen.

The first pharmaceuticals developed and marketed specifically for their antidepressant effects were the monoamine oxidase inhibitors (MAOIs), discovered in the 1950s. Examples of MAOIs currently on the market are isocarboxazid, phenelzine, tranylcypromine, and selegiline. Via inhibition of the enzyme MAO, these compounds may produce enhanced activity in circuits utilizing the neurotransmitters serotonin, norepinephrine, and dopamine.

A second class of contemporary pharmaceuticals developed and marketed for their antidepressant effects are the TCAs, so called because their molecular structures contain a three-ringed central core. They include imipramine, amitriptyline,

desipramine, nortriptyline, doxepin, and clomipramine. TCAs inhibit monoamine reuptake transporters, primarily for norepinephrine and serotonin.

Newer-generation antidepressants include the serotonin selective reuptake inhibitors (SSRIs), represented by fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), fluvoxamine (Luvox), citalopram (Celexa), and escitalopram (Lexapro). Other antidepressant drugs include trazodone (Desyrel), nefazodone, bupropion (Wellbutrin and Zyban), venlafaxine (Effexor), desvenlafaxine (Pristiq), mirtazapine (Remeron), and duloxetine (Cymbalta). These later compounds interact in various ways with monoamine neurotransmitter receptors and reuptake transporters.

The prevailing hypothesis regarding antidepressant mechanism is that some sort of change in serotonin and/or norepinephrine synaptic chemistry underlies their clinical action, but exactly what sort of change it is remains unclear. As these neurotransmitters act on a variety of GPCRs, it is likely that the ultimate antidepressant effects involve modulation of gene transcription, resulting in production of nerve growth factors and subsequent synaptic plasticity and neurogenesis.

Mood Stabilizers

These substances are used in the treatment of bipolar or manic-depressive disorder. The most well-known such mood stabilizer is lithium, administered as a salt that produces lithium ion upon ingestion. The therapeutic effects of lithium in the treatment of manic depression were discovered in 1949, and it has been widely used as a medication in psychiatry for more than half a century. The most robust neurochemical effect of lithium thus far elucidated is its interference with G-protein-coupled pathways using phosphatidylinositol as an intracellular messenger, thereby producing a damping effect on many GPCR systems.

Several chemicals, first discovered for their antiseizure properties and used to treat epilepsy and other seizure conditions, are also used to stabilize mood in manic-depressive disorder. These include carbamazepine (Tegretol), valproic acid (Depakote), lamotrigine (Lamictal), and oxcarbazepine (Trileptal). This connection between unstable mood and seizures suggests that similar neuronal properties of hyperexcitability may be involved in both conditions.

Drugs and the Brain

The functioning of the brain can be understood in part by way of a symphony of complex chemical interactions. Psychoactive drugs are believed to work by influencing the chemistry of the brain, primarily by perturbing activity at synapses. This gives rise to short-term behavioral effects such as relaxation, alertness, euphoria, analgesia, sleep, and so forth, presumably related to changes in activity in various brain networks. Repeated perturbation of the brain's chemistry brings about changes in the circuitry of the brain and results in lasting changes in behavior: improved mood from antidepressants, decreased psychosis from antipsychotics, symptoms of dependence and addiction from a variety of drugs, movement disorders from antipsychotics, and so forth. Changes in the

brain's circuitry presumably reflect the strengthening and weakening of synapses through mechanisms such as changes in the number of receptors, changes in the amount of neurotransmitter released, and modulation of intracellular biochemical pathways activated by membrane receptors. Growth of dendrites to form new synapses or deterioration of existing synapses may also be involved. Many of these processes may be regulated by calcium entering the cell via ionotropic receptors or gene transcription modulated by way of GPCRs.

Withdrawal, Dependence, and Addiction

Changes in brain physiology resulting from repeated exposure to psychoactive drugs may result in withdrawal symptoms when use of the drug is decreased or stopped. It is likely that extended use of any psychoactive drug will bring about homeostatic changes in brain physiology that result in symptoms of withdrawal if use of the drug is stopped. In some cases the withdrawal symptoms will be clinically significant and in other cases they may not. For example, repeated use of sedative-hypnotics may produce rebound withdrawal symptoms of arousal, anxiety, and insomnia, and in more severe cases, hallucinations, delirium, and seizures. Situations of clinically significant withdrawal are taken to indicate physical dependence.

Some psychoactive drugs, especially those that produce an experience of pleasure, euphoria, or reduced anxiety, appear to influence neural circuits in the limbic system of the brain. These so-called reward circuits contribute to reinforcement of behaviors important for survival, such as eating, drinking, sexual activity, and finding shelter. Euphorogenic psychoactive drugs may hijack these circuits and produce unusually intense stimulation. The resulting homeostatic changes in the circuits might then produce symptoms of withdrawal that include cravings (intense desires) for the drug, dysphoria, anxiety, and compulsive drug-seeking actions. Clinically significant compulsive drug use is termed addiction.

The reward circuits connect the ventral tegmentum with the nucleus accumbens and the frontal cortex. The primary neurotransmitter in these circuits is dopamine. Various drugs known to be euphorogenic and potentially addiction-producing have been shown to increase the release and activity of dopamine in these circuits. While different psychoactive drugs (sedatives, stimulants, opioids, etc.) have a variety of different effects on the brain and behavior, it is possible that their actions on the dopaminergic reward circuits may be part of a common neurochemical mechanism involved in addiction.

Whether or not an individual develops an addictive relationship with a drug is in part dependent on the drug's pharmacology and its direct effects on brain neurochemistry. These factors are modulated by genetic risk factors for addiction, as well as psychological and sociocultural factors, such as availability of coping strategies for stress and extent of drug use by others in one's surroundings.

Drugs and the Mind

Let 'mind' refer to the collection of mental processes – including thoughts, feelings, and perceptions – experienced by the

organism. Of such mental processes, one may be conscious (aware) or unconscious. There is abundant evidence that the mind is intimately associated with brain physiology: damage to the brain results in specific changes to mental processes, and chemical perturbations of the brain with psychoactive drugs produce specific effects on mental processes. Exactly how mind is related to brain physiology is one of the great unsolved problems of psychology and neuroscience – the so-called mind–body problem. Drugs that affect conscious awareness and other qualities of the mind are powerful probes to the mind–brain connection.

Pioneering neuroscientist, psychologist, and philosopher William James (1842–1910), whose thinking on the nature of the mind was profoundly influenced by experiences with nitrous oxide, said more than a century ago, in words that are every bit as relevant today:

One conclusion was forced upon my mind at the time and my impression of its truth has since remained unshaken. It is that our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, while all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different. We may go through life without suspecting their existence; but apply the requisite stimulus, and at a touch they are there in all their completeness, definite types of mentality which probably somewhere have their application and adaptation. No account of the universe in its totality can be final which leaves these other forms of consciousness quite disregarded. How to regard them is the question. . . .

Glossary

Causal modeling The use of statistical models to assess the causes of a skill/disorder within a conceptual framework.

Comorbidity The tendency for two or more developmental disorders to occur together.

Dyslexia A learning disorder primarily characterized by reading delay and spelling difficulties, usually accompanied by phonological deficits.

Heritability An index of the amount of variance in a quantitative trait or skill that is due to genetic factors.

Phonological pathway A set of mappings between orthography and phonology.

Poor comprehender Term given to describe a child who can decode accurately but has specific difficulty in understanding what they read (also known as reading comprehension impairment).

Semantic pathway A set of mappings between orthography, semantics, and phonology.

Treatment nonresponders Term given to child who show no or at least a poor response to intervention.

Reading is a uniquely human accomplishment, essential to educational achievement, career prospects, and ultimately adult well-being. It is therefore crucial to understand why children have reading difficulties. Reading is not just a simple matter of recognizing and understanding individual words as our eyes pass over text. The purpose of reading is to understand text. Being a successful reader requires building up a mental representation of the text, a process that requires integration of multiple sources of information, from lexical features to event knowledge and prior experience. In developing this skill, children make a transition from learning to read, to reading to learn.

Models of Reading

The 'triangle model' provides a framework for understanding the development of word recognition (Figure 1). According to this model, the process of learning to read consists of creating mappings between orthography (print) and phonology (speech sounds; the phonological pathway), and between orthography and phonology via semantics (the semantic pathway). The phonological pathway is crucial for reading unfamiliar words which can only be read by translating letter strings into phonological forms (referred to as orthography-phonology mappings). The semantic pathway, on the other hand, is important for accurate and fluent reading and in English, for reading irregular and inconsistent words (e.g., yacht), which cannot be read accurately using orthography to phonology mappings. Early in reading development, children rely heavily on the phonological pathway but there is an increasing need, as development proceeds, for the semantic pathway to be used in order to develop reading fluency and automatic word recognition.

The simple view of reading (see Figure 2) suggests that reading is the product of two distinct but related processes, which are essential for learning to read; word recognition and language comprehension (i.e., understanding the message that the print conveys). Children can vary in their aptitude on these two dimensions and this model can be used to describe different patterns or 'profiles' of performance. Recently, this model

has been adopted by the government in England to provide a framework to guide the teaching of reading and also to help identify children whose reading skills are developing out of step, as illustrated by cases of dyslexia and reading comprehension impairment. Children who fall within either the upper or lower left quadrants are those who have dyslexic difficulties because of poor word recognition skills. Children with good word reading but poor comprehension (lower right quadrant) are often referred to as poor comprehenders. As reflected in the dimensional nature of the simple view model of reading, both dyslexia and reading comprehension impairment are best thought of as continuum, rather than distinct categories with clear cut-off points. Whilst dyslexia is well understood, research into reading comprehension impairment is in its infancy.

What Is Dyslexia?

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM V) of the American Psychiatric Association plans to use the term dyslexia rather than reading disorder (RD) which was used previously. DSM V defines dyslexia as difficulties in the "accuracy or fluency of reading that are not consistent with the person's chronological age, educational opportunities, or intellectual abilities" that "without accommodations, significantly interferes with academic achievement or activities of daily living that require these reading skills."

The definition of dyslexia used by the International Dyslexia Association (IDA), on the other hand, highlights both the neurological and cognitive underpinnings of the disorder as well as its symptoms. The IDA defines dyslexia as "a specific learning disability of neurological origin which is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities" resulting from "a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction." In line with this, a recent government review in England led by Sir Jim Rose also highlights difficulties in phonological awareness, verbal memory, and verbal processing speed as being characteristic of dyslexia.

Figure 1 The triangle model of word recognition.

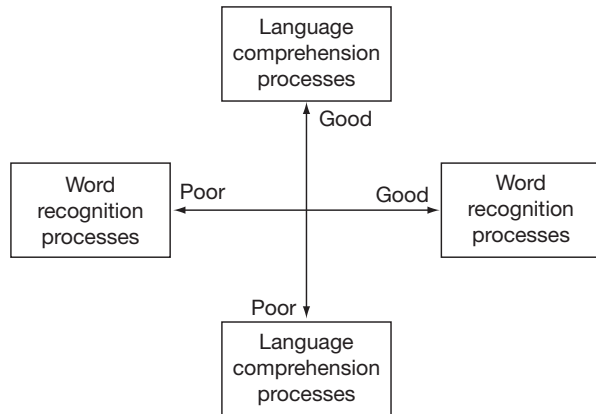

Figure 2 The simple view of reading.

The Discrepancy Definition

For years dyslexia has been considered as a specific reading disability that is unexpected in relation to an individual's IQ. However, the use of this IQ discrepancy definition of dyslexia is controversial. Recent research evidence suggests that, at a cognitive level of description, children with reading difficulties of lower and higher IQ, share deficits in phonological processing and make equivalent responses to intervention programmes targeting phonological skills. Moreover, dyslexia can occur across a wide range of intellectual abilities. The use of the IQ discrepancy definition means that many children who have significant reading difficulties that interfere with daily living and scholastic achievement fail to fulfill diagnostic criteria even though their reading is significantly below age expectations. For these reasons, the DSM V does not make any recommendations about using IQ discrepancy in the definition of dyslexia.

What Is Reading Comprehension Impairment?

Children referred to as 'poor comprehenders' present the mirror image of dyslexia: they have difficulty understanding what they read, despite having age appropriate word reading accuracy and fluency, normal phonological skills and nonverbal ability. Thus, poor comprehenders can read passages of text as accurately and as fluently as their peers but have significant difficulties when questioned about the content of the text. Given the demands on comprehension in primary and secondary school, poor comprehenders are at a significant disadvantage.

In the DSM V, reading comprehension impairment is separated from dyslexia. Instead it is to be considered as a

communication disorder or a learning disability characterized by impairments in both reading and listening comprehension (in the absence of decoding difficulties). The precise definition remains vague in comparison to dyslexia. However, the majority of research studies adopt variants around the following selection criteria for poor comprehenders:

- Reading comprehension below the average range on standardized tests (i.e., below a standard score of 85).
- Word and/or passage reading accuracy in the average range on standardized tests (i.e., above a standard score of 90).
- A discrepancy between reading comprehension and word/passage reading accuracy (e.g., one standard deviation in standard scores or 1 year in age equivalent scores).

Prevalence

RD affects a sizeable minority of the child-population. Prevalence rates vary depending on the criteria used to define the disorders, the measures used to assess reading skills and environmental factors. Prevalence rates of dyslexia vary between 3% and 15% of school age children. Several epidemiological studies have reported that dyslexia is only slightly more frequent in males than in females (about 1.5:1). However, a metareview including all such studies showed that dyslexia is more frequently diagnosed in males than in females and studies of referred samples have found male to female ratios as high as 6:1. This overrepresentation of males in referred samples has often been attributed to a higher frequency of comorbid behavioral disorders, such as attention deficit hyperactivity disorder (ADHD), in males with dyslexia than in females with dyslexia. Fewer studies have investigated prevalence rates of poor comprehenders, however, recent studies suggest that this RD affects between 7.5% and 10% of primary school children in unselected samples. In contrast to dyslexia, reading comprehension impairment appears to affect similar numbers of males and females. Of course dyslexia and reading comprehension impairment are best thought of as extremes of the normal distribution of reading ability rather than distinct categories; hence prevalence rates depend on the arbitrary cut-off points used to define the disorder.

Referral Routes and Assessment

It is important to consider the routes by which children with dyslexia and poor comprehenders are referred for assessment since these will account for the kinds of diagnosis and interventions prescribed. Children with dyslexia are readily recognized by teachers and parents; hence the most common referral route is through educational professionals. Children with dyslexia are also occasionally referred for assessment by optometrists, general practitioners, occupational therapists, and speech language therapists, particularly if the child has a comorbid condition. In comparison, poor comprehenders often go unnoticed in the classroom and are rare in clinically referred samples of children with reading difficulties. However, this is likely to be a reflection of referral bias and the fact that there are currently no established referral routes for these children. Assessments for RDs are

usually conducted by educational psychologists or chartered research psychologists trained in educational assessment.

A comprehensive assessment of reading should comprise measures of reading accuracy (reading aloud a list of single words which increase in difficulty), decoding (reading aloud nonsense words graded in difficulty), reading fluency (reading a list of single words which increase in difficulty at speed), prose reading and comprehension (passage reading followed by an assessment of understanding). Spelling performance should also be considered. Given the evidence that a phonological deficit is central in dyslexia, assessments should include tests of phonological skills; phonological awareness (e.g., phoneme deletion/isolation); phonological/verbal memory (e.g., nonword repetition or digit recall) and naming (e.g., Rapid Automatized Naming (RAN)). Furthermore, difficulties in reading comprehension are often accompanied by deficits in broader oral language (OL), for example, semantics (vocabulary) and grammar; hence it is also important to assess these skills.

Causes of RDs

So far we have focused on the behavioral features of RDs; a proper understanding of these difficulties requires consideration of their causes. A general 'causal modeling' framework can be used to consider causation at biological, cognitive, and behavioral levels, with environmental factors interacting at each level. **Figure 3** illustrates several factors thought to be causally associated with dyslexia (to the left) and reading comprehension impairment (to the right). Within this model, solid lines represent causal pathways that have been empirically validated, while dotted lines represent putative causes which are not yet proven.

Cognitive Explanations

Cognitive theories seek to explain the processes underlying behavioral features of disorders. Indeed, cognition provides an important bridge between biological and behavioral levels of explanation; with respect to dyslexia, a great deal of research during the past 40 years has focused on cognitive explanations of the disorder.

Phonological Deficit of Dyslexia

An important cognitive theory of dyslexia proposes that a core phonological deficit underlies the reading difficulties characteristic of dyslexia. The phonological deficit hypothesis suggests that a failure to develop adequate phonological skills interferes with the learning of grapheme-phoneme correspondences, which are critical in reading acquisition; within the triangle model discussed earlier, poorly specified phonological representations compromise the development of the 'phonological pathway' to reading. A considerable amount of research has found that children with dyslexia perform significantly worse than typically developing children on measures of phoneme awareness, which requires the ability to make explicit judgements about the sound structure of words. Unlike phonological awareness, phonological processing (such as nonword repetition, RAN, and paired-associate learning) requires the use of speech and is free of metacognitive demands. Children with dyslexia also perform poorly on measures of phonological processing supporting the idea that they have poorly specified phonological representations – difficulties with which the brain codes phonology.

Further support for the phonological deficit hypothesis comes from longitudinal studies which suggest that children's early phonological skills and letter knowledge play a causal

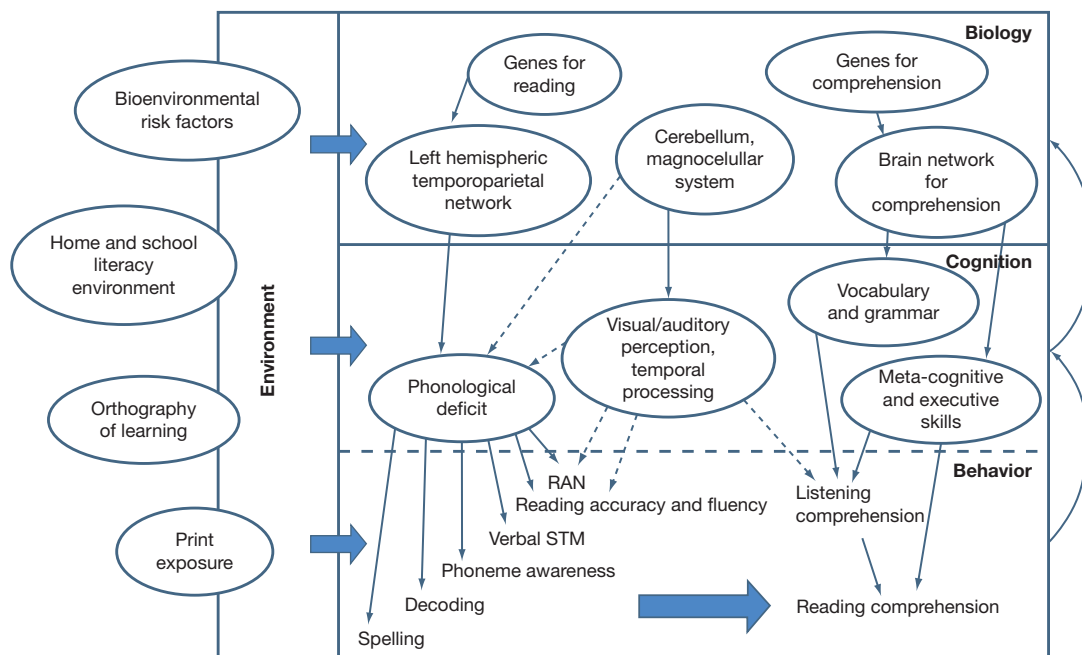

Figure 3 Causes of dyslexia and reading comprehension impairment.

role in their later reading development. Children at risk of dyslexia, who go on to receive a diagnosis, display deficits in phonological skills prior to reading instruction (at around age 4 years). These children also exhibit weaknesses in nonphonological OL skills compared to children at risk of dyslexia who do not go on to receive a diagnosis. However, mild deficits in phonological skills are sometimes present in children at risk of dyslexia but who do not fulfill diagnostic criteria. This suggests that a phonological deficit could represent an 'endophenotype' or risk marker of dyslexia that can be moderated by other risk and protective factors, such that some of the 'at risk' children develop dyslexia while others compensate and do not succumb to reading problems.

Two factors that may potentially impede phonological development are speech perception and auditory processing skills. Research has aimed to establish whether a deficit in the perception of speech sounds, possibly underpinned by a broader weakness in auditory processing, may cause the phonological deficit in dyslexia (Figure 4). However, deficits in auditory processing are not characteristic of all children with dyslexia and although there is some evidence that children with dyslexia have mild impairments in speech perception, this may be restricted to those who have broader OL impairments. Longitudinal studies are needed to elucidate the causal relationships among these skills.

Alternative Causal Theories of Dyslexia

The phonological deficit hypothesis is successful in accounting for the reading failure, the nonword reading deficit and the weak spelling skills, characteristic of individuals with dyslexia. However, some researchers have identified a range of difficulties associated with dyslexia not easily accounted for by this theory. Proponents of the double-deficit hypothesis of dyslexia, suggest that some children with dyslexia have impairments in phonology, others have problems in temporal processing and perceptual speed and a third group has impairments in both.

The magnocellular deficit hypothesis suggests that individuals with dyslexia have impairments in processing rapidly presented auditory and visual stimuli resulting from impairments in the magnocellular pathway in the brain. However, there is little evidence that these skills predict variations in reading in the typical population and not all studies have replicated findings of magnocellular processing deficits in

dyslexia; arguably such deficits may be associated with broader neurological abnormality rather than playing a critical role in the determination of reading difficulty.

Other researchers argue that the apparent link between reading disability and timing deficits is associated with abnormal cerebellar activation and functioning; this has been termed the 'automatization deficit' or the 'cerebellar deficit' hypothesis. This theory suggests that children with dyslexia have problems automatizing cognitive/motor skills and impaired time perception – difficulties that originate from mild cerebellar dysfunction. In support of this, the cerebellum has been implicated in motor activities, balance, skill automatization and adaptive learning, and in perceptual tasks that require the precise representation of temporal information. However, it is possible that cerebellar/automaticity impairments may be associated with comorbid conditions such as ADHD or developmental coordination disorder. Consistent with this hypothesis, balance deficits have been found to be associated with ADHD rather than dyslexia.

Cognitive Theories of Reading Comprehension Impairment

Reading comprehension is a complex skill and consequently there are many potential routes for failure. Knowledge of word meanings is critical for comprehension and poor comprehenders have been reported to have difficulties on a range of tasks that require access to a knowledge of vocabulary (*semantic deficit hypothesis*). Poor comprehenders are often slower and less accurate when naming pictures with low-frequency names and are poorer at making synonym judgements (e.g., when asked to decide whether two words have a similar meaning) particularly for more abstract words. Impairments in semantic processing can also compromise some aspects of word recognition in poor comprehenders. For example, they tend to be poor at reading irregular and low-frequency words although they are able to read regular and high-frequency words. It has been argued that irregular and low-frequency words are harder to read using the phonological and orthographic skills alone and they require greater input from the 'semantic pathway' to word recognition. Semantic processing impairments in poor comprehenders should be considered in the context of broader weaknesses in OL skills including listening comprehension, receptive and expressive vocabulary, oral expression, narrative production, and grammar though phonological skills are normal.

Beyond OL weaknesses, poor comprehenders also have text level difficulties. Successful comprehension relies on making inferences that go beyond what is written in the text to construct an adequate and coherent representation. Inferences are either 'cohesive' (i.e., they are necessary for comprehension and support text integration) or 'elaborative' (i.e., they embellish information provided in the text). Poor comprehenders have difficulties inferring specific meanings of nouns from sentence context (e.g., inferring that 'fish' is most likely a 'shark' in the following sentence: 'The fish frightened the swimmer'). Poor comprehenders have also been shown to generate fewer constructive inferences that require the reader to integrate information from two different sources in text. However, it remains possible that poor inference-making in poor comprehension is due to impairments in accessing relevant

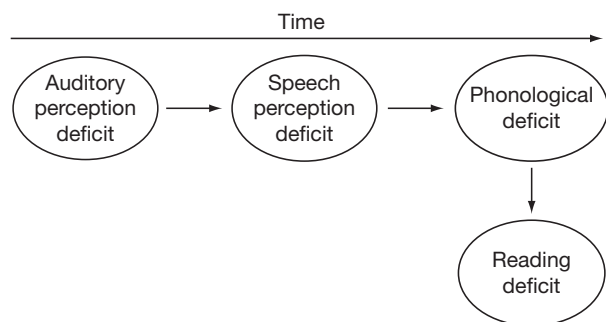

Figure 4 Figure showing the possible causal role of an auditory perception deficit in the development of reading problems.

knowledge, maintaining motivation and a drive to read for meaning, or due to a processing limitation (e.g., poor working memory or the failure to inhibit irrelevant information).

Reading comprehension also relies on metacognitive strategies such as comprehension monitoring (the ability to regulate reading to the demands of the task and engage with the comprehension process). For example, if an individual realizes that their comprehension is inadequate, they can take appropriate steps, such as slowing their reading speed or rereading to remedy the situation. There is evidence to suggest that poor comprehenders have weak metacognitive knowledge and/or are less good at applying this knowledge during comprehension.

Considering the complex nature of reading comprehension, and the range of associated deficits, it seems likely that multiple causal factors will explain reading comprehension impairment. Poor comprehenders are a heterogeneous group and no clear cognitive profile has emerged from the extant research. Although many poor comprehenders have weaknesses in OL, a substantial proportion of the population do not show such weaknesses and some poor comprehenders show average or even good performance on measures of verbal working memory, comprehension monitoring, and inference making.

Biological Bases

It has been known for many years that reading skills are heritable and therefore that reading difficulties run in families. Several 'family-risk' studies have suggested that between 30% and 50% of children whose parents have dyslexia, will also develop the disorder. However, families share genes and also environments so findings of familial aggregation of RDs alone are not sufficient to demonstrate that reading skills are heritable. Twin studies that compare the reading skills of monozygotic twins (who share 100% of their genes) with dizygotic twins (who share on average 50% of their genes) provide a more sensitive design for separating genetic and environmental influences. Such studies suggest that the concordance rates for dyslexia are higher for monozygotic twins than for dizygotic twins, confirming the genetic liability for dyslexia.

More recent research on the heritability of reading and its difficulties has moved away from the use of a categorical 'diagnosis' of dyslexia to define reading as a continuous trait. Within this view, quantitative genetic analyses confirm that reading skills are significantly heritable across the distribution, as are the skills which underlie them, including phonological abilities and other language skills. Moreover, studies with a longitudinal perspective have shown that there is shared genetic variance between preschool phonological awareness and early measures of reading, and also new sources of genetic variance in reading which emerge after reading instruction (perhaps contributing to orthographic learning). Findings such as these illustrate that reading is underpinned by a range of more primitive cognitive skills, many of which are also heritable. However it needs to be borne in mind that genes act through environments and individual differences in any trait, and reading is no exception, also depend on environmental factors. A recent behavior-genetic analysis assessed the genetic and environmental influences on both initial

performance and growth in reading skills. While there were significant genetic and environmental contributions to initial reading level, some of the environmental influences on growth in decoding ability were independent of initial performance. It can be concluded that new environmental influences operate on reading as it develops, over and above those that determine initial performance; it is plausible that these are mediated by the home and school environment and/or the child's personal motivation to read.

Turning to reading comprehension, similar analyses, using the quantitative approach, have shown that shared genetic influences on word recognition and reading comprehension are partly independent of shared genetic influences on listening and reading comprehension. Such findings, which are in line with the simple view of reading, support the position that individual difference in word recognition and reading comprehension are partly underpinned by different genetic etiologies.

Findings of family and twin studies showing the heritability of RDs set the stage for molecular genetic approaches which aim to identify genes that may be associated with the disorder. Dyslexia, in common with other developmental cognitive disorders is genetically heterogeneous and the risk of inheriting dyslexia depends on the combined influence of many genes as well as environmental influences. At the time of writing, a number of gene markers and several candidate genes (on chromosomes 6, 15, and 18) have consistently been associated with dyslexia; moreover the same genes appear to operate across the normal distribution underpinning component reading skills. To date, the genes associated with individual differences in word-level reading are different from those associated with the language impairments implicated in reading comprehension impairments but further research is needed to investigate these associations.

Genetic differences between good and poor readers are likely to have an impact on the neurodevelopment in children with dyslexia. Indeed there is considerable evidence that dyslexia is associated with structural and functional abnormalities in various systems in the left hemisphere of the brain, particularly structures within the temporal lobe which are involved in language and learning to read. More specifically, studies have shown disrupted temporoparietal brain responses during phonological tasks and less left prefrontal brain response during tasks that require the rapid processing of auditory stimuli in both adults and children with dyslexia. However, in interpreting such findings it is important to be aware that becoming literate has an impact on brain structure and function, so some of the effects observed may be a consequence rather than a cause of dyslexia.

Findings from neuroimaging studies also provide some support for alternative, sensory, theories of dyslexia. Support for the magnocellular (visual) theory of dyslexia comes from studies which have found abnormalities in the magnocellular layers of the lateral and medial geniculate nuclei, in individuals with dyslexia. Additionally, in support of the cerebellar deficit hypothesis of dyslexia, studies have shown that the cerebellum, an area of the brain that plays an important role in motor control, is also implicated in cognitive processes involved in reading and verbal memory. Furthermore, the cerebellum has been found to be underactive in adults with dyslexia during performance of a motor sequencing task. However, it is unclear

how deficits in cerebellar function can cause the phonological deficit which underpins dyslexia. Furthermore, the specificity of impairments in the cerebellum to dyslexia is questionable given that the cerebellum is also implicated in disorders such as ADHD.

Far less attention has been devoted to understanding the functional neuroanatomy of comprehension than of phonology and word reading. However, studies using positron emission tomography (PET) have revealed increases in blood flow to the left and right temporal poles during reading when stories are compared with incomprehensible stories. Such regions may therefore be involved in linking propositions to build a mental representation of the text, and the anterior medial parietal/posterior cingulate cortex has been associated with linking incoming information with prior knowledge. Furthermore, neuropsychological studies have reported deficits following right brain damage in narrative comprehension and semantic integration. Only one study to date has investigated neuroanatomical abnormalities in poor comprehenders. This study revealed that reading comprehension impairment is associated with smaller cerebral volume and less leftward asymmetry of the planum temporal, plana, and cerebellar anterior lobe.

Environment

A range of environmental factors affect the development of language and literacy. Significant effects of social and economic circumstances typically associated with parental education level, affect the language skills that children bring to the task of learning and such differences may be compounded by factors such as the amount of literacy related activities in the home. Studies of home literacy environment have shown that direct reading instruction in the home, focusing on letter knowledge and print-related concepts, have positive effects on children's development of decoding skills whereas language activities surrounding shared book reading primarily affect reading comprehension. All of these factors can be assumed to affect the behavioral manifestation of dyslexia in the early school years, and after school entry, different types of reading instruction will also exert an influence on the extent to which an early risk may translate into an identifiable RD. Beyond reading instruction, it has been demonstrated that the amount of reading practice a child undertakes affects reading development such that good readers, who are more likely to enjoy reading, practice more and gain further benefits (Matthew effect). Contrary to this, for children with dyslexia, declining levels of motivation may feed into low levels of print exposure and a downward spiral of poor reading, low levels of literacy and educational achievement (a powerful example of gene-environment correlation is that children who inherit a risk of reading difficulty select an environment not conducive to reading development).

At the level of the 'macroenvironment' the effects of culture will also impinge on the child's emergent literacy skills. Amongst these, a potent example is the language of instruction. Languages vary in the transparency or consistency of the orthography-phonology mappings as well as in the accessibility of different phonological units. There is now a large body of

evidence showing that learning to read in an alphabetic system is easier in more transparent languages and hence it has been predicted that the behavioral manifestation of dyslexia varies among languages. For example, problems of reading accuracy are the primary sign of dyslexia in English whereas in Finnish which is highly consistent, the main manifestation is a problem of reading fluency. Notwithstanding this, the cognitive deficits underpinning dyslexia appear to be universal among alphabetic readers. Burgeoning research with readers of logographic (e.g., Chinese) and, alphasyllabic (e.g., Korean) languages indicates that the predictors of individual differences in reading are somewhat different and include morphological awareness. Against this backdrop, the predictors of dyslexia may be different in these languages.

Development

Clinical observation reveals that, although dyslexia is a persistent disorder across the life-span, the primary signs of dyslexia change with development, and longitudinal studies have begun to elucidate the developmental trajectory of dyslexia (Table 1).

Comorbidities

Comorbidity refers to the tendency for two or more developmental disorders to occur together. Dyslexia frequently co-occurs with difficulties in aspects of language, motor coordination, mathematics, attention, and organization but these difficulties

Table 1 Developmental changes in the cognitive and behavioral features of dyslexia

<i>Developmental phase</i>	<i>Behavioral signs of dyslexia</i>	<i>Cognitive features consistent across time</i>
Preschool	Delayed or problematic speech Poor expressive language Difficulty learning letters	Poor verbal short-term memory Slow naming of familiar objects and colors Slow speed of verbal processing
Early school years	Poor letter sound knowledge Poor phoneme awareness Poor decoding skills Idiosyncratic spelling Problems copying	
Middle school years	Slow reading Poor decoding when faced with new words Poor spelling that is phonetic or nonphonetic	
Adolescence and adulthood	Poor reading fluency Slow speed of writing Poor organization and expression in written work Poor spelling	

by themselves are not thought to be markers of dyslexia. Rather, they are likely to reflect the comorbidity between dyslexia and other developmental disorders such as specific language impairment (SLI), dyspraxia/developmental coordination disorder, dyscalculia, and ADHD. Both dyslexia and SLI have phonological impairments at their core however children with SLI also have additional difficulties with vocabulary and grammar. It is debated whether the overlap between these two disorders truly reflects comorbidity or whether SLI is a more severe form or an earlier manifestation of dyslexia.

Difficulty with reading comprehension has been reported in a number of different clinical disorders, including early onset hydrocephalus, autism, nonverbal learning disorder, SLI, Turner's syndrome, ADHD, pragmatic language impairment, and William's syndrome. However, it is likely that the comprehension difficulties in these disorders have different manifestations. As with dyslexia it is tempting to draw parallels between poor comprehenders and children with SLI. As outlined above, poor comprehenders have weaknesses in spoken language similar to children with SLI and there is a raised incidence of poor reading comprehension in SLI. However, poor comprehenders have clear strengths in phonological processing, which is an area of deficit for many children with SLI. Given the reported weaknesses in attention and working memory in poor comprehenders there is also speculation as to whether poor comprehenders have some form of ADHD but this remains to be formally tested.

Although the extant research precludes strong conclusions, **Figure 5** illustrates the putative overlap of dyslexia and reading comprehension impairment (PC) with ADHD and SLI.

Interventions

Interventions for dyslexia have been in use for many years and there are accepted guidelines for good practice. However, it is only recently that the effects of interventions have been evaluated rigorously using controlled designs.

In the ideal scenario of a virtuous circle, causal theories of dyslexia lead directly to principled interventions and the efficacy of these interventions in turn provide a powerful test of the causal theories. Thus, starting from the premise that poor readers have phonological deficits, if training in phonological skills leads to improvements in reading skills, then this provides evidence for the causal theory. Findings from a large number of studies now show that boosting phonological skills is an effective intervention for poor readers provided it is combined with training in letter-sound knowledge and linking

the two. Arguably such interventions aim to improve the functioning of the phonological pathway in the triangle model. However, it is important to bear in mind that not all children with dyslexia respond to such effective interventions to the same degree. Current research is focusing on the characteristics of these 'treatment resisters' and assessing the validity of 'response to intervention' as a measure of the severity of dyslexia.

Meanwhile, an unfortunate consequence of the poor response of some children is to encourage parents to seek alternative therapies for dyslexia. Such interventions, such as the use of colored filters or of motor programs, have a poor evidence-base and are likely to impact comorbid features, such as visual stress or dyspraxia, rather than the RD per se.

Very few studies have evaluated support for children with reading comprehension impairment. Encouraging children to use representational and transformational drawings to visualize stories and answers to comprehension questions in their minds has been shown to improve reading comprehension in poor comprehenders compared with training that involves reading and question answering. Studies that have trained children's ability to make inferences have also been shown to be effective. Such training has involved asking children to pick out words from passages and explain how they contributed to the overall meaning of sentences or stories, and asking them to generate questions and predictions about the text. However, many of the studies that have supported this position have methodological weaknesses that render the results difficult to interpret.

Moving beyond text-level training, a recent randomized controlled trial has evaluated the effectiveness of three multi-componential training programs on reading comprehension in poor comprehenders aged 8–9 years. The training programs were designed to promote text level processing (TC), OL skills, or a combination of the two (COM). The progress of children in the intervention groups was compared against the progress of a waiting control group. All intervention groups made significant improvements in reading comprehension relative to the control group immediately following training. Furthermore, 11 months after training, gains increased for the OL group beyond the TC and COM groups. The OL and COM groups also made significant progress in expressive vocabulary and this was a mediator for these groups' improved reading comprehension. These results provide strong support for a causal relationship between OL and reading comprehension and suggest that specific reading comprehension difficulties reflect (at least partly) underlying OL weaknesses.

Progress has been made in recent years in understanding both the nature of the difficulties experienced by children with reading difficulties and the best methods for supporting their development. Future research must endeavor to identify the factors that influence response to intervention and to replicate and extend previous findings in educationally realistic contexts in order to determine their practicality outside research settings.

Future Directions

The field of research on RDs is rapidly expanding to encompass studies of dyslexia in different languages, its genetic foundations and neural correlates; against this backdrop, there is a

Figure 5 Possible comorbidities with dyslexia and reading comprehension impairment.

growing evidence base regarding interventions. There is likely to be major expansion in research on the neuroscience of dyslexia in the coming decade, including investigation of the neural markers of response to intervention. For this research agenda to succeed it will be important to continue the emerging trend away from considering dyslexia as a categorical diagnosis to viewing it as a the culmination of a number of different risk factors (or endophenotypes) with no clear cut offs. Essentially then the threshold for diagnosis will become free to vary according to the language, age and stage of learning, and the extent to which the difficulties affect everyday functioning in the classroom or workplace. Arguably, progress in the understanding of endophenotypes will depend upon the findings of longitudinal studies, which investigate how risk and protective factors conspire to produce or compensate for the risk of dyslexia. In turn, such studies should improve our understanding of both the comorbidities of dyslexia and the broader phenotype and will be essential to progress in genetics and neuroimaging. In contrast to dyslexia, much less is known about the many causes of reading comprehension impairment (of which dyslexia is of course one). Here the field is wide open for longitudinal studies examining its nature and causes.

Finally, research on RDs and their interrelationships with other developmental neurocognitive disorders is critical to developing effective interventions. At the present time we know a lot about interventions to develop decoding in the early stages and a little about reading comprehension interventions. However, the evidence base is lacking for those with dyslexia who have moderately well developed skills but still struggle to achieve their potential and for those with broader language impairments. Since reading is fundamental to educational achievement, adult employment and mental capital, this research agenda is well worth pursuing.

ABOUT THE EDITOR-IN-CHIEF

V.S. Ramachandran, MD, PhD., is Director of the Center for Brain and Cognition and professor with the Psychology Department and the Neurosciences Program at the University of California, San Diego, and Adjunct Professor of Biology at the Salk Institute. Ramachandran trained as a physician and obtained an MD from Stanley Medical College and subsequently a PhD from Trinity College at the University of Cambridge, where he was elected a Senior Rouse Ball Scholar. Ramachandran's early research was on visual perception, but he is best known for his work in neurology.

He has received many honors and awards, including a fellowship from All Souls College, Oxford, an honorary doctorate from Connecticut College, a gold medal from the Australian National University, the Ariens Kappers Medal from the Royal Netherlands Academy of Sciences for landmark contributions in neuroscience, and the presidential lecture award from the American Academy of Neurology. He is also a fellow of the Neurosciences Institute in La Jolla and a fellow of the Institute for Advanced Studies in Behavioral Sciences at Stanford. He was invited by the BBC to give the Reith Lectures on 'The Emerging Mind' in 2003 and is the first physician/experimental psychologist to be given this honor since the series was begun by Bertrand Russell in 1949 – these lectures were subsequently published as *A Brief Tour of Human Consciousness: From Impostor Poodles to Purple Numbers*.

In 1995, he gave the Decade of the Brain Lecture at the 25th annual (silver jubilee) meeting of the Society for Neuroscience and more recently, the inaugural keynote lecture at the Decade of the Brain conference held by NIMH at the Library of Congress and a public lecture at the Getty Museum in Los Angeles. He also gave the first Hans Lucas Teuber lecture at MIT, the D.O. Hebb lecture at McGill, the Rudel–Moses lecture at Columbia, the Dorcas Cumming (inaugural keynote) lecture at Cold Spring Harbor, the Raymond Adams neurology grand rounds at Massachusetts General Hospital, Harvard, and the Jonas Salk memorial lecture, Salk Institute.

Ramachandran is a trustee for the San Diego Museum of Art and has lectured widely on art, visual perception, and the brain. Ramachandran has published over 120 papers in scientific journals (including three invited review articles in *Scientific American*), coauthor (with Sandra Blakeslee) of *Phantoms in the Brain* that has been translated into eight languages and formed the basis for a two-part series on Channel Four TV in the UK and a one-hour PBS special in the United States. His work is featured frequently in the major news media including BBC and PBS. *Newsweek* magazine recently named him a member of 'The Century Club,' one of the "hundred most prominent people to watch in the next century."

ABOUT THE EDITORIAL ADVISORY BOARD

David M. Buss received his BA from the University of Texas at Austin and his PhD from the University of California at Berkeley. He served in professorial positions at Harvard University, the University of Michigan, and the University of Texas, where he is currently professor of psychology. David Buss received the American Psychological Association (APA) Distinguished Scientific Award for Early Career Contribution to Psychology, the APA G. Stanley Hall Award, and the APA Distinguished Scientist Lecturer Award. The University of Texas awarded Buss the President's Associates Teaching Excellence Award. He served as President of the Human Behavior and Evolution Society (HBES). He is currently Head of the Individual Differences and Evolutionary Psychology Area of the Psychology Department at the University of Texas at Austin.

Buss's books include *The Evolution of Desire: Strategies of Human Mating* (Basic Books; translated into 11 languages); *Evolutionary Psychology: The New Science of the Mind* (Allyn & Bacon); *The Dangerous Passion: Why Jealousy is as Necessary as Love and Sex* (Free Press; translated into 13 languages); *The Murderer Next Door: Why the Mind is Designed to Kill* (Penguin; translated into 12 languages); *The Handbook of Evolutionary Psychology* (Wiley), for which he served as editor; *Why Women Have Sex* (Holt; co-authored with Cindy Meston; translated into 16 languages); and *The Evolution of Personality and Individual Differences* (Oxford University Press). Buss has more than 250 scientific publications to his credit.

Buss has extensive cross-cultural research collaborations and lectures widely within the United States and abroad. His primary research interests include the psychology of sex differences, human sexuality, mating strategies, conflict between the sexes, why people kill, warfare, terrorism, stalking, and the psychology of prestige, status, and reputation.

Richard B. Buxton received his BS (1976) and PhD (1981) degrees in physics from the Massachusetts Institute of Technology, followed by a postdoc in biomedical imaging (PET and MRI) at the Massachusetts General Hospital. He has been on the faculty of the Department of Radiology at the University of California, San Diego, since 1990. Buxton's primary research is in functional magnetic resonance imaging (fMRI), focused on understanding the connections between neural activity, blood flow, and energy metabolism in the human brain. His experimental work combines arterial spin labeling (ASL) methods with blood oxygenation–level dependent (BOLD) methods to estimate changes in brain oxygen metabolism in response to a stimulus or a drug. His more theoretical work involves mathematical modeling of the imaging methods, the BOLD effect, and oxygen transport from blood to tissue. Buxton is based at the Center for fMRI and served as the center's founding Director (2000–2007). He has written a textbook on fMRI, now in its second edition, published by Cambridge University Press (2009).

Nicholas Christenfeld received a bachelor's degree in psychology and social relations from Harvard, and a doctorate in social psychology from Columbia, and joined the faculty at the University of California – San Diego and has remained there for two decades. His research program comprises multiple, changing, only partly overlapping areas. He has addressed such topics as why some people say 'um' so often, whether babies look like their mothers or their fathers, how we choose which box of cereal to buy, why a baseball season is ten times as long as a football season, which parts of the month carry the greatest risk of untimely death, whether the support of a woman is better for one's blood pressure than that of a man, what sort of music might be useful in stress reduction, whether some initials extend and some shorten the lives of their bearers, if people who live in, or even just visit, New York City are at risk of heart attacks, and whether story spoilers do spoil stories. Currently, Christenfeld is also exploring the role of forgiveness in poststress cardiovascular recovery, the impact of crying on hormones, and the nature of a sense of humor. An overarching theme, if one exists, might be the empirical exploration of the everyday phenomena of the world.

Orrin Devinsky is professor of neurology, neurosurgery, and psychiatry at New York University (NYU). He directs the NYU Epilepsy Center and St. Barnabas Institute of Neurology. His research on epilepsy includes phenomic-genomic relations, sudden unexpected death in epilepsy, surgical therapies, new medicines and devices, quality of life, cognition and behavior, and neuroinflammation. His research on behavioral neurology includes hyperfamiliarity, delusions, autonomic nervous function, and anterior cingulate cortex functions. He founded the organization Finding A Cure for Epilepsy and Seizures and cofounded epilepsy.com and the Epilepsy Therapy Project. He serves on the boards of these organizations and has served on the board of the American Epilepsy Society and Epilepsy Foundation. His other interests include the history of neuropsychiatry, evolution, anthropology, and animal intelligence.

Albert M. Galaburda is a cognitive neurologist and neuroscientist, specializing in developmental cognitive disorders in adults and children. He received his medical degree from Boston University in 1971, trained in neurology at Harvard Medical School from 1973 to 1976, and began his research on dyslexia in 1979, when with neuropathologist Thomas Kemper, he reported for the first time minor cortical malformations in the brain of an adult dyslexic who had died in an accident. Following that original report, he published several other cases with similar malformations and launched a research program modeling these malformations in rodent models, which continues to this date.

He uses RNAi and transgenic technologies in his present research to induce cortical malformations in rat and mouse brains, which in turn are tested anatomically, molecularly, and behaviorally in collaboration with Glenn Rosen, Joseph LoTurco, and Holly Fitch, respectively. This latest research has shown that manipulation of dyslexia candidate gene homolog's 1 rodent embryos results in molecular interference with neuronal migration, cell autonomous and noncell autonomous effects on cortical development that mimic the changes seen in dyslexic brains, and behavioral changes affecting auditory perception. *Ex vivo* imaging of the brains of genetically manipulated animals discloses changes in cortical circuits affecting corticocortical and corticothalamic relationships.

Galaburda is presently the Emily Fisher Landau Professor of Neurology at Harvard Medical School, and Head of the Cognitive Neurology Unit at Beth Israel Deaconess Medical Center in Boston. He has published more than 150 scholarly articles on various topics of cognitive anatomy, cognitive

neurology, and dyslexia, as well as several books on related topics. Galaburda has received the Pattison Prize in Neuroscience, the Neuronal Plasticity Prize from the IPSEN Foundation of France, Scientist of the Year from the Association for Children with Learning Disabilities (now, Learning Disorders Association), and has been elected to membership in the American Neurological Association. He has delivered the Rita Rudel Memorial Lecture, the Norman Geschwind Memorial Lecture, the Sylvio Conte Decade of the Brain Symposium Lecture, and the Curt von Euler Memorial Lecture, among others. His research is funded by the Eunice Kennedy Shriver National Institute of Child Health & Human Development. His teaching is funded by the National Institute of Neurological Disorders and Stroke.

William Hirstein is Professor and Chair of the Philosophy Department at Elmhurst College, Elmhurst, IL, USA. He received his PhD from the University of California, Davis, in 1994. He is the author of several books, including *On the Churchlands* (Wadsworth Publishing, 2004), *Brain Fiction: Self-Deception and the Riddle of Confabulation* (MIT Press, 2005), and *Mindmelding: Consciousness, Neuroscience, and the Mind's Privacy* (Oxford University Press, 2012). His other interests include autism, sociopathy, brain laterality, sense of self, and the misidentification syndromes.

William G. Iacono is Regents Professor of Psychology, Psychiatry, Law, and Neuroscience; Distinguished McKnight University Professor; Adjunct Professor of Child Development; and Codirector of the Minnesota Center for Twin & Family Research at the University of Minnesota.

He studies the development of common mental disorders, focusing on the genetic liability for substance abuse and antisocial behavior. He is past president of the Society for Psychophysiological Research (SPR). He has also received the Distinguished Contributions to Psychophysiology Award from SPR for his lifetime contributions to this field. In addition, he has been awarded the Distinguished Scientist Award from the Society for a Science of Clinical Psychology. His research is funded by grants from the National Institute of Mental Health, National Institute on Drug Abuse, and National Institute on Alcoholism and Alcohol Abuse. He currently holds a National Institute of Health MERIT (Method to Extend Research in Time) Award for his research achievement. He has published over 350 scientific articles.

John T. Jost is Professor of Psychology at New York University. His research, which addresses stereotyping, prejudice, political ideology, and system justification theory, has appeared in top scientific journals and received national and international media attention. He has published over 90 articles and chapters and coedited four books: *The Psychology of Legitimacy* (2001), *Perspectivism in Social Psychology* (2004), *Political Psychology: Key Readings* (2004), and *Social and Psychological Bases of Ideology and System Justification* (2011). Jost has received numerous honors, including the Gordon Allport Intergroup Relations Prize (three times), Erik Erikson Award for Early Career Research Achievement in Political Psychology, International Society for Self and Identity Early Career Award, Society for Personality and Social Psychology Theoretical Innovation Prize, Society of Experimental Social Psychology Career Trajectory Award, and the Morton Deutsch Award for Distinguished Scholarly and Practical Contributions to Social Justice.

Jerome Kagan is Emeritus Professor of Psychology at Harvard University. His research over the past 57 years has centered on the cognitive and emotional development of infants and children. During the last 30 years, he and his colleagues have concentrated on the temperamental biases called high and low reactivity in infants. He is a fellow of the American Academy of Arts and Sciences and a member of the Institute of Medicine in the National Academy of Sciences. He has received distinguished scientist awards from the American Psychological Association, the Society for Research in Child Development, and the Child-Mind Institute. Kagan received his PhD from Yale University in 1954 and taught at the Ohio State University and Antioch College before joining the Harvard faculty in 1964.

Leif Edward Ottesen Kennair, PhD, is Head of Department at the Department of Psychology, Norwegian University of Science and Technology, Trondheim, Norway. He graduated as a clinical psychologist from the University of Bergen, 1999, and is a specialist of clinical adult psychology (Norwegian Psychology Association), and a qualified cognitive therapist and supervisor of cognitive-behavioral therapy (Norwegian Cognitive Therapy Association). He has worked as a clinical psychologist/chief psychologist at the Nordfjord Psychiatric Centre and as a researcher at St. Olav's Hospital, Trondheim. His research interests span from mainstream clinical psychology efficacy research (generalized anxiety disorder, OCD) to evolutionary psychology (evolutionary psychopathology, the evolutionary psychology of war, mate choice and sexual behavior). Kennair's PhD thesis was on the topic of evolutionary clinical psychology. He has written an introduction to evolutionary psychology, which has been published in Norwegian and Danish. He lectures on evolutionary psychology, behavioral genetics, and personality psychology and is a much-used lecturer for training psychologists and psychiatrists on topics such as cognitive-behavior therapy and treatment of anxiety and OCD.

David E. Presti is a neurobiologist and cognitive scientist at the University of California in Berkeley, where he has taught in the Department of Molecular and Cell Biology for more than 20 years. For more than a decade (1990–2000) he also worked in the treatment of addiction and of posttraumatic stress disorder (PTSD) at the Department of Veterans Affairs Medical Center in San Francisco. His areas of expertise include the chemistry of the human nervous system, the effects of drugs on the brain and the mind, the treatment of addiction, and the scientific study of the mind and the consciousness. He has doctorates in molecular biology and biophysics from the California Institute of Technology and in clinical psychology from the University of Oregon. Since 2004, he has also been teaching neuroscience to Tibetan monks in India in a program initiated by the Dalai Lama. His primary research interest is the relation between mentality, consciousness, and brain physiology, the so-called mind-body problem.

HOW TO USE THE ENCYCLOPEDIA

The *Encyclopedia of Human Behavior* is intended for use by students, research professionals, and interested others. Articles have been chosen to reflect major disciplines in the study of human behavior, common topics of research by professionals in this domain, and areas of public interest and concern. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

Articles in the encyclopedia are arranged alphabetically by subject. Complete tables of contents appear in all volumes. The index is located in Volume 3. Because the reader's topic of interest may be listed under a broader article title, we encourage use of the index for access to a subject area, rather than use of the table of contents alone.

Each article contains a glossary, cross-references, and a further reading list. The outline allows a quick scan of the major ideas discussed within each article. The glossary contains terms that may be unfamiliar to the reader, with each term defined *in the context of its*

use in that article. Thus, a term may appear in the glossary of another article defined in a slightly different manner, or with a subtle nuance specific to that article. For clarity, we have allowed these differences to remain so that terms are defined relative to the context of each article.

Each article has been cross-referenced to other related articles in the encyclopedia. Cross-references will always appear at the end of an article. Where multiple cross-references apply to an article, the cross-references will be listed alphabetically. We encourage readers to use the cross-references to locate other articles in the encyclopedia that will provide more detailed information about a particular subject.

The further reading section lists recent secondary sources to aid the reader in locating more detailed or technical information. Review and research articles that are considered to be of primary importance to the understanding of a given subject area are also listed. The further reading lists are not intended to provide a full reference listing of all the material covered in the context of a given article, but are provided as guides.

PREFACE

The social scientists have a long way to go to catch up, but they may be up to the most important scientific business of all, if and when they finally get to the right questions. Our behavior toward each other is the strangest, most unpredictable, and almost entirely unaccountable of all the phenomena with which we are obliged to live.

Lewis Thomas

Psychology, the study of the human mind, has made many rapid strides during the past four decades. There is now, more than ever before, a real need for a standard reference work covering all aspects of human behavior. The *Encyclopedia of Human Behavior* is the most up-to-date and comprehensive collection of reviews currently available. The essays will be of interest not only to clinical and experimental psychologists but also to students in fields such as psychiatry, neuroscience, philosophy, cognitive science, and medicine. Indeed, given the enormous range of topics covered, no one interested in human nature can fail to find something of interest in each volume. The format of the volumes lends itself just as readily to casual perusal as it does to serious inquiry.

My colleagues and I are often asked questions such as: What is the superego? What is repression? How reliable is eyewitness testimony? How much sleep do we need? What do we know of the psychology of laughter, language, cruelty, or politics? Or of love, cunning, and deceit? We have all experienced the frustration of not being able to answer such questions or find the answers quickly without recourse to extensive library research. This encyclopedia should prove to be an invaluable resource in such situations. Also, students of psychology and related health professions will find this collection of articles useful as a starting point when they embark on new research projects dealing with specific aspects of human behavior.

The study of human behavior is an enterprise that covers an enormous variety of subjects, ranging from the minutiae of neurophysiology to such familiar but poorly understood topics as Freudian psychology. Psychology is a science that is still very much in its infancy even though it has had a very long history, almost as long as that of physics and biology. Anyone interested in the history of ideas should be puzzled by the differences between advances in biology and advances in psychology. The progress in biology has been characterized by a number of landmark discoveries, each of which resulted in a breakthrough in understanding, for example, the discoveries of cells, Mendel's laws of heredity, chromosomes, mutations, and most recently DNA and the genetic code. Psychology, however, has until recently been characterized by an embarrassingly long sequence of 'theories,' each of which was really nothing more than a passing fad that rarely outlived the person who proposed it. I have always found this contrast to be quite remarkable and can think of no simple explanation for it other than the fact that human behavior is inherently more complex, quixotic, and difficult to fathom. Fortunately, the picture has changed radically over the past four decades, particularly in psychiatry and cognitive neuroscience. There are two reasons for this change: First, there has been a growing dissatisfaction with metaphorical explanations (Peter Medawar calls explanations of this kind "analgesics," for "they dull the ache of incomprehension without removing the cause") and a healthy trend toward replacing them with more mechanistic explanations. Second, progress has been aided by the advent of several new technological innovations for studying the structure and function of the human brain. This encyclopedia covers as many of these recent advances as possible within a three-volume set.

My own experience is mainly in neuropsychology, medicine, and visual science, and I am therefore indebted to the editorial advisory board, as they selected the authors in other areas and saw each essay through the long process of peer review, revisions, and copy-editing. Most of the entries are by acknowledged experts in the field.

Given the nature and scope of this enterprise, some degree of overlap among the essays was not only inevitable but also desirable since our goal was to ensure that each article was a self-contained summary of one specific aspect of human behavior. Given the space limitations, each author was encouraged to provide an overview and convey the general flavor of an area of research rather than attempt an exhaustive review. The result is a very stimulating and informative collection of essays.

I have no doubt that this work will prove useful to specialists. If it also succeeds in kindling a spark of interest in some aspect of human behavior among undergraduate and graduate students, then our efforts will have been amply rewarded, for no enterprise is more important to the future of our species than an understanding of human nature in all its diverse manifestations.

V S Ramachandran

Glossary

Amenorrhea In women and postpubertal girls, loss of three consecutive menstrual periods.

Anorexia nervosa An eating disorder in which one is significantly underweight and exhibits fear of gaining weight, body image disturbance, and amenorrhea. It is explicit or inferred that the weight loss is purposeful.

Binge eating Episodes of uncontrolled eating of a larger amount of food than is usual under the circumstances, within a 2-h period of time.

Bulimia nervosa An eating disorder in which one experiences recurrent episodes of binge eating and inappropriate compensatory behavior, and one's self-evaluation is unduly influenced by one's shape and weight.

Compensatory behavior Inappropriate behaviors undertaken with the intent to lose or avoid gaining weight. Encompasses both purging and nonpurging behaviors.

DSM An abbreviation for the Diagnostic and Statistical Manual of Mental Disorders, which provides definitions of mental disorder categories. It is sometimes referred to as the 'psychiatrist's Bible.' The DSM is currently in its fourth edition (DSM-IV) and is used by mental health professionals who are primarily located in North America.

Eating disorder A persistent, severe disturbance in eating behavior that is not better explained by a medical disorder or another psychological disorder. Typically also involves pathological attitudes related to eating, shape, and/or weight.

Nonpurging behavior Inappropriate compensatory behaviors, such as excessive exercise or fasting for a day or more, that do not involve purging.

Not otherwise specified (NOS) In DSM-IV, this residual category is reserved for disorders of clinical severity that do not fit other, more specific categories. For eating disorders, the specific categories are anorexia nervosa and bulimia nervosa.

Purging Compensatory behaviors such as self-induced vomiting or misuse of laxatives, diuretics, or enemas, which are undertaken to induce immediate or rapid weight loss or to prevent weight gain.

Residual A type of diagnostic category composed of symptom patterns of clinical severity that are left over and not otherwise accounted for by existing diagnoses.

Subsyndromal Symptoms exhibited that do not meet a diagnostic threshold for severity or frequency. For example, subsyndromal bulimia nervosa might involve binge eating on average once a week for 3 months, in contrast to full-threshold bulimia nervosa in which binge eating occurs at least two times a week for 3 months.

Far from being fixed entities, definitions of mental disorders may change over time, as research findings and clinical observations continue to impact experts' understanding of these problems. In particular, an evolution in conceptualization has profoundly affected eating disorders, which have become relatively common and have sprung to the attention of mental health researchers and practitioners and the general public only since the final quarter of the twentieth century. Among eating disorders, this evolving conceptualization is particularly relevant for the residual diagnostic category of eating disorder not otherwise specified (EDNOS).

What is EDNOS? In a nutshell, an EDNOS diagnosis describes clinically significant eating disorders that do not satisfy the criteria for either of the two, officially recognized eating disorders: anorexia nervosa and bulimia nervosa. The EDNOS category spans binge-eating disorder, subsyndromal variants of anorexia nervosa or bulimia nervosa, and a range of other symptom patterns.

A Brief History of EDNOS

Like it or not, our understanding of mental disorders relies to a great extent on our nosology, or classification system. Classification systems provide a lens through which psychopathology

is construed, a framework within which mental disorders are studied and treated, and a critical means of communication among professionals about the problems they encounter in clinical practice and research. The classification system used in North America is summarized in a text called the Diagnostic and Statistical Manual of Mental Disorders (DSM), which is published and updated periodically by the American Psychiatric Association. It describes mental disorders and provides criteria for their diagnosis, and is currently in its fourth edition (i.e., DSM-IV). A revision of the descriptive material, but not the diagnostic criteria, was published in 2000 (i.e., DSM-IV-TR); for simplicity, however, only DSM-IV is referred to here.

The residual diagnostic category of EDNOS was first introduced in the 1987 revised version of the DSM (i.e., DSM-III-R). In the 1980 edition of the DSM (i.e., DSM-III), a comparable residual category was included under a different name: atypical eating disorder. Despite the name change, in both cases this residual diagnosis was intended to be used when an individual experienced clinically significant eating-disorder symptoms that did not meet specific criteria for either anorexia nervosa or bulimia nervosa. In the current DSM system, not otherwise specified (NOS) diagnoses are used to describe atypical, presumably uncommon variants within a diagnostic category. NOS categories exist for all major mental disorder categories

in the DSM. The DSM-IV retained the EDNOS definition used in DSM-III-R but added more examples of symptom patterns eligible for an EDNOS diagnosis.

Current Definition of EDNOS

EDNOS encompasses diverse, clinically significant eating disturbances. Six specific examples of subtypes of EDNOS were provided in DSM-IV, although other, unspecified variants of clinical severity – in other words, syndromes that cause distress, impairment in functioning, or both – may be included as well. Roughly speaking, the EDNOS category can be divided into the following three parts, which do not necessarily reflect their relative prevalence in the population at large. The first domain is subsyndromal anorexia nervosa and bulimia nervosa. The second domain is binge-eating disorder, included in DSM-IV as a provisional diagnosis that merited further study. The third domain includes patterns of eating disturbances distinct from the officially recognized eating disorders (anorexia nervosa and bulimia nervosa) and other forms of EDNOS already described.

As a residual category, EDNOS is primarily a diagnosis of exclusion. In other words, to date it has been defined largely by what it is *not* (i.e., anorexia nervosa or bulimia nervosa) rather than what it is. To understand the diverse patterns of symptoms described by this diagnostic category, first it is essential to understand how the core eating disorders of anorexia nervosa and bulimia nervosa are defined.

Subsyndromal Anorexia Nervosa and Bulimia Nervosa

In DSM-IV, anorexia nervosa is described as the refusal to maintain a minimally normal body weight, accompanied by the following symptoms:

- intense fear of gaining weight;
- distortions in the experience and significance of body weight and shape, or undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight;
- amenorrhea, in girls who have started menstruating.

The weight threshold guideline provided for a diagnosis of anorexia nervosa – $<85\%$ of expected body weight for age and height, or a body mass index of 17.5 kg m^{-2} – tends to be strictly observed, providing a sharp cut-off at a given point in time between those whose weight meets this criterion and those whose weight does not. Two subtypes of anorexia nervosa are recognized: restricting type, characterized by no regular binge-eating or purging behavior, and binge-eating/purging type, characterized by regular binge-eating or purging behavior. Note that the primary difference between the binge-eating/purging type of anorexia nervosa and bulimia nervosa is weight: by definition, one must be significantly underweight to qualify for a diagnosis of anorexia nervosa.

DSM-IV lists two examples of EDNOS that constitute deviations from the prototypical presentation of anorexia nervosa. Many individuals with anorexic-like problems are not deemed eligible for a diagnosis of anorexia nervosa because, although underweight, they do not quite meet the weight criterion (i.e., their weight is 85–90% of ideal body weight), or, alternatively, because, if female, they continue to menstruate. Currently,

individuals with either of these anorexic-like eating disorders would be diagnosed with EDNOS rather than anorexia nervosa.

In DSM-IV, bulimia nervosa is defined as involving binge-eating and compensatory behaviors to influence weight that occur, on average, at least twice weekly for 3 months, along with self-evaluation that is disproportionately influenced by one's body weight and shape. By definition, an episode of bulimia nervosa may not occur exclusively during an episode of anorexia nervosa. A third example of EDNOS that is listed in DSM-IV describes symptoms that fall short of the prototype for bulimia nervosa. This example describes those with subsyndromal bulimic-like symptoms: in other words, those who binge eat and use compensatory behaviors regularly, yet less often than twice weekly for 3 months or for a shorter duration than 3 months.

Binge-Eating Disorder

Although formally still considered a specific subtype of EDNOS, binge-eating disorder was introduced as a provisional eating-disorder diagnosis in DSM-IV, with the aim of furthering research to ascertain the validity of the diagnosis. The inclusion of diagnostic criteria for binge-eating disorder in DSM-IV has indeed facilitated a subsequent proliferation of research on this syndrome. Since its publication, more research by far has been conducted on binge-eating disorder than on any of the other specific examples of EDNOS listed in DSM-IV. Research on binge-eating disorder has aimed to determine, among other things, its severity, effective treatments, its distinctiveness from bulimia nervosa, and its utility as a diagnostic category.

According to the DSM-IV's provisional criteria, binge-eating disorder entails recurrent, distressing episodes of binge eating, as described earlier. In binge-eating disorder, binge-eating episodes must not be accompanied by regular compensatory behavior such as that seen in bulimia nervosa, that is, purging, fasting, or excessive exercise. Binge eating must occur on at least 2 days a week for 6 months, on average. In addition, binge-eating episodes must be accompanied by at least three of the following five features:

- eating more rapidly than normal;
- eating until one feels uncomfortably full;
- eating large amounts of food when not hungry;
- eating alone due to embarrassment or guilt;
- eating amounts that lead one to feel disgusted, depressed, or very guilty.

Finally, binge-eating disorder may not occur exclusively during a period in which one has either anorexia nervosa or bulimia nervosa.

Atypical Symptom Patterns

Other eating disturbances that are distinct from anorexia nervosa, bulimia nervosa, their subsyndromal variants, and binge-eating disorder also fall into the EDNOS diagnostic category. The following two examples are presented in DSM-IV as additional subtypes of EDNOS.

Purging disorder

The fifth example of EDNOS has been referred to variously as purging disorder, subjective bulimia nervosa, compensatory

eating disorder, and EDNOS-purging only. It involves the regular use of inappropriate compensatory behaviors among normal-weight individuals after eating small amounts of food, accompanied by intense fear of gaining weight or becoming fat. Although the topic has begun receiving intensive study by researchers, the precise boundaries of this problem relative to anorexia nervosa and bulimia nervosa have not yet been widely agreed upon, and its validity as a unique diagnostic category remains under debate. Most experts believe that insufficient evidence has accrued so far to merit the designation of purging disorder as a diagnosis in DSM. A few studies suggest that purging disorder may be as common as anorexia nervosa and bulimia nervosa and that it involves significant distress and impairment, although the findings have not been entirely consistent.

Chewing and spitting food

The sixth example of EDNOS included in DSM-IV is the recurrent chewing and spitting out of large amounts of food without swallowing. Little systematic study has addressed this problem, but it may be common among those with eating disorders, and may be associated with food restriction rather than binge eating. It is unclear to what degree chewing and spitting occurs among people who do not have other eating disorders.

Other atypical EDNOS symptom patterns

Several other atypical eating disturbances that have been described in the empirical literature are not listed as examples of EDNOS in DSM-IV, yet may still qualify for an EDNOS diagnosis if they are of clinical severity and not due to an underlying medical illness. These problems include, but are not limited to, non-fat phobic anorexia nervosa (a self-starvation syndrome that is not associated with a fear of fatness) and night-eating syndrome (overeating at night, including after having fallen asleep). Our knowledge of these symptom patterns tends to be limited.

Epidemiology and Significance of EDNOS

Given the initial, common sense view that problems described by NOS categories are inherently rare and less severe than their officially recognized counterparts, several myths about EDNOS have been hard to shake, despite the accumulation of research findings contradicting them. First, eating disorders have been recognized by the scientific community as significant, noteworthy conditions only since approximately the late 1970s. In the years immediately following the initial inclusion of eating disorders in DSM-III in 1980, almost all eating disorder related clinical and research attention focused on anorexia nervosa and bulimia nervosa, which were widely believed to be the most common and severe forms of eating disturbance.

Subsequent research has demonstrated that ~40–60% of those seeking treatment for an eating disorder do not, in fact, have anorexia nervosa or bulimia nervosa. Instead, they merit an EDNOS diagnosis. Similarly high rates of EDNOS have also emerged from studies of nonclinical samples. These consistent findings indicate that, far from being a rarity, as currently defined, EDNOS actually is the most common eating-disorder diagnosis. Studies of the prevalence of eating disorders suggest that as many as 12% of young women experience some type of

eating disorder, including EDNOS. However, because EDNOS is not a unitary phenomenon and because the diagnosis lacks inclusion criteria, it is difficult to estimate population prevalence of EDNOS in a precise manner.

Second, EDNOS is often mistakenly believed to affect mainly, or only, Caucasian girls and young women. However, EDNOS affects a wide range of people, probably in part because it includes such a diversity of different symptom patterns. It affects men, ethnic minorities, athletes in aesthetic sports such as ballet and gymnastics, young children, and the elderly.

Third, there is a widespread misperception among mental health professionals, other health care professionals, third-party payers, and the general public about the meaning and import of a residual eating-disorder diagnosis. Although EDNOS is often believed to describe eating disturbances that are subclinical and therefore less severe, research has shown that the consequences or impact of EDNOS symptoms are often no less severe or problematic than in anorexia nervosa or bulimia nervosa. That is, people with EDNOS tend to experience a degree of general psychopathology, distress, and impairment that is on a par with anorexia nervosa and bulimia nervosa. Thus, the EDNOS diagnosis describes serious, problematic mental disorders, not merely atypical or minor variants of eating disorders.

Binge-Eating Disorder

As noted above, the inclusion of specific, provisional diagnostic criteria for binge-eating disorder in DSM-IV sparked a great deal of research related to it, including its epidemiology and significance. The diagnosis of binge-eating disorder affects ~3–6 % of adults in their lifetimes, which is at least twice as common as diagnoses of bulimia nervosa (1–3% of women) or anorexia nervosa (0.5% of women). Binge-eating disorder is more common among obese individuals, with some estimates indicating that as many as 30% of obese individuals have binge-eating disorder. Those with binge-eating disorder also typically exhibit poor psychosocial functioning and poor social adjustment and often experience other mental disorders as well.

Binge-eating disorder is the most prevalent form of EDNOS. The gender ratio for binge-eating disorder is approximately two males to three females, indicating that it affects a much greater proportion of males than does anorexia nervosa or bulimia nervosa, which are estimated to affect about ten times as many females as males. The average duration of illness for binge-eating disorder among those studied is at least 14 years, suggesting that it is a chronic and reasonably stable disorder, similar to bulimia nervosa. Family studies demonstrate that it is transmitted separately from anorexia nervosa and bulimia nervosa.

Taken as a whole, the body of research conducted on binge-eating disorder demonstrates that this syndrome is distinct from anorexia nervosa and bulimia nervosa on a number of key dimensions, and that it poses a significant problem for those it affects. Given its severity, it is likely that binge-eating disorder will be added to future versions of the DSM.

Assessment of EDNOS

As with all eating disorders, careful, rigorous assessment is critical for obtaining accurate estimates of the prevalence of the component symptoms as well as symptom patterns of

EDNOS. Because the lay person's understanding of binge eating is broader than the scientifically accepted definition, rates of binge eating tend to be higher when assessed by self-report rather than by diagnostic interview. As a result, self-reports of binge eating should be interpreted cautiously. Rather, semi-structured interviews administered by trained individuals, who apply standardized definitions to criteria that are often not clear-cut and who may ferret out answers to often complicated questions, are considered the gold standard for diagnosis. Semistructured interviews commonly used to assess eating-disorder symptoms and diagnoses are the Eating Disorder Examination and the Structured Interview for DSM-IV Disorders. A substantial investment of time and expertise is required for training in the proper conduct of these interviews.

Self-report questionnaires are often used in assessing eating-disorder symptoms and associated constructs, such as body image. Self-report questionnaires may be used to screen for or to more fully describe one's eating-disorder symptoms. The choice of questionnaire should depend on the constructs one wishes to assess. Some frequently used questionnaires of eating-disorder symptoms include the Eating Disorder Examination Questionnaire, Eating Disorder Inventory, Eating Attitudes Test, Multiaxial Assessment of Eating Disorder Symptoms, Stirling Eating Disorder Scales, Eating Disorder Questionnaire, DSM-IV Diagnostic Questionnaire, Minnesota Eating Behavior Survey, and Questionnaire on Eating and Weight Patterns-Revised.

Treatment of EDNOS

To date, very few researchers have attempted to design and study treatments addressing the broad assortment of problems comprising EDNOS. The single exception has been transdiagnostic cognitive-behavioral therapy for eating disorders, which represents a recent, promising approach for ameliorating a variety of eating-disorder symptoms including EDNOS as well as bulimia nervosa, although it excludes individuals whose body mass index falls below 17.5 kg m^{-2} . This treatment has a focused form, targeting eating-disorder symptoms alone, and a broad form, also targeting mood intolerance, clinical perfectionism, low self-esteem, or interpersonal difficulties.

By contrast, research focused on treatments for binge-eating disorder has flourished. Cognitive-behavior therapy, including individual and group formats as well as self-help versions, has proved to be the most effective treatment for symptoms of binge-eating disorder thus far. There is evidence that interpersonal psychotherapy may be similarly effective in reducing binge-eating symptoms. Other forms of psychotherapy that show promise in treating binge-eating disorder are dialectical behavior therapy, behavioral weight loss programs, and motivational interviewing. Certain medications have also demonstrated short-term efficacy in reducing binge-eating frequency and inducing modest weight loss among individuals with binge-eating disorder.

Problems with the EDNOS Diagnosis

The fact that a single EDNOS diagnosis describes a hodgepodge of eating problems poses several substantial problems that affect our understanding of eating disorders as a whole.

As noted earlier, residual categories are usually assumed to apply only to the minority of individuals who experience atypical manifestations of a type of problem. In that light, EDNOS presents a problem because it encompasses numerous symptom patterns, none of which constitutes a majority of the category. People with an EDNOS diagnosis may experience entirely distinct symptoms and are bound together only loosely through their shared characterization as experiencing eating pathology. The breadth of symptom patterns encompassed by the EDNOS category hampers efforts to identify epidemiology, course, prevention strategies, and effective treatments for these problems. Researchers and clinicians need a common language to advance knowledge, and an EDNOS diagnosis describes too many symptom patterns to make it meaningful. The heterogeneity of this diagnosis has been a major impediment to our accumulation of knowledge about, and treatment of, eating disorders.

The lack of inclusion criteria for EDNOS means that there is no clear demarcation between EDNOS and eating disturbances that may be unusual but are not pathological. Clinical judgment, which is inherently subjective, is required to make this determination, and the necessity of using clinical judgment has the effect of impeding reliability, or agreement across experts and, therefore, communication. In short, the basic problem is that the syndromes and symptoms we look for inevitably affect what we find. For example, we thought previously that binge-eating disorder was uncommon and not very problematic, but systematic research has indicated that the opposite is true. This pattern may prove to be evident with other forms of EDNOS, such as purging disorder.

It is important to note that an eating disorder diagnosis describes a person's symptoms at a single point in time (or for a fairly short period of time) and does not consider the longer-term trajectory or course of the symptoms. Thus, an EDNOS diagnosis may describe a person who is on the way toward developing, or recovering from, anorexia nervosa or bulimia nervosa, as well as a person whose eating-disorder symptoms are not in flux. EDNOS is associated with symptoms that vary from mild to severe, in part according to one's symptom course and the phase of the disorder being currently experienced. Longitudinal research has also shown that diagnostic migration, or movement among diagnostic categories, including EDNOS, is common among those affected with eating disorders. This movement is not random, but shows trends over time from more restrictive behaviors toward more dyscontrolled ones, such as binge eating and purging behaviors, as well as trends toward recovery for a substantial number of those affected.

Certain time-related elements of binge-eating disorder criteria have been criticized by experts, including the appropriateness of the 2-h maximum duration for each binge-eating episode, the frequency of 2 days a week of binge eating, and the 6-month duration for the symptom pattern. Specifically, questions have been raised about the utility of such strict inclusion criteria when those with symptoms slightly less severe than these have been shown to be indistinguishable from those with full-threshold binge-eating disorder. As a result, some or all of these time-related elements may be revised if binge-eating disorder receives full disorder status in a future edition of DSM.

As the reader may have already noticed, there has been little discussion of children or adolescents thus far. Indeed, a large proportion of eating disorders related research is conducted with individuals university-aged and older; much less research is available on adolescents and even less on children. As eating disorders are most common among those who have reached puberty, and affect large numbers of adolescents in particular, the lack of data on younger sufferers may be largely attributable to the greater number of challenges inherent in studying children.

Clinical presentations of children and adolescents with eating disorders may differ from those described in DSM-IV in part because of their stage of development, and the consequences of delaying an eating-disorder diagnosis may be severe. In particular, experts from the Workgroup for Classification of Eating Disorders in Children and Adolescents have argued for the use of lower, more sensitive thresholds of severity as diagnostic boundaries in children and adolescents, for example, lower frequency of purging behaviors, and significant declines from growth curves for determining whether a child or adolescent satisfies the weight criterion for anorexia nervosa. These experts have also recommended that behavioral indicators of fear of gaining weight and body image disturbance should be allowed in lieu of self-reported symptoms, and have pointed out that requiring that certain symptoms be articulated by the child or adolescent may be developmentally inappropriate. Furthermore, these experts have recommended that multiple informants, including parents, be used in determining eating-disorder symptom patterns. If adopted, these alterations to DSM criteria would reduce the number of EDNOS cases and simultaneously increase the number of officially recognized eating disorders that are seen in children and adolescents.

Current Trends

At the time of writing in early 2010, proposed criteria for the next edition of the DSM (i.e., DSM-5) had been recently published online and a call for experts' feedback gone out. These draft criteria are subject to change before the DSM-5 publication, but the proposed changes suggest that concerns over the excessive breadth and heterogeneity of EDNOS will probably yield a tightening of its criteria by creating a new diagnostic category and shifting the boundaries of the other eating disorders. Specifically, binge-eating disorder may achieve the status of a full-fledged eating disorder comparable to anorexia nervosa and bulimia nervosa, and criteria for both anorexia nervosa and bulimia nervosa may be loosened to accommodate those with anorexic-like and bulimic-like syndromes. Anorexia nervosa may no longer require amenorrhea for diagnosis, and bulimia nervosa and binge-eating disorder both may require binge eating only once a week, on average, for 3 months. Altogether, these changes would diminish the number of individuals captured within the EDNOS category, allowing researchers to focus on and better characterize the remaining symptom patterns. Efforts are under way to identify and examine the remaining symptom patterns that make up EDNOS, such as atypical anorexia nervosa, atypical bulimia nervosa, atypical binge eating disorder,

purging disorder and night-eating syndrome. In DSM-5, the category of Eating Disorders may also be broadened and renamed, *Feeding and Eating Conditions Note Elsewhere Classified*.

Summary and Conclusions

EDNOS is a residual diagnosis for those clinically significant eating disorders that do not fit the criteria for either of the two officially recognized eating disorders, anorexia nervosa and bulimia nervosa. EDNOS spans symptom patterns that include binge-eating disorder and subsyndromal variants of anorexia nervosa or bulimia nervosa, as well as other problematic eating disturbances, such as purging disorder. Its symptoms may include food restriction, binge eating, compensatory behaviors, preoccupation with weight and shape, and body image disturbance. Studies of clinical and community samples have demonstrated that EDNOS is the most common eating-disorder diagnosis. Furthermore, EDNOS tends to be just as severe, persistent, and problematic as anorexia nervosa or bulimia nervosa.

The most common subtype of EDNOS is binge-eating disorder, which has been well characterized and affects at least twice the number of people as do anorexia nervosa and bulimia nervosa together. Binge-eating disorder affects men as well as women, children as well as the elderly, athletes in aesthetic sports, and people of diverse cultural backgrounds and ethnicities. It is often a chronic problem that increases the risk of weight gain and obesity. Cognitive-behavior therapy is considered the first-line treatment for binge-eating disorder, although other treatment approaches also have shown promise.

The heterogeneous nature of the EDNOS diagnosis has proved to be unwieldy, and has slowed efforts to further our understanding of eating disorders as a whole, as well as to identify effective treatments. Consideration is being given to diminishing the scope of this diagnostic category in future editions of our nosological scheme, the DSM, by broadening criteria for the diagnoses of anorexia nervosa and bulimia nervosa, and by designating binge-eating disorder as an officially recognized, specific eating disorder. Taking these steps would enable experts to isolate and study in depth the atypical symptom patterns that remain within the EDNOS category, and would help bring EDNOS into line with the other residual diagnostic categories for mental disorders that are recognized in the DSM.

Glossary

Activities of perception Self-generated movements that expose organisms to patterns of ambient energy, especially when particular movements make it possible to perceive things that would otherwise be missed.

Affordance The relationship between a given organism and aspects of its environment that make specific actions (or outcomes by means of action) possible.

Behavior setting A bounded, self-regulated, and ordered system composed of replaceable human

and physical components that interact in a synchronized fashion to carry out the activities expected to take place in the setting.

Higher-order invariants Patterns in ambient energy that specify environmental properties.

Perceptual system All parts of an organism involved in actively looking, smelling, touching, etc. This is contrasted with the more limited parts of the organism studied for their role in passive sensation.

Ecology in the Biological Sciences

Ecology, derived from a Greek word meaning 'household,' is the branch of biology that studies the relationships between organisms and their surroundings, especially with regard to the adaptations of organisms to environments and the resulting population distributions. It also studies invasion and succession among communities and the gradual replacement of one species by another that is more suited to a changed environment.

Ecological study of a species requires a description of its habitat and the species' relationship to that habitat, its social organization, and its relationships to other species, emphasizing functional adaptations. Because of its broad scope, the term has been introduced into the social and behavioral sciences and is used in different ways, often in combination with other terms as in social ecology, human ecology, ecological psychology, and ecopsychology. All these fields describe how organisms are affected by their surroundings and how they, in turn, contribute to changes in those surroundings through their behavior. Studies of human populations from an ecological perspective are not as common as in the case of other species. The great diversity of human habitats and the ability of humans to adapt to different environments as well as to change their environments are likely reasons for the lesser influence of an ecological perspective in the behavioral sciences.

Ecological Approaches in Psychology

The term *ecological psychology* is most commonly applied to J. J. Gibson and E. J. Gibson's approach to studying perception and to R. Barker's approach to studying social interactions. H. Heft traces the origins of both approaches to William James's radical empiricism. James was one of the early proponents of incorporation of evolutionary thinking into psychology. He advocated a psychology that did not neglect normal everyday experience.

The term 'psychological ecology' was introduced by K. Lewin in 1943 in an attempt to shift the emphasis in psychology away from individual organisms and their mental processes to organism–environment relationships. Coming out of gestalt psychology, Lewin's usage of the term was primarily psychological, referring to a person's interpretations of the external environment in terms of goals, barriers, and boundaries. Lewin defined psychological ecology as the relationship between psychological and nonpsychological factors. In approaching a problem, a researcher examines nonpsychological data first to find out how they determine the conditions of life for an individual or group. Only after the nonpsychological factors are known can research begin on the psychological dimensions of a problem. A. Wicker describes how this approach necessarily focuses on the ordinary environments in which people spend most of their time. Wicker and Sommer developed this strategy further in a paper documenting psychology's lack of interest in common, mundane behavior settings.

E. Brunswik, Lewin's contemporary and also from the gestalt tradition, developed an ecological model of perception in an attempt to widen the scope of research beyond the narrow range of stimuli used in laboratory experiments. Brunswik maintained that research on perception should employ stimuli typical of real life situations in an approach called 'ecological sampling.' According to Brunswik, the researcher's task is to locate within the richness and variety of real-world stimuli invariant patterns that are capable of representing a stable external world and relevant to the functional adaptation of a species.

These approaches influenced two separate lines of research and theory in psychology, both calling themselves 'ecological,' one emphasizing perception and the other, behavioral adaptations. Although the two lines of research share the ecological perspective of examining functional adaptations of organisms to their environments, they are concerned with different issues, employ different methods, and publish their studies in different journals for different audiences. The perception research is most closely identified with J. J. Gibson and the behavioral studies with R. Barker and his associates. Gibson's studies are

almost entirely experimental and theory driven, while Barker's work is largely observational and atheoretical. Because the two approaches to ecological psychology are so different, they will be described separately.

The terms 'ecological' and 'psychology' have also been blended into *ecopsychology*, an applied field whose central tenet is the reciprocal relationship between the personal well-being of individuals and the well-being of the planet. This approach gained recognition in a 1992 book and subsequent anthology by T. Roszak. Ecopsychology uses examples of traditional peoples who have evolved a harmonious relationship with nature. Similar to E. O. Wilson's concept of biophilia, which describes the innate bond between humans and other living organisms, ecopsychology emphasizes positive emotions such as caring, connectedness, and the healing powers of contact with nature. The latter is the basis of ecotherapy, which is accumulating a research base. There is increasing research evidence on the psychological benefits of nature contact, especially wilderness experience and human-animal bonds. Separation of humans from nature is viewed as responsible for environmental destruction as well as people's alienation and sense of incompleteness. Restoration of the connection between humans and nature is considered beneficial to both. The field has also brought psychological principles into environmental education and promoted sustainable lifestyles. Related intellectual movements are Conservation Psychology and Deep Ecology.

Gibson's Ecological Psychology

J. J. Gibson and E. J. Gibson's professional careers were dedicated to explaining how organisms used perception to successfully match their behaviors to their circumstances. Early in their partnership, the two agreed to focus on slightly different aspects of the problem, J. J. Gibson focusing broadly on established perceptual abilities, and E. J. Gibson focusing on perceptual development. Each of their four independently authored books appeared on a recent list of the 100 most important publications in the history of cognitive psychology, and they continue to influence the current generation of researchers, though the more devoted enthusiasts remain a bit marginalized. As *ecological psychology* is most closely associated with J. J. Gibson's work, and he was more interested in the theoretical novelty of their approach, the references to 'Gibson' below will be to him.

Gibson completed his graduate studies at Princeton in 1920 under the direction of E. B. Holt (1842–1910) who was a protégé of William James and a leader in the philosophical movement known as New Realism. Thus, Gibson's work can be seen as part of a continuing lineage of American philosophy. It has hints of pragmatism, a general rejection of dualism, and, in toto, is taken by its supporters as a successful explanation for how direct perception can occur. The term 'direct' has kindled a number of debates regarding Gibson's approach. It draws contrast with 'indirect' theories of perception in which some psychological intermediary, such as mental interpretation or past memories, supports perceiving. Gibson considered perception as a type of relationship between the organism and the environment; presaging modern systems theory. Gibson's approach does not attribute the activity of

the organism–environment system to any single component of the system (i.e., the brain), nor does it allow us to treat the bidirectional causality of the system as if it were linear (making it incorrect to imply that sensation causes perception). Because much attention is drawn to the philosophical aspects of Gibson's work, the methodological innovations developed in tandem with the theory are often neglected. Gibson claimed that the main purpose of empirical studies should be to demonstrate something unexpected. To that end, his thinking often dwelled on results that did not seem to fit within established models and addressed research questions not easily answered by established theories.

Gibson's thinking developed over time, and one could treat his books as rough markers of stages in his career. Many of Gibson's early-career innovations highlighted in *The Perception of the Visual World* are now widely accepted. In that period, he popularized the notion that people were sensitive to optic flow, moving patterns of stimulation on the retina. He also argued for the value of naturalistic studies of perception, providing evidence that real-world perceptual accuracy is often far better than what is suggested by constraining laboratory studies or research on picture perception. He also provided some of the earliest studies using motion pictures in psychological research. In contrast, many of Gibson's mid-career innovations described in *Senses Considered as Perceptual Systems* are still viewed with skepticism: At that stage, he argued that we could study the ecology of energy (light rays, sounds waves, etc.) to identify the environmental structure that an organism's perceptual abilities evolved to monitor. His first paper explicitly on that topic was titled '*Ecological Optics*,' from which his approach acquired the term 'ecological.' He also explained perception in terms of an almost whole-body attunement, in which the brain could play a minor role. This was largely motivated by an attempt to define perception in a manner that was egalitarian with respect to organisms that bear little resemblance to humans, but still perceive their world (insects, squid, etc.). Many of Gibson's late-career innovations, outlined in *The Ecological Approach to Visual Perception*, have become popular, but not typically in connection with his larger system of thinking. During this period, he emphasized the concept of affordances, which he saw as opportunities for action created by a match between environmental properties and organism properties (i.e., given my hand shape, my coffee mug affords picking up, whereas it does not afford the same to a deer or an ant). He also claimed that his approach could make obsolete many of the classic debates regarding perception. Most notably, he argued for 'direct perception' and laid out a sophisticated argument that many supposedly complex cognitive problems were solvable quite easily via perception.

The central tenets of Gibson's last approach are (1) perception is possible because of higher-order invariants in ambient energy arrays that specify environmental properties, (2) perception is an active process, and (3) organisms are specifically sensitive to the actions afforded them by their surroundings. If these points are treated as purely axiomatic, they can easily become the type of 'very abstract' or 'purely theoretical' jargon to which many research scientists are averse. However, if they are treated as working hypotheses, then each tenet opens lines of research that are grounded in past empirical observations and can make clear predictions:

1. *Higher-order invariants*: Perception is a process of discriminating between different types of situations. Patterns in energy fluxes are created by aspects of the world and some of the structure of the ambient energy specifies (is specific to) the properties of the environment. As a working hypothesis, this suggests that (1) we can identify the specific patterns of energy to which people are sensitive, (2) some pattern of energy exists that can be used to accurately make whatever perceptual distinction we are interested in, and (3) over the course of development, the specifying patterns become the patterns to which we are sensitive. For example, the optic parameter *tau* specifies time-to-contact when velocity is constant. D. Lee and colleagues demonstrated that gannet dives and pigeon landings are guided by sensitivity to that higher-order invariant. Research has subsequently shown that people exhibit direct sensitivity to *tau* in tasks ranging from baseball catching to automobile braking.
2. *Active perception*: Because the higher-order invariants are spread out across time and space, sensitivity to them requires movement. Thus, it can be argued that perception is an active process, and that every part of our body involved in the acts of perception can be considered part of the perceptual system. As a working hypothesis, this suggests that (1) people should perceive more accurately when they are allowed to move freely, (2) not all ways of moving will lead to better perception, and (3) over the course of development, people's movements should come to approach the ideal movements. For example, the length of an object (such as a rod) is specified by its inertial tensor, which can be detected only if the object is moved around in multiple dimensions. M. Turvey and C. Carello have demonstrated that people trying to determine the length of a rod they cannot see are remarkably accurate in a multiplicity of conditions (varying from holding the rod to having the rod taped to their backs), under a variety of circumstances (even underwater). However, participants are accurate only if they are allowed to move the rod, and only if they are allowed to move the rod in the right ways – ways that reveal the inertial tensor 'I.'
3. *Affordances*: In different situations, different actions are possible. Thus, relative to any given organism, the world can be described in terms of what it affords. The world is made up of affordances, opportunities for action. Due to evolutionary and developmental factors, organisms are able to perceive these affordances. As a working hypothesis, this suggests that (a) we can identify the physical properties of an organism and its environment that determine which actions are possible, (b) we can identify patterns of energy that specify many, if not all, of those affordances, and (c) organisms should be (or should develop to be) sensitive specifically to transitions between situations in which actions are possible and situations in which they are not. For example, K. Adolph and colleagues have shown that infants rapidly learn to attend to the steepness of slopes when determining whether or not to crawl down a surface and that they accurately distinguish dangerous from safe situations. Further, infants must learn these sensitivities anew for different styles of locomotion, as they develop.

Certainly, a theoretical or methodological commitment to any one of these points does not necessitate a commitment to the other two. However, those in the tradition of Gibson's ecological psychology see them as intimately intertwined: Organisms successfully match their behavior to the environment because they learn to discriminate between complex patterns of energy that specify which actions are possible. Perceptual systems attune to higher-order invariants that specify affordances.

Gibson's ecological approach thus offers an explanation for the way organisms can accomplish many sophisticated things through perceptual processes. This has led to a great deal of controversy as it offers the potential for a broad assault on traditional cognitive psychology. In the extreme, some ecological psychologists argue in favor of the radical position that perceptual explanations can be used to solve all supposedly 'cognitive' tasks. For example, traditional explanations of how people learn to drive rely on their remembrances of past driving experiences. However, ecological explanations can explain the same changes in terms of improved attunement to driving-relevant affordances, without reference to memory of any kind. That is, if a person's perceptual system is developed properly, he or she can directly perceive how to drive. Problems like stopping before you hit another car need not involve 'thinking' about how hard to press the brake or 'computation' based on distance and velocity, nor need it involve other cognitive processes such as 'anticipation,' 'representation,' or 'simulation.' A simpler explanation is that one can perceive what to do, probably through a real-time coupling between brake pressure and optic invariants specifying time to impact. While this style of explanation becomes more awkward in certain circumstances, such as when dealing with picture perception, abstract activities such as higher math, or complex verbal interactions, those of the more radical persuasion believe that the awkwardness will disappear when we learn to phrase the problems in a proper manner.

While Gibson's ecological psychology began as a somewhat narrow attempt to provide more sophisticated answers to classic perceptual problems, it has developed into an approach capable of making insightful contributions to many fields of psychology. Methods developed by Gibson and neo-Gibsonian researchers continue to lead to new discoveries in an expanding array of experimental settings.

Barker's Ecological Psychology

Barker was strongly influenced by the field theory of Lewin, with whom he collaborated on several classic experiments in child psychology. Barker subsequently became disenchanted with experimentation, which he believed failed to provide information about the frequency, duration, and complexity of behavior as it occurred in actual life. While admiring Lewin's choice to study problems from real situations, Barker maintained that behavior should be studied without outside manipulation or imposition of structure. Rather than the study of contrived artificial conditions in the laboratory, he advocated the study of behavior settings that already existed, using methods that exerted as little influence as possible upon the situation being studied. Barker's method relied almost exclusively upon nonreactive observations of people

in their ordinary environments. With his associates H. Wright and P. Gump, Barker initially called this approach psychological ecology, then ecological psychology, and subsequently, eco-behavioral science. The methodology drew more heavily from natural sciences such as botany and geology, which encourage documentation of processes as they occur naturally, than from physical sciences such as physics and chemistry, whose laboratory experiments isolate elements from their natural contexts.

Barker realized that psychology differed from other sciences in having proceeded directly from theory to laboratory experimentation without passing through a separate descriptive phase. As a consequence, psychology generally lacks ways to systematically describe, classify, and conduct research on human behavior in its natural context. To remedy this deficiency, Barker and Wright established in 1947 a field station in Oskaloosa, Kansas, a small community with a population of about 700. Field stations had been used previously in psychology to study animal behavior, but not human behavior. The goal of the field station was to bring to psychology the opportunities long available to biologists – easy access to the subject matter of the science unaltered by the selection and processing that occurs in the laboratory or clinic.

The small size of the community, and the fact that Barker resided there, made it possible for him to study local behavior settings for 25 years. As Barker had intended, the psychological field station was an established organizational unit continuing over time, whose staff included a cadre of long-term researchers and staff, with space for visiting researchers. It contained facilities for collecting, preserving, and retrieving naturalistic data; archives of primary data comparable to those collected in other natural sciences over long periods of time, which will be accessible to other researchers who can analyze them in their own ways; and statistical methods appropriate for naturalistic data, perhaps similar to those used in quantitative botany and geology.

Observers from the field station ranged throughout the town to record everyday activities of children. Sometimes a researcher followed a single child for a designated period of time, recording where the child went, who was present there, and what the child did. At other times, a researcher remained in a designated location and recorded which children visited and their activities while they were there. Based on these observations, Barker concluded that the behavior of a child could be predicted more accurately from knowing the situation the child was in than from knowing the child's individual characteristics. This laid the groundwork for studies by S. Milgram, P. Zimbardo, and others demonstrating the power of situations to influence behavior vis-à-vis personality characteristics. Throughout the existence of the field station, there were continuous attempts to keep the community informed about the project's methods and goals. The approach followed the naturalists' credo of studying phenomena without changing them, although there is some question as to whether, and if so, how the presence of professors and graduate student observers affected life in a small community. Subsequently, Barker and P. Schoggen compared the results of behavior setting surveys in Oskaloosa and Yoredale, England.

Barker maintained that the ecological environment has an objective reality with observable geographical, physical, and

temporal attributes. He stated the agenda for ecological psychology as a series of questions, such as 'What are environments like?'; 'How do environments select and shape the behavior of their occupants?'; and 'What are the structural dynamics of environments to which people must adapt?' Barker's conception of ecological psychology rested on several assumptions: (1) the systems of relationships that link individuals and groups with their social and physical environment are complex; (2) such systems cannot be understood piecemeal; (3) environment-behavior systems have properties that develop and change over long periods of time; (4) change in one part of the system is likely to affect the other parts of the system; (5) the challenge of ecological psychology is to obtain sufficient understanding about environmental systems to be able to predict and control the effects of planned and unplanned interventions.

The initial methodological problem of ecological psychology, as Barker saw it, was the identification of the natural units into which environments could be divided. These units, called behavior settings, have replaceable human and physical components that interact in a synchronized fashion to carry out an ordered sequence of events, which constitutes the setting program. Because they are discovered through observation, they are in no way imposed or created by the experimenter. To the lay observer, behavior settings such as a gas station or a lunch counter are as objective as a building or a river. Units are identified through a behavior setting survey – a comprehensive inventory and description of all the public behavior settings in a community or institution. Even though the occupants may change, the behavior setting will persist. Behavior settings are common phenomena in everyday life and lay people have no difficulty recognizing them; ecological psychology is thus linked to readily understood concepts. The same behavior setting might provide different inputs to the same person as that individual's behavior changes. Adding to Barker's construct, Wicker maintains that behavior settings have developmental cycles, including a beginning and an end, and are linked to other settings, thus requiring a larger and more complex range of investigations, including the effects of founders and successors upon setting functions.

Barker's ecological psychology tended to be atheoretical. One exception is now called Staffing Theory (originally known as Manning Theory). Comparison of the behavior of inhabitants of underpopulated, adequately populated, and overpopulated settings provides a test of the proposition that the environment is an interdependent whole with predictable effects on its human inhabitants. According to Staffing Theory, when there are too few people to perform the necessary roles, the number and range of pressures on each inhabitant increases because the same pressure to perform necessary roles will be distributed over fewer inhabitants. From this, it follows that inhabitants of underpopulated settings, in comparison with those in adequately populated settings, are likely to be more active within the setting and engage in a greater variety of actions. Admission standards may be lowered, differences among applicants may be virtually ignored, and occupants must work harder at more difficult tasks to keep the setting going. Each occupant will be more valued and given greater responsibility. Overpopulated settings encourage the creation of mechanisms to control the number of applicants

along with attempts to increase the capacity of the setting, either through enlargement or through shifts to alternative larger settings. Predictions based on population size have generally been confirmed in studies conducted in schools, churches, and workplaces.

Barker's interpretation of ecological psychology as a descriptive naturalistic behavioral science has been extended and refined in recent years. Behavior setting surveys have been conducted in a variety of locations, including schools, churches, workplaces, retail shops, mental health centers, virtual communities, and clinics for HIV patients. K. Fox has linked Barker's eco-behavioral approach to social accounting theories, showing how data from large-scale inventories of behavior settings can reveal changes in the quality of community life, thereby complementing other social and economic indicators. J. Barker has extended the approach to political science, demonstrating how residents can make behavior setting inventories to obtain valid knowledge about community activities in order to improve their situation. G. Kaminski has focused attention on individual and group goal-setting in the formulation of behavior setting programs. G. Taylor has used an ecological perspective to study urban crime. E. Morris attempts to integrate ecological psychology with Applied Behavioral Analysis. Wicker has extended both the methods and objectives of ecological psychology, and recommends a combination of qualitative and quantitative approaches with the latter used to study the purposive goal-directed behavior of individuals. While Barker emphasized commonalities among behavior settings of the same type, Wicker focuses on the uniqueness of settings. As an alternative to laborious and lengthy specimen records of individual behavior, Wicker uses intensive longitudinal case studies. He also extends Barker's nonintrusive descriptive methods to provide a framework for positive interventions to improve community settings and to develop new settings to meet new community needs.

Future of Ecological Psychology

Barker and Gibson shared a deep suspicion of laboratory experiments that distorted the processes they were designed to study. They preferred to study behavior in its natural context rather than in the artificial conditions of the laboratory or clinic. When they started their research careers, both men found that the laboratory-based techniques they had learned in graduate school were inadequate for encompassing the real-world phenomena that interested them. Gibson realized that elaborate methods for studying the perception of static stimuli by a stationary observer in a darkened experimental room would be useless in explaining pilot responses in a moving aircraft. As for Barker, it meant recognizing that elaborate developmental studies using conceptually loaded artificial tasks did not provide insight into the everyday lives of children at lunch, on the playground, and at church.

Present Status and Future of Gibson's Approach

In many ways, the present and future of Gibson's approach look far brighter than its past. There are still many who

view Gibson's work with suspicion, almost as a type of mysticism, but typically their only exposure is to the philosophical arguments associated with the approach. As the public face of the field comes to include more and more in-depth studies, the methodological advances offered become hard to deny, and the appeal of the approach is broadened. Thus, Gibson's approach continues to inspire a considerable amount of research and theory. Work by ecological psychology purists has managed to become at least slightly more mainstream, aided by the growing popularity of dynamic-systems approaches and by the success of ecological psychologists in analyzing problems faced by people with degenerative diseases that affect perception-action systems. In addition, ecological psychology has begun to have tremendous influence in fields such as kinesiology and sports psychology. In addition, some of the tenets of ecological psychology have proved to be appealing to researchers less interested in the system as a whole. Most obviously, the term 'affordance' has become commonplace in many areas of psychology and computer science.

Much of this success can be attributed to dedicated adherents at major universities. The International Society for Ecological Psychology, though small, continues to grow. Its biannual meeting, the International Conference on Perception and Action, is well attended, as is the European Workshop of Ecological Psychology. The society's publications include the journal *Ecological Psychology* and a book series '*Resources for Ecological Psychology*.' The current academic headquarters of the field is the Center for the Ecological Study of Perception and Action at the University of Connecticut. Many past and current leaders of the field taught at or graduated from this program.

There are obstacles yet to be overcome. Ecological psychology has yet to gain many of the trappings of more mainstream approaches. There are few academic courses in the subject; there are neither any textbooks nor other book-length surveys attempting to codify a broad range of recent advances in the field (except perhaps some published conference proceedings); and universities rarely think they need an ecological psychologist on the staff to round out their departments. In the end, it may be that the ecological approach is too far removed from lay beliefs to flourish to the same degree as cognitive psychology, but its influence continues to grow.

The long-term direction of any field is difficult to guess, but some short-term trends in psychology should be predictable: (1) While past work typically focused on object perception, future work will forge links between the ecological approach and social psychology. (2) While past work typically took participants' motives for granted, future work, inspired largely by the work of B. Shaw, will try to understand how intentionality affects the perceptual control of behavior. (3) While past work focused on philosophical systems with which the ecological approach clashed, future work will try to contextualize ecological theory with respect to traditions with which it is more compatible. (4) It is also clear that ecological psychologists will continue to be at the forefront of generating and applying ever more sophisticated mathematical models of behavior and behavior control, and will continue to be important in creating and utilizing the equipment required to test such models.

Present Status and Future of Barker's Approach

Barker's interest in real-world behavior in ordinary settings has had a mixed reception in the behavioral sciences. Although some cognitive researchers venture outside the laboratory to study behavior in mundane settings, the majority remain in their laboratories. Environmental psychologists have been more open to leaving the laboratory, but their methods typically involve paper-and-pencil tests, interviews, and questionnaires. Few have adopted Barker's reliance on naturalistic observation. Qualitative sociologists were never wedded to the laboratory, are familiar with case study methods, and do not object to observing mundane settings. However, they have shown little interest in the measurement of reliability or in quantification, both hallmarks of Barker's approach. By the 1980s, Barker's ecological psychology was described as an isolated and self-contained enterprise. Since then, its marginalization has increased as the field station in Oskaloosa closed without being replicated. Barker, his associates, and his students have retired from academic positions without being replaced, and there is no journal or Ph.D. program specifically devoted to Barker's type of eco-behavioral research. The labor-intensive, costly, time-consuming surveys that Barker advocated require decades rather than years: as such, they do not find favor with grant-supporting agencies, and publishers are uninterested in lengthy monographs that devote hundreds of pages to mundane behaviors of ordinary people. In addition, Barker's approach lacked an action component, either to halt environmental degradation or to remedy its effects and promote more sustainable settings and communities.

While Barker's work at the Midwest Field Station remains largely a footnote in developmental and social psychology, there have been some changes that suggest a future for an ecological approach in psychology. The effects of context or situation upon behavior are widely recognized. Milgram's obedience studies and Zimbardo's simulated prison research, along with real-world examples such as the conduct of American guards at Abu Ghraib prison, have demonstrated the inadequacy of trait-based explanations of behavior relative to the power of situations. The actions of two people in a single situation (e.g., sitting in a dentist's chair or shopping in a grocery store) will be more similar due to situational constraints than the action of a single individual in these two different situations. This raises questions about the predictive value of personality trait measures when information about situational influences is lacking. While Barker remained committed to the naturalist's hands-off style of research, future researchers may want to explore the behavior setting model not only to predict but also to change behavior. Whether Barker's ecological psychology, which involved an adult researcher following children throughout the day or stationed in a public location taking notes, is truly nonreactive, is debatable. There is no question that some habituation to a researcher's continued presence in a setting will occur, but issues of residual reactivity remain.

Technical developments, such as the availability of small inexpensive motion-activated video cameras to record behavior, software programs for classifying and digitizing visual data,

and easy compact storage of highly detailed digital specimen records, should make it easier to conduct eco-behavior studies. No longer will rooms of file cabinets with paper notes be required. Digitized material can be distributed online, circumventing publisher resistance to books and monographs containing essentially raw behavioral data, and making it easier for investigators to access original data.

Ecological psychology is taught in many different academic departments and institutionalized under headings such as ecopsychology, ecotherapy, human ecology, and conservation psychology, which have journals, training programs, and practitioners. In its insistence on external validity, ecological psychology has some resemblance to anthropological and sociological fieldwork. However, there are major differences. Most ethnographic fieldwork is qualitative, while Barker's approach was entirely quantitative. Furthermore, Barker's ecological psychology was nonevaluative and showed little interest in changing, improving, or even questioning the settings studied in terms of power relationships (e.g., What is the purpose of a school system or of a school board?), which contrasts with a more activist and critical social science. Nor does it view the topics it studies within a larger cultural context. As a remedy, D. Georgiou and D. Carspecken attempt to integrate Barker's Behavior Setting Survey with Critical Qualitative Research.

Gibson drew his examples from the outside world, but he and his students, when possible, tested their hypotheses in the laboratory which is not often done in anthropology or sociology. Gibson's and Barker's versions of ecological psychology are both different from each other and from mainstream trends in the social and behavioral sciences.

Glossary

Dorsolateral prefrontal cortex (DLPFC) Frontal lobe area, which coordinates executive functioning.

Major depressive disorder (MDD) Clinical syndrome characterized by low mood, anhedonia, and multiple

somatic symptoms. ECT is primarily used for MDD that has not responded to antidepressant medications.

Psychosis Characterized by delusions, hallucinations, and abnormal thought processes leading to disorganized speech and behavior.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is the most effective somatic treatment available in psychiatry today. Over seven decades, a refinement in the delivery of electrical stimulus, use of anesthetic agents (usually a short-acting barbiturate), and muscle relaxants (succinylcholine) have established ECT as a safe, rapid, and effective treatment in clinical psychiatry. It is one of the safest procedures under general anesthesia, with a reported mortality rate of <0.002%. ECT is most commonly used for severe or medication-resistant major depressive disorder (MDD). Compared to antidepressant medications, ECT has a quicker onset of action and a higher response rate. However, the response rate varies from around 80–90% in patients who were given ECT as a first line treatment or early on in the course of illness to around 60% in patients who were resistant to treatment with antidepressants. Often, it has been used in elderly patients with MDD, especially those with psychotic features, and also in pregnant patients in whom a quicker response is needed and use of medications may be restricted. It is also a valuable option for intractable psychosis, mania, and catatonia. Furthermore, it has also been used effectively in refractory Parkinson's disease, neuroleptic malignant syndrome, and intractable epilepsy. Due to the higher and more rapid response rates of ECT, it is trending toward an earlier placement in treatment algorithms.

While the mechanism by which ECT delivers its therapeutic benefits is unclear, etiological theories range from neurogenesis (with an increase in brain-derived neurotrophic factors), alterations in regional cerebral blood flow, modulation of numerous neurotransmitters and hormones, and the anticonvulsant effects of ECT. A comprehensive pre-ECT work up involves taking a detailed history and performing a thorough physical examination as well as screening blood tests, such as complete blood count and comprehensive metabolic profile. Additional tests such as an electrocardiogram, chest radiography, or computerized tomogram of the head may be ordered if clinically relevant. Baseline cognitive functioning should be assessed. ECT has been performed with both unilateral and bilateral electrode placement. The most common electrode placements involve bilateral temporal or unilateral (nondominant) placement with electrodes in temporal and vertex positions. Bilateral placement is often more efficacious but also more prone to

adverse effects, notably pertaining to confusion and memory. With the evolution of ECT, there has also been a significant shift in using brief and ultra-brief pulse-wave stimulation rather than prolonged sine-wave stimulation, since the brief pulse wave is less likely to produce cognitive adverse effects. Though there is no consensus on stimulus dosing, doses that have usually been found to be effective are 1.5–2.5 times above the seizure threshold for bilateral and 2.5–6.8 times above the threshold for unilateral placement. The duration of a seizure does not correlate with ECT outcome. A course of ECT is usually 6–12 in number, with ECTs delivered twice or thrice weekly. There is no consensus on continuation and maintenance ECT to prevent relapse and recurrence but this is often offered to patients who are resistant to medications and have responded well to ECT. Usually, antidepressants and antipsychotic medications are continued but it is advisable to taper anticonvulsants and benzodiazepines since they increase seizure threshold. Lithium is also best avoided as it can contribute to confusion and prolonged seizures. There is no absolute contraindication for ECT. Relative contraindications of ECT include recent myocardial infarction, arrhythmias, decompensated congestive heart failure, and intracranial hypertension. Common adverse effects of ECT include transient elevation in blood pressure, irregular heart rate, headache, and muscle aches. Rarely, prolonged seizures and even *status epilepticus* can occur although these typically can be quickly diagnosed and treated given constant EEG monitoring. A spectrum of cognitive impairments can occur from use of ECT. These include acute confusion due to the actual seizure, which resolves within minutes to hours, and anterograde amnesia, which resolves in about 1–3 weeks after ECT discontinuation. Another cognitive adverse effect, retrograde amnesia, involves episodic memory from about 1–3 months prior to the commencement of ECT. Unilateral electrode placement with brief and ultra-brief pulse-wave stimulus delivery has improved the tolerance of ECT and minimized some of the above mentioned cognitive impairments. Subjective reports of persistent or severe memory impairments are not confirmed when assessed by available testing.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a neuromodulatory technique that involves passing of brief current through a

stimulating coil placed over a particular area of the scalp to induce a magnetic field. This magnetic field, in turn, induces a low grade electrical current in underlying brain region. TMS has been used for research purposes in the field of neurosciences for more than two decades, is now approved by the US Food and Drug Administration (FDA) for refractory depression, and continues to be tested for further clinical use in a variety of neurological and psychiatric disorders. The use of current with a frequency <1 Hz is referred to as *low frequency* or *slow* and has inhibitory effects. Current above 1 Hz is termed as *high frequency* or *fast* and has excitatory effects. Delivery of a series of pulses or a *train of stimulation* is termed as *repetitive TMS* (rTMS). This is believed to have longer-lasting effects on neurotransmission. rTMS is being tested for both research and clinical purposes involving neuropsychiatric disorders. Single pulse TMS has been used to map motor cortex output and paired pulse TMS has been used to identify interactions involving various cortical areas. An rTMS device was approved for the first time by the FDA in 2008 for treatment of MDD in adult patients who have failed one antidepressant trial in the current episode of illness. In MDD, TMS is usually delivered 5 days a week with each course lasting between 20–30 sessions. One of the parameters used in TMS is motor threshold (MT). MT is defined as the minimal amount of energy required to activate a motor area. In each session, current is delivered at a strength of 80–120% of the MT over the left dorso-lateral prefrontal cortex (DLPFC). Though the mechanism of action is not clear, TMS is hypothesized to modulate serotonin transmission and alter regional blood flow. In an interesting study, Li et al. reported that 1 Hz TMS over the left prefrontal cortex was associated with increased activity at the site of stimulation as well as in connected limbic regions, including bilateral middle prefrontal cortex, right orbital frontal cortex, left hippocampus, mediodorsal nucleus of the thalamus, bilateral putamen, pulvinar, and insula. Interestingly, significant deactivation was found in the right ventromedial frontal cortex.

TMS is a completely noninvasive procedure administered in an outpatient setting. Unlike ECT which has a recovery period with caution against driving on the same day, patients receiving TMS can immediately resume their day-to-day activities. Some of the more common side effects include headache and pain at the application site. In some studies, TMS has been associated with transient increase in the auditory threshold

which can rarely become permanent. Use of ear plugs has been recommended as a protective measure and should be accompanied by regular monitoring for emergence of side effects such as hearing difficulties and tinnitus. One of the most serious side effects reported till date with TMS is the occurrence of seizures and its incidence is estimated at 1 for every 10 000 treatment sessions administered. The risk of seizures increases with increase in stimulation intensity, increased frequency, increased train duration, and decreased intertrain interval. Another rare side effect reported has been treatment-emergent mania. There are ongoing clinical trials involving TMS for schizophrenia, MDD, bipolar, anxiety disorders, Alzheimer's disease, addictions, obsessive compulsive disorder, smoking cessation, chronic pain, Parkinson's disease, migraine, aphasia, tinnitus, stroke, and Tourette's syndrome.

Glossary

Cerebral cortex The outer layer of mammalian brains; in humans about 2–5 mm thick with surface area of roughly 1500–3000 cm².

Coherence A squared correlation coefficient measuring the phase consistency between two signals, expressed as a function of signal frequency.

Conductivity ($\Omega^{-1} \text{mm}^{-1}$) The property of a material (living tissue, for example) that determines the ease with which charges move through the medium to produce current.

Current density ($\mu\text{m mm}^{-2}$) The flux of positive plus negative charge passing through a unit cross-sectional area.

Electric potential (mV) The negative gradient of the local electric field vector.

Electrocorticogram (ECoG) Electric potential recorded directly from the brain surface.

Electroencephalography (EEG) The electric potential recorded from the human scalp; sometimes used more generally to include intracranial recordings in humans and lower mammals.

Event-related potential (ERP) Average brain electric potential produced by a combination of sensory stimulus and cognitive task.

Evoked potential (EP) Brain electric potential produced on average by a sensory stimulus.

Ohm's law for a volume conductor Vector current density equals the product of conductivity and vector electric field. Ohm's law simplifies to the usual scalar expression.

Voltage change = Current \times Resistance For current flow confined to one spatial direction, for example, in electric circuit wires.

Window on the Mind

Human electroencephalography (EEG) provides a convenient, but often opaque, 'window on the mind,' allowing observations of electrical processes near the brain surface. The outer brain layer is the cerebral cortex, believed to be largely responsible for cognition: perception, memory, thinking, emotions, actions, and behaviors. Cortical processes involve electrical signaling between neurons that change over many times in the 10 ms (0.01 s) range. EEG is the only widely available technology with sufficient temporal resolution to follow these quick dynamic changes.

EEG can be recorded using electrodes placed inside the skull to study nonhuman mammals or human epilepsy patients. Such intracranial recordings provide measures of cortical dynamics at small spatial scales, dependent on electrode size. However, there are significant limitations to intracranial EEG recording for studies of cognition and behavior. Intracranial recordings in humans are mostly limited to patients with intractable epilepsy, often in preparation for brain surgery. These recordings are called electrocorticograms (ECoGs). ECoG recordings are usually obtained only over a very limited portion of the cortex, areas which vary widely across individuals, partly guided by EEG recordings of epileptic activity using electrodes placed on the scalp prior to surgery.

In both clinical and research studies, EEG is nearly always recorded from electrodes placed on the scalp. Each scalp electrode records electrical activity at large scales, measuring electric currents (or potentials) generated in cortical tissue containing about 30 million to 500 million neurons. Luckily, these large-scale estimates provide important measures of brain dysfunction for clinical work and cognition or behavior for basic scientific

studies. Human 'mind-measures' are easily obtained at the large scale of scalp recordings. EEG monitors the state of consciousness of patients in clinical work or experimental subjects in basic research. Oscillations of scalp voltage tell a very limited but important part of the story of brain functioning. For example, states of deep sleep, coma, or anesthesia are mostly associated with very slow EEG oscillations and larger amplitudes. Modern signal analyses allow for identification of distinct sleep stages or quantitative measures of the depth of anesthesia. More sophisticated experimental designs and methods of signal analysis have revealed robust connections to detailed cognitive events.

On the other hand, EEG spatial resolution is poor, compared to modern brain functional imaging methods such as PET and MRI. But these latter methods have very poor temporal resolutions on the timescale of seconds and thus do not offer detailed information about the rapid neural dynamics available to EEG. The related technology, magnetoencephalography (MEG), consists of recordings of the magnetic field generated by brain current sources. MEG also provides high temporal resolution and low spatial resolution, similar to EEG. MEG is preferentially sensitive to brain current sources oriented tangential to the scalp surfaces, which are typically located in the sulcal walls (folded cortex), while EEG is more sensitive to radial sources that are mainly located in the gyral surfaces (see [Figure 1](#)).

Sources of Scalp Potentials

The *generators* of scalp potentials are best described as micro-current sources at cell membranes. Relationships between such very small-scale sources and macroscopic potentials at the

Figure 1 Sources of EEG and MEG. Neocortical sources can be generally pictured as *dipole layers* (or ‘dipole sheets’, in and out of cortical fissures and sulci) with mesosource strength varying as a function of cortical location. EEG is most sensitive to correlated dipole layer in gyri (regions ab, de, gh), less sensitive to correlated dipole layer in sulcus (region hi), and insensitive to opposing dipole layer in sulci (regions bcd, efg) and random layer (region ijklm). MEG is most sensitive to correlated and minimally apposed dipole layer (hi) and much less sensitive to all other sources shown, which are opposing, random or radial dipoles. For this reason, MEG signals are more likely to ‘fit’ localized equivalent sources while ignoring the dominant EEG sources.

scalp are made easier by employing an intermediate (*mesoscopic*) descriptive scale. This approach makes use of the columnar structure of the neocortex, believed to contain the dominant sources of spontaneous scalp potentials. For macroscopic measurements, the ‘mesoscale source strength’ of a volume of tissue is defined by its electric (current) dipole moment per unit volume

$$\mathbf{P}(\mathbf{r}', t) = \frac{1}{W} \iiint_W \mathbf{ws}(\mathbf{r}', \mathbf{w}, t) dW(\mathbf{w}) \quad [1]$$

Here, the three integral signs indicate integration over a small, local volume W of tissue where $dW(\mathbf{w})$ is the tissue volume element. $s(\mathbf{r}', \mathbf{w}, t)$ is the local volume source current ($\mu\text{A mm}^{-3}$) near membrane surfaces inside a tissue volume with vector location \mathbf{r}' . \mathbf{w} is the vector location of sources within $dW(\mathbf{w})$. The current dipole moment per unit volume $\mathbf{P}(\mathbf{r}', t)$ in a conductive medium is fully analogous to charge polarization in a dielectric (insulator). Macroscopic tissue volumes satisfy the condition of electroneutrality at EEG frequencies. That is, current consists of the movement of positive and negative ions in opposite directions, but the total charge in any mesoscopic tissue volume is essentially zero. Cortical morphology is characterized by its columnar structure with pyramidal cell axons aligned normal to the local cortical surface. Because of this layered structure, the volume elements $dW(\mathbf{w})$ may be viewed as cortical columns with height $\approx 2\text{--}5$ mm. For purposes of describing scalp potentials, the choice of basic cortical column diameter is somewhat arbitrary. Anything between the cortical *minicolumn* (≈ 0.03 mm) and *macrocolumn* scales (≈ 1 mm) may be used to describe scalp potentials. The main consideration is that tissue volumes are assumed to be sufficiently large such that current conservation within the volumes is satisfied. Otherwise, monopole contributions to distant potentials are expected.

The microsources $s(\mathbf{r}', \mathbf{w}, t)$ are generally mixed positive and negative due to local inhibitory and excitatory synapses, respectively. In addition to these active sources, the $s(\mathbf{r}', \mathbf{w}, t)$ include passive membrane (return) current required for current conservation. Dipole moment per unit volume $\mathbf{P}(\mathbf{r}', t)$ has units of current density ($\mu\text{A mm}^{-2}$). For the idealized case of sources of one sign confined to a superficial cortical layer and sources of the opposite sign confined to a deep layer, $\mathbf{P}(\mathbf{r}', t)$ is roughly the (negative) diffuse current density across the column, $-\mathbf{J}(\mathbf{r}', t)$. This might occur due to superficial inhibitory synapses and deep excitatory synapses, for example. Generally, column source strength $\mathbf{P}(\mathbf{r}', t)$ is reduced as excitatory and inhibitory synapses overlap along column axes. In the case of fully mixed synapses, $\mathbf{P}(\mathbf{r}', t) \approx 0$, and a so-called *closed field* results.

Human neocortical sources may be viewed as forming a large *dipole sheet* (or *layer*) of perhaps $1500\text{--}3000\text{ cm}^2$ over which the function $\mathbf{P}(\mathbf{r}', t)$ varies continuously with cortical location \mathbf{r}' , measured in and out of cortical folds. **Figure 1** shows an idealized cortical surface with sources generally oriented normal to the cortical surface. In limiting cases, this dipole layer might consist of only a few discrete regions where $\mathbf{P}(\mathbf{r}', t)$ is large, consisting of localized or *focal sources*. But, more generally, $\mathbf{P}(\mathbf{r}', t)$ is distributed over the entire folded surface. The question of whether $\mathbf{P}(\mathbf{r}', t)$ is distributed or localized in particular brain states is often controversial. The averaging of evoked potentials over trials substantially alters the nature of this issue. Such time averaging strongly biases evoked potentials toward (trial to trial) time stationary sources, for example, sources confined to the primary sensory cortex.

Volume Conduction of Head Currents

Scalp potential may be expressed as a volume integral of dipole moment per unit volume over the entire brain, provided $\mathbf{P}(\mathbf{r}', t)$ is defined generally rather than in columnar terms. For the important case of dominant cortical sources, scalp potential may be approximated by the following integral of dipole moment over the cortical volume Θ

$$V(\mathbf{r}, t) = \iiint_{\Theta} \mathbf{G}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{P}(\mathbf{r}', t) d\Theta(\mathbf{r}') \quad [2]$$

If the volume element $d\Theta(\mathbf{r}')$ is defined in terms of cortical columns, the volume integral may be reduced to an integral over the folded cortical surface. **Equation [2]** indicates that the time dependence of scalp potential is the weighted sum (or integral) of all dipole time variations in the brain. Deep dipole volumes typically make negligible contributions because of the greater separation from the scalp electrodes. The weighting function is called the vector Green’s function $\mathbf{G}(\mathbf{r}, \mathbf{r}')$, essentially an inverse *electrical distance*. $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ contains all geometric and conductive information about the head volume conductor. The most common head models consist of three or four concentric spherical shells, representing the brain, cerebrospinal fluid, skull, and scalp tissue with different electrical conductivities σ as shown in **Figure 2**. In genuine heads, however, $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ is much more complicated. More complicated numerical methods may also be used to estimate $\mathbf{G}(\mathbf{r}, \mathbf{r}')$, sometimes employing MRI to determine tissue boundaries. However, the accuracy of both analytic

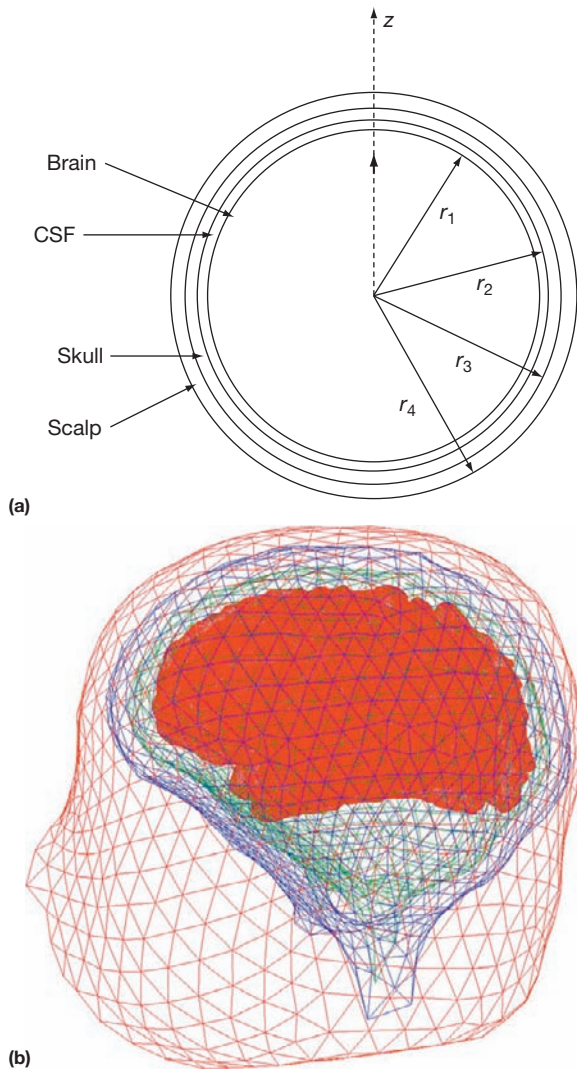

Figure 2 Volume conduction models for EEG. (a) A dipole is shown in the inner sphere of a 4-concentric spheres head model consisting of the inner sphere (brain) and three spherical shells representing CSF (cerebral spinal fluid), skull, and scalp. The parameters of the model are the radii (r_1, r_2, r_3, r_4) of each shell and the conductivity ratios ($\sigma_1/\sigma_2, \sigma_1/\sigma_3, \sigma_1/\sigma_4$). Typical values are radii (8, 8.1, 8.6, 9.2 cm) and conductivity ratios (0.2, 40, 1). (b) A realistically shaped boundary element model (BEM) of the head. The brain and scalp boundaries were found by segmenting the images with a threshold, and opening and closing operation respectively, while the outer skull boundary was obtained by dilation of the brain boundary (ASA, Netherlands). Although geometrically more accurate than the spherical model, the (geometrically) realistic BEM suffers a potentially fatal flaw because tissue resistivity is poorly known.

and numerical methods may be severely limited by incomplete knowledge of tissue conductivities. MRI has also been suggested as a future means of estimating tissue conductivities, based on the close relationship of diffusion to current flow processes.

Despite these limitations preventing highly accurate estimates of the function $G(\mathbf{r}, \mathbf{r}')$, a variety of studies using concentric spheres or numerical methods have provided reasonable

quantitative agreement with the experiment. The cells generating scalp EEG are believed to have the following properties:

1. In the case of potentials recorded without averaging, cells generating EEG are mostly close to the scalp surface. Potentials fall off with distance from source regions. In real heads, tissue inhomogeneity (location-dependent properties) and anisotropy (direction-dependent properties) complicate this issue. For example, the low conductivity, three-layered skull tends to spread currents (and potentials) in directions tangent to its surface. Brain ventricles, the subskull cerebrospinal fluid layer, and skull holes (or local reductions in resistance per unit area) may provide current shunting. But generally, sources closest to electrodes are expected to make the largest contributions to scalp potentials.
2. The large *pyramidal cells* in the cerebral cortex are aligned in parallel, perpendicular to local surface. This geometric arrangement encourages large extracranial electric fields due to linear superposition of contributions by individual current sources. Columnar sources $\mathbf{P}(\mathbf{r}', t)$ aligned in parallel and synchronously active make the largest contribution to the scalp potential. For example, a 1-cm² crown of cortical gyrus contains about 110 000 minicolumns, approximately aligned. Over this small region, the angle between $\mathbf{P}(\mathbf{r}', t)$ and $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ exhibits relatively small changes. By 'synchronous' sources, it is meant that the time dependence of $\mathbf{P}(\mathbf{r}', t)$ is roughly consistent (phase locked) over the area in question. In this case, eqn [2] implies that individual synchronous column sources add by linear superposition. By contrast, scalp potentials due to asynchronous sources are due only to statistical fluctuations, that is, imperfect cancellation of positive and negative contributions to the integral in eqn [2]. Scalp potential may be estimated as roughly proportional to the number of synchronous columns plus the square root of the number of asynchronous columns. For example, suppose 1% ($s_1 \approx 10^3$) of the gyral minicolumns produce synchronous sources $\mathbf{P}(\mathbf{r}', t)$ and the other 99% of minicolumns ($s_2 \approx 10^5$) produce sources with random time variations. The 1% synchronous minicolumn sources are expected to contribute roughly $s_1/\sqrt{s_2}$ or about three times as much to scalp potential measurements as the 99% population of random minicolumn sources.
3. The observed ratio of brain surface (dura) potential magnitude to scalp potential magnitude for widespread cortical activity like alpha rhythm is roughly in the 2–6 range. By contrast, this attenuation factor for very localized cortical epileptic spikes can be 100 or more. A general clinical observation is that a spike area of at least 6 cm² of cortical surface must be synchronously active to be identified on the scalp. This area contains about 700 000 minicolumns or 70 000 000 neurons forming a dipole layer. These experimental observations are correctly predicted by eqn [2].
4. For dipole layers partly in fissures and sulci, somewhat larger areas are required to produce measurable scalp potentials. First, the maximum scalp potential due to a cortical dipole oriented tangent to the scalp surface is estimated to be about 1/3 to 1/5 of the maximum scalp potential due to a dipole of the same strength and depth, but orientated normal to the surface. Second, tangential dipoles tend to be located more in fissures and (deeper) sulci, and

may also tend to cancel due to opposing directions on opposite sides of the fissures and sulci. Third, and most importantly, synchronous dipole layers of sources with normal orientation covering multiple adjacent gyri can form, leading to large scalp potentials due to the product $P(\mathbf{r}', t) \cdot \mathbf{G}(\mathbf{r}, \mathbf{r}')$ having a constant sign over the integral in eqn [2].

Recording Methods

EEG Machines

Human EEG is recorded using electrodes with diameters typically in the 0.4–1-cm range, held in place on the scalp with special pastes, caps, or nets, as illustrated in Figure 1. EEG recording procedures are noninvasive, safe, and painless. Nevertheless, experimental subjects used in research laboratories must provide informed consent. Special gels are applied between electrodes and scalp to improve electrical contact. Wires from scalp electrodes connect to special EEG machines containing amplifiers to boost raw scalp signals, which are typically in the 5–200-mV range or roughly 100–1000 times smaller than EKG (heart) signals.

Electrode Placement

The electrode positions (which are referred to collectively as the electrode ‘montage’) vary considerably across laboratories. Standard electrode-placement strategies use the 10-20, 10-10, and 10-5 placement systems. These montages are based on systematic extensions of the clinical standard 10-20 electrode montage, and they are widely but not universally used. The basis of these standard electrode placements is to define contours between skull landmarks (e.g., nasion and inion) and to subdivide the resulting contours in proportional distances. The 10-5 system uses proportional distances of 5% of the total length along contours between skull landmarks, compared to the 20% and 10% distances used in the 10-20 and 10-10 systems, respectively. EEG caps are commonly commercially available with these electrode positions. However, most modern EEG systems in research laboratories that use a larger number of channels (perhaps 64–130 or more) make use of other placement systems developed with the aim of obtaining more regularly spaced sampling of the EEG, with nearly equal nearest-neighbor electrode separations.

Potential differences between electrode pairs are recorded with EEG machines containing amplifiers, filters, and other hardware. A ground electrode is also required to provide a reference signal to the differential amplifiers. The distinction between ‘recording’ and ‘reference’ electrodes is mostly artificial since it is the potential differences between the two sites that allow closed current loops through the tissue and the EEG machine. In *referential recordings*, potentials between each recording electrode and a fixed reference electrode are measured over time. The potential difference between any pair of electrodes can then be easily obtained by subtracting one signal from the other. A widely used strategy in research EEG is the *common average reference*, where the average potential of all channels is subtracted from each channel. *Bipolar recordings* measure potential differences between adjacent scalp electrodes and are a

commonly used strategy in clinical EEG. When such bipolar electrodes are placed close together (say 1 or 2 cm apart), potential differences are estimates of the tangential electric fields (or current densities) in the scalp between the electrodes.

Standard clinical practice makes use of a 10-20 electrode montage consisting of only 21 electrodes. Often 48–136 recording electrodes are used in research; some laboratories now use as many as 256 channels to obtain more detailed information about brain sources by means of sophisticated computer algorithms. The resulting multichannel data are submitted to two distinct types of computer algorithms: (1) *High-resolution EEG* methods estimate potentials on the brain surface by accounting for distortions caused by intervening tissue and the physical separation of electrodes from the brain. (2) *Dipole localization* methods can estimate the location of source regions in the brain in a few specialized applications where EEG is expected to be generated mainly in only one or two isolated source regions.

Artifact

Potentials recorded from the scalp are generated by brain sources, environmental and hardware system noise, and biological artifacts. Biological artifacts often contaminate EEG records and generally pose a more serious problem than environmental or system noise, the latter substantially reduced by modern amplifier systems. Common artifact sources include whole body movement, heart, muscle, eye movements, and eye blink. EEG records containing large artifacts are usually discarded. Artifact removal by computer is typically successful only for a highly stereotypical low-frequency artifact such as eye blinks. The effectiveness of automated artifact editing is severely limited because the frequency bands of biological artifacts substantially overlap the important EEG bands, making distinctions between artifact and brain signal very difficult. This problem is severe at frequencies above 20 Hz, where the electrical artifact from scalp muscles is recorded along with the EEG. Such high-frequency muscle artifact can easily dominate EEG in the same high-frequency range.

The Reference Electrode

Ideally, an EEG would represent the *reference-free potential* or *nominal potential with respect to infinity*. The label ‘nominal’ means that even if it were possible to measure scalp potentials with respect to ‘infinity’ (or a distant wall of the laboratory), such large potentials (measured in volts) would have no physiological relevance, being dominated by power line fields and other environmental sources. The ‘nominal potential with respect to infinity’ is defined as the potential with respect to infinity due only to sources generated by the brain. For many years, EEG scientists seemed to insist (based on both word and deed) that if only some body location could be found with no active local sources, such a reference location would allow for genuine reference-free recordings. This old idea has long been discredited using both simulations and genuine data; EEG always represents the potential difference between two body locations. Any set of data recorded with some reference location may be referenced to another location. For example, the average reference is obtained by simply adding up all recorded

potential differences and subtracting this sum from each individual potential difference. Like any other choice of reference, the average reference provides imperfect estimates of reference-independent potentials, but when used with large number of electrodes (>64) it often performs reasonably well.

Time Dependence

Oscillatory Waveforms

Voltage traces of EEG signals recorded from each electrode pair oscillate with mixtures of component waveforms with different frequencies. Standard EEG analyses often begin with the spectral analysis of the EEG signal using Fourier methods. Each frequency component may be defined in terms of three parameters, its amplitude (A_{nm}), frequency (f_{nm}), and phase (ϕ_{nm}). The subscript n denotes the frequency component and the subscript m indicates an electrode pair used to record a potential difference. The electrical power associated with each frequency component is proportional to the square of the corresponding amplitude. One may express any physical waveform as a sum of components with different frequencies, amplitudes, and phases called a Fourier series. Fourier series are analogous to expressions of music or other sounds as compositions of tones or of white light composed of many colors. The EEG voltage $V_m(t)$ recorded from any electrode pair m may be expressed generally as a sum over frequency components

$$V_m(t) = \sum_{n=1}^N A_{nm} \sin(2\pi f_{nm}t - \phi_{nm}) \quad [3]$$

Waveform frequencies f_{nm} are expressed in terms of number of cycles per second (or Hertz, abbreviated Hz). EEG frequency ranges are categorized as *delta* (1–4 Hz), *theta* (4–8 Hz), *alpha* (8–13 Hz), and *beta* (>13 Hz). Very high frequencies (typically 30–40 Hz) are referred to as *gamma* activity. These distinctive labels correspond roughly to frequency ranges (or bands) that often dominate particular human brain states. Disparate rhythms may be associated with behavioral or cognitive state, brain location, or other criteria. For example, delta activity with frequencies lower than about 1 or 2 Hz provides the largest EEG amplitudes (or power) during deep sleep and in many coma and anesthesia states. Alpha, often mixed with low-amplitude delta, theta, and beta, is typically predominant in awake-resting states. Alpha is the dominant rhythm in *alpha coma* and is superimposed on delta activity during some sleep stages. Distinct rhythms can also occur in the same frequency range. Thus, the plural terminology, alpha rhythms, beta rhythms, and so on, appropriately describes the wide variety of EEG phenomena.

Modern methods of time series analysis are often used to simplify complicated waveforms like EEG. Many industrial applications involve such methods, including electric circuits, signal processing (television, radar, astronomy, etc.), voice recognition, and so on. Most time series analyses are based on spectral (or Fourier) methods. Computers extract the amplitudes A_{nm} and phases ϕ_{nm} associated with each data channel (m) and frequency (n) from the often complicated EEG, represented by eqn [3]. The computer ‘unwraps’ the waveform $V_m(t)$ to reveal its individual components. Such spectral analysis is

analogous to the physical process performed naturally by atmospheric water vapor to separate white light into its component colors. Each color is composed of electromagnetic waves within a narrow frequency band, providing the basis for rainbows.

The Rhythmic Zoo

Human EEG exhibits many waveforms, especially in the experience of clinical electroencephalographers (neurologists with this specialized training). Some EEG have known clinical significance and some do not. Any complicated waveform can be described as a mixture of oscillations with different frequencies and amplitudes, as indicated by eqn [3]. But more picturesque descriptions are often preferred by clinical electroencephalographers to characterize the ‘zoo’ of EEG waveforms. Such labels include *paradoxical alpha*, *spike and wave*, *delta focus*, *sharp transient*, *sleep spindle*, *nonspecific dysrhythmia*, and others.

Cortical EEG (ECoG) typically consists of even more complex waveforms, composed of rhythms with different frequencies, locations, and spatial extent. Such highly localized cortical rhythms are not recorded on the scalp. Cortical beta and gamma rhythms are often strongly attenuated between cortex and scalp because they are more localized or less synchronized over cortical areas than some of the alpha, theta, and delta band activity. EEG during sleep, coma, and anesthesia typically exhibits large scalp amplitudes of low-frequency oscillations, implying widely distributed and highly synchronous cortical source activity.

Alpha Rhythms

Alpha rhythms provide an appropriate starting point for clinical EEG examinations. Some initial clinical questions are: Does the patient show alpha rhythms, especially over the posterior scalp? Are their spatial–temporal characteristics appropriate for the patient’s age? How do they react to eyes opening, hyperventilation, drowsiness, etc.? For example, pathology is often associated with pronounced differences in EEG recorded over opposite hemispheres or with low alpha frequencies. A resting alpha frequency lower than about 8 Hz in adults is considered abnormal in all but the very old.

Alpha rhythms may be recorded in roughly 95% of healthy adults with closed eyes. The normal waking alpha rhythm usually has larger amplitudes over posterior regions, but is typically recorded over widespread scalp regions. Posterior alpha amplitude in most normal adults lies in the range of 15–50 mV; alpha amplitudes recorded from frontal electrodes are usually lower. A posterior rhythm of ~ 4 Hz develops in babies in the first few months of age. The amplitude increases with eye closure and is believed to be a precursor of mature alpha rhythms. Maturation of the alpha rhythms is characterized by increased frequency and reduced amplitude between the ages of about 3 and 10.

Normal resting alpha rhythms may be substantially reduced in amplitude by eye opening, drowsiness, and in some subjects, by moderate to difficult mental tasks. Alpha rhythms, like most EEG phenomena, typically exhibit an inverse relationship between amplitude and frequency.

For example, hyperventilation and some drugs (alcohol, for example) may cause reductions of alpha frequencies together with increased amplitudes. Other drugs (barbiturates, for example) are associated with increased amplitude of low-amplitude beta activity superimposed on scalp alpha rhythms. The physiological bases for the inverse relation between amplitude and frequency and most other properties of EEG are largely unknown, although physiologically based dynamic theories have provided several tentative explanations.

Figure 3 describes a 60-s recording of alpha rhythm from two scalp locations. The subject is a healthy waking adult, relaxed with eyes closed. By examining the power spectra for the occipital (**Figure 3(a)**) and frontal sites (**Figure 3(b)**) for individual epochs with frequency resolution of 0.5 Hz, support for two different kinds of oscillation within the alpha band is obtained. At the occipital channel, individual epochs display distinct peaks at 9.5 and 10.5 Hz. The first 15 epochs show a strong response at 10.5 Hz but the later epochs show a stronger response at 9.5 Hz. The dominant frequency in each epoch is summarized in the peak power histograms in **Figure 3(c)** showing that individual epochs displayed peak frequencies at both 9.5 and 10.5 Hz. By contrast, very few epochs have a peak frequency of 10.5 Hz at the frontal site (**Figure 3(d)**); most epochs have peak frequencies either at 9.5 Hz or in the delta band (<2 Hz). Note that during most epochs with strong delta activity as in **Figure 3(b)**, the alpha peaks are attenuated. The amplitude spectra show mixtures of frequencies that depend partly on scalp location; however, alpha rhythm is dominant at all locations in this typical example. This subject has two frequency peaks near 10 Hz, a relatively common finding. These two alpha oscillations are partly distinct phenomena as

revealed by their separate distributions over the scalp and their distinct behaviors during mental tasks. The multiple underlying source regions are believed to overlap substantially.

Alpha, Theta, Cognitive Tasks, and Working Memory

Two prominent features of human scalp EEG show especially robust correlation with mental effort. First, alpha band amplitude normally tends to decrease with increases in mental effort. Second, frontal theta band amplitude tends to increase as tasks require more focused attention. A common but oversimplified view of alpha rhythms is one of brain idling. But upper and lower alpha band amplitudes may change independently, depending on scalp location and task. Some working memory tasks cause lower alpha band amplitude to decrease while upper alpha band amplitude increases. Alpha amplitude reductions may reflect local cortical desynchronization occurring in task-relevant brain areas, whereas task-irrelevant regions may be unchanged or even produce larger alpha amplitudes. Another (possibly complementary) hypothesis is that increases in higher frequency alpha amplitudes reflect a specific memory processing function and not simple idling.

Generally, intracerebral electrodes record a variety of alpha rhythms. Some intracerebral alpha rhythms are blocked by opening the eyes and some are not. Some respond in some way to mental activity and some do not. The alpha band rhythms recorded on the scalp represent spatial averages of multiple alpha phenomena and a large number of alpha components. For an alpha rhythm of a particular type to be observed on the scalp, it must be synchronized (roughly in phase) over a large cortical area.

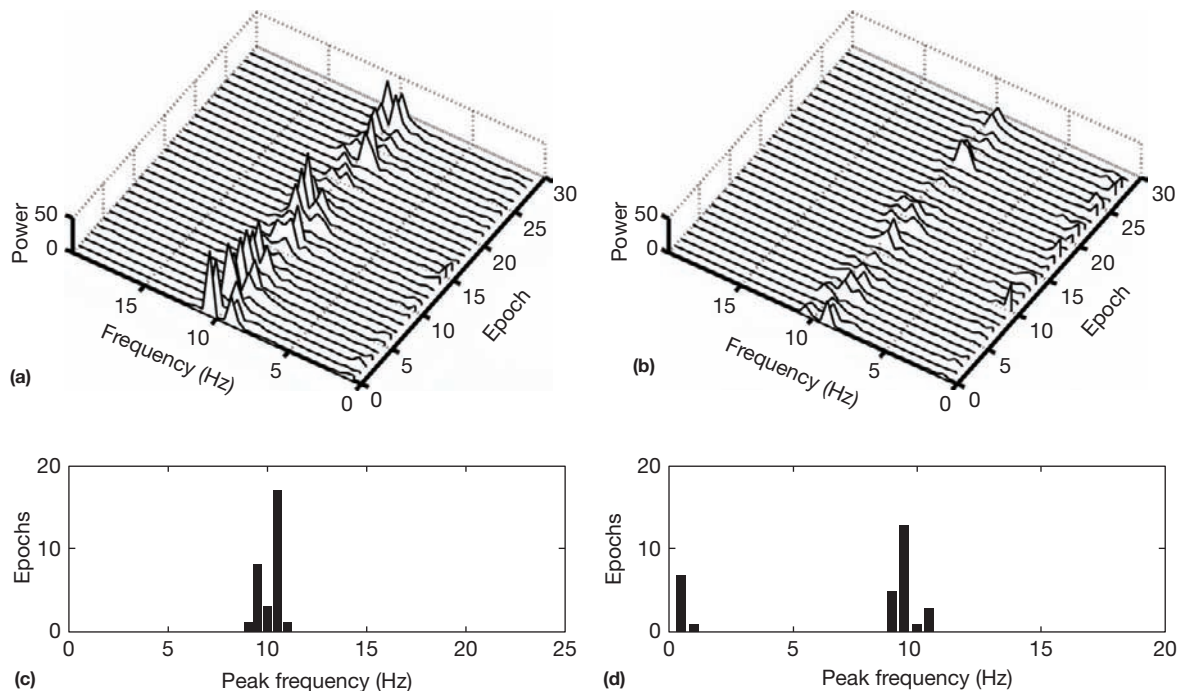

Figure 3 An example of power spectra from a single subject (female, 22 years). The subject is at rest with eyes closed. (a) Plots of 30 (individual 2-s epoch) power spectra for a channel over the occipital lobe. (b) Plots of the same 30 individual epoch spectra for a frontal channel. (c) Peak power histograms show the distribution of peak frequencies for the 30 epochs shown in (a). (d) Peak power histograms for the 30 epochs shown in (b).

Topography

Dynamic Measures that Depend on Spatial Location

The EEG recorded from a single electrode pair is fully characterized by its time dependence, as in eqn [3]. In spatially extended systems, however, dynamic behavior generally depends on time and spatial location, the usual independent variables of spatially extended dynamical systems. Thus, multi-channel recordings potentially introduce many new measures of brain dynamic behavior. Amplitude, phase, and frequency, for example, may vary with scalp or cortical spatial location.

Spatial Distribution of Alpha Rhythms

Alpha rhythms have been recorded from nearly the entire upper cortical surface (ECoG), including frontal and prefrontal areas. High-resolution EEG scalp recordings also show widespread distribution of alpha rhythms over nearly the entire scalp in healthy, relaxed subjects. EEG clinical populations differ, typically involving patients who are older, have neurological problems, and may be anxious during recording. These factors all tend to work against the production of robust, widespread alpha rhythms. Second, the clinical definition of alpha is based on raw waveforms rather than the spectra. Often alpha is identified simply by counting the number of zero crossings of recorded waveforms. This can sometimes provide a misleading picture because raw EEG composed of broad frequency bands can appear very 'nonalpha' to visual inspection, even though its amplitude spectrum shows substantial contribution from the alpha band. Such alpha rhythms may consist of mixtures of both localized and widely distributed activity.

Larger amplitude frontal alpha often occurs as subjects become more relaxed, for example, by employing relaxation or meditation techniques. Alpha rhythms of unusually large amplitude or exhibiting frontal dominance may be associated with mental retardation and some types of epilepsy. Large amplitude and dominant frontal alpha rhythm may also be recorded in some coma and anesthesia states. In summary, frontal alpha rhythms of moderate amplitude are common in healthy relaxed subjects with closed eyes, but very large frontal alpha is associated with disease or anesthesia. The physiological relationships between these disparate alpha phenomena are unknown, but they appear to share some underlying physiological mechanisms since their frequencies and widespread distributions are similar.

Coherence

Other dynamic measures involve a combination of location and time measures. For example, the (normalized) covariance of two signals is a correlation coefficient expressed as a function of time delay for characteristic waveforms recorded at the two locations. Covariance is used in ERP studies of cognition. A measure similar to covariance is the coherence of two signals, which is also a correlation coefficient (squared). It measures the phase consistency between pairs of signals in each frequency band. Scalp potential (with respect to a reference) recorded at many scalp locations over (say) a 1-min record may be represented by eqn [1]. Consider any two locations

with time-dependent voltages $V_i(t)$ and $V_j(t)$. The methods of Fourier analysis may be used to determine the phases ϕ_{ni}^p and ϕ_{nj}^p associated with (say) each 1-s period or *epoch* (indicated by superscript p) of the full 60-s record. The frequency component is indicated by subscript n and the two electrode locations are indicated by subscripts i and j . If the voltage phase difference $(\phi_{ni}^p - \phi_{nj}^p)$ is fixed over successive epochs p (*phase locked*), the estimated EEG coherence between scalp locations i and j is equal to 1 at frequency n . On the other hand, if the phase difference varies randomly over epochs, estimated coherence will be small at this frequency.

The low spatial resolution of conventional EEG limits the information available using coherence (or any correlation measure) between electrodes. High-resolution EEG methods improve the spatial resolution of EEG, minimizing the smearing of the potentials by volume conduction through the head. High-resolution EEG coherence between one electrode (labeled x) and a set of electrodes (1–8) at progressively larger distances from posterior to anterior locations of the left hemisphere is shown in Figure 4. (High-resolution EEG was estimated by using the entire 111 channel data set.) The subject was at rest with eyes closed to facilitate a robust alpha rhythm. Power spectra for two midline channels of this subject are shown in Figure 3, demonstrating two peaks in the alpha band (9.5 and 10.5 Hz). Even the closest neighbor pair ($x:1$) indicates very low coherence except at the coherence peaks at 9.5 and 10.5 Hz. At the next closest pair ($x:2$) a different pattern is seen with stronger coherence at 10.5 Hz. The electrode pairs involving prefrontal electrodes ($x:7$ and $x:8$) show higher coherence at 9.5 Hz than 10.5 Hz. For two pairs ($x:3$ and $x:6$) coherence is very low over the entire frequency range. The highest coherences at 9.5 and 10.5 Hz involve temporal electrodes ($x:4$ and $x:5$). For these pairs additional peaks can be seen at the harmonics (19 and 21 Hz). In summary, coherence estimates show significant spatial specificity and reveal much more detailed patterns of synchronization of neuronal activity across the brain.

Dynamic Behavior of Sources

EEG waveforms recorded on the scalp are due to a linear superposition of contributions from billions of microcurrent sources or, expressed another way, by thousands to millions of columnar sources $P(\mathbf{r}', t)$ located in the cerebral cortex, as indicated by eqn [2]. However, the underlying physiological bases for the dynamic behavior of the sources themselves are mostly unknown. The 10-Hz range oscillations of alpha rhythm, the 1-Hz range oscillations of deep sleep, and other waveforms in the EEG 'zoo' must be based on some sort of characteristic time delays produced at smaller scales. Such delays can evidently be developed in *cell assemblies* (*neural networks*) that cover a wide range of spatial scales. Locally generated activity in small networks and more globally generated activity involving spatially extensive networks up to the global scale of the entire cerebral cortex may be reasonably assumed. The local network category includes the so-called *thalamic pacemakers* that could possibly impose oscillations in specific frequency ranges on the cortex (*local resonances*). Other possible mechanisms occur at intermediate scales between the local and

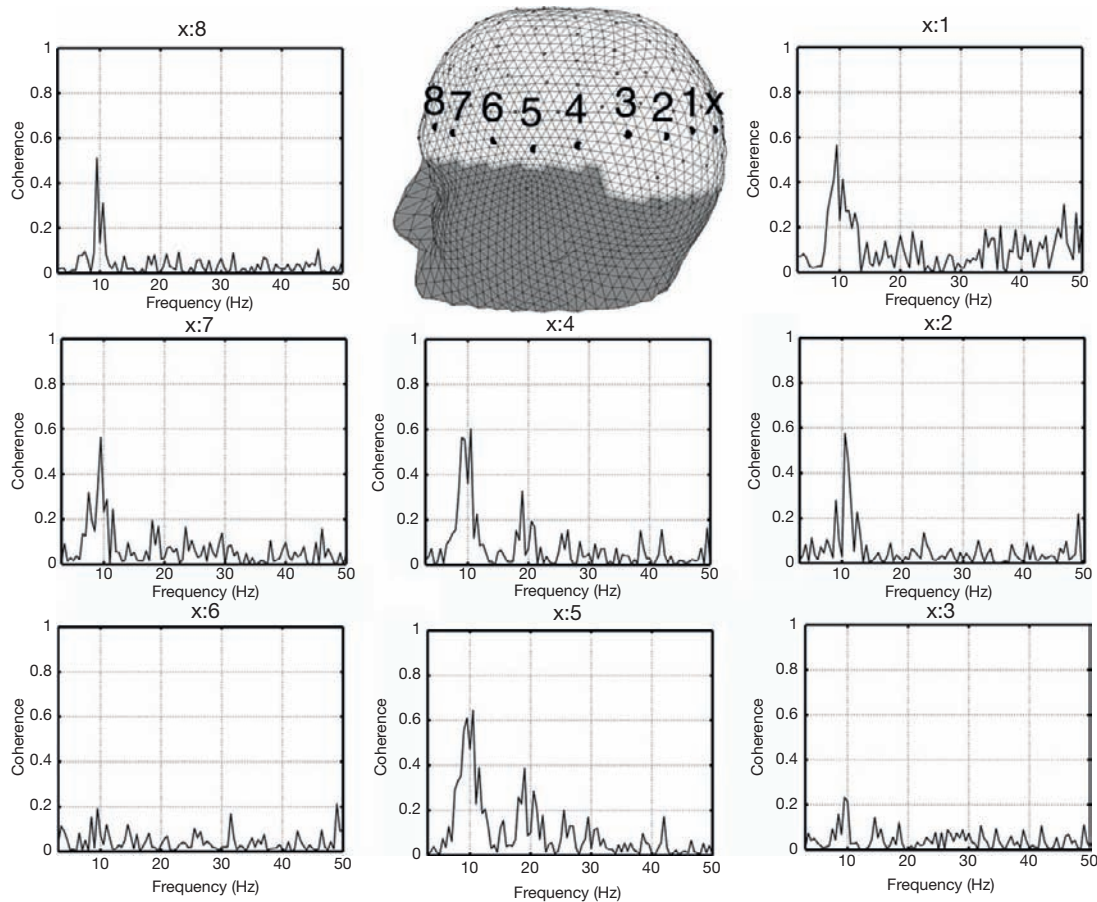

Figure 4 Coherence spectra from a 22-year-old female subject at rest with eyes closed (to maximize alpha coherence). Coherence was estimated with $T = 2$ s ($\Delta f = 0.5$ Hz) in a 60-s record. The head plot shows the location of 9 electrodes, labeled x and 1 through 8. Coherence spectra between electrode x and each of the other electrodes 1–8 are shown, with increasing separations along the scalp. High-resolution EEG methods were used to increase the spatial resolution of 128 EEG signals by removing the effect of smearing by the skull. This process can also remove genuine EEG signals that are broadly distributed. The coherence spectra show complex patterns of coherence according to frequency and scalp locations, changing even with small changes in frequency or location.

the global. These involve feedback between the cortex and the thalamus or between specific cortical locations. Preferred frequencies generated at intermediate scales may be termed *regional resonances*. At the global scale, the generation of resonant frequencies (*global resonances*) due to *standing waves* of synaptic action has been proposed.

Delays in local networks are believed to be mainly due to *rise and decay times of postsynaptic potentials*. By contrast, global delays occur as a result of *propagation of action potentials* along axons connecting distant cortical regions (*corticocortical fibers*). Delays in regional networks may involve both local and global mechanisms. A working conjecture is that local, regional, and global resonant phenomena all potentially contribute to source dynamics. However, the relative contributions of networks with different sizes may be quite different in different brain states. The transition from awake to anesthesia states is an example of a local to global change. The ECoG changes from rhythms depending strongly on location to rhythms that appear similar over widespread cortical locations. Another example is the desynchronization (amplitude reduction) of alpha rhythms that occurs with eye opening and certain mental tasks.

A number of mathematical theories have been developed since the early 1970s to explain the physiological bases for source dynamics, that is, the underlying reasons for specific time-dependent behaviors of the source function $P(\mathbf{r}', t)$. Distinct theories may compete with, or complement each other, or both. Some common EEG properties for which plausible quantitative explanations have emerged naturally from mathematical theories include the following observed relations: frequency ranges, amplitude versus frequency, spatial versus temporal frequency, maturation of alpha rhythm, alpha frequency–brain size correlation, frequency versus corticocortical propagation speed, frequency versus scalp propagation speed, frequency dependence on neurotransmitter action, and mechanisms for cross-scale interactions between hierarchical networks. Because the brain is so complex, such theories must involve many approximations to genuine physiology and anatomy. As a result, verification or falsification of specific theories for the physiological bases for EEG is difficult. However, such mathematical theories can profoundly influence our general conceptual framework of brain processes and suggest new studies to test these ideas. Furthermore, this

framework can strongly influence the design of cognitive studies, for example, when estimating various measures of functional connections between cortical regions such as EEG coherence or ERP covariance.

Glossary

Appeasement display A display by which individuals seek to placate or pacify others or as a 'remedial display' serving to mitigate others' negative reactions to behaviors that might otherwise result in public humiliation or loss of self-esteem.

Blushing Spontaneous reddening or darkening the face, ears, neck, and/or upper chest caused by blood vessels dilating and increasing blood volume in those areas in response to social evaluation or public scrutiny.

Embarrassment A state of emotional discomfort resulting from a projection of an undesired image to others present.

Face saving All coping actions, both verbal and nonverbal, taken by both the embarrassed person and observers to the event to overcome feelings of embarrassment in an attempt to regain social composure.

Self-consciousness The focusing of attention upon oneself either as a result of the situation (e.g., in the presence of an audience) or as a result of individual differences in the tendency to be self-attentive.

Self-presentation Attempts to control the image of ourselves that we present to others.

Social phobia A marked or persistent fear in social situations that the person concerned will behave in a manner which is perceived by others as being embarrassing or humiliating.

Introduction

Embarrassing blunders, faux pas, and improprieties are everyday social occurrences. However, because embarrassment is essentially a state in which a person has failed to maintain social poise or a desired image in the presence of others, it is an uncomfortable social state which people seek to avoid. Because of the aversive nature of embarrassing situations people try to avoid them when possible or, if embarrassment has occurred, make efforts to restore identity or self-view, as well as attempt to save face or preserve a desired identity in the eyes of others present. In addition to external cues, which can relate either to the nature of the social accident or to the reactions of others to our faux pas, a feeling of embarrassment can also be elicited by internal cues (notably blushing) in the absence of an intrinsically embarrassing situation. Indeed, Arnold Buss described blushing as the hallmark of embarrassment and numerous authors including Charles Darwin writing in 1872 have argued that the blush is the primary nonverbal signal of embarrassment. While there is not a one-to-one link between embarrassment and blushing, it is possible to be embarrassed without blushing and to blush without being embarrassed; nevertheless, for some people the fear of blushing can be a socially debilitating experience. Many people who suffer from social phobia are particularly concerned that they will blush and that others will then interpret this as a sign of social ineptitude.

Theoretical Explanations for Embarrassment and Blushing

Although embarrassment is a common and dramatic experience with which nearly everyone is familiar, there is a lack of agreement about both the precise psychological circumstances underlying embarrassment and the function of blushing. Indeed, proposals about the factors underlying embarrassment

do not link precisely to those delineating the function of blushing. Three broad theoretical explanations for embarrassment have been advanced; the first focuses upon self-presentational concerns and fear of negative evaluation; in this context, blushing is also explained as being evoked following undesired attention; the second emphasizes the individual's flustered uncertainty about how to proceed following a social accident and the third focuses upon anxiety and worry about the need to create a desired impression. Additional explanations for blushing are that it serves as an appeasement display by which individuals seek to placate or pacify others or as a 'remedial display' serving to mitigate others' negative reactions to behaviors that might otherwise result in public humiliation or loss of self-esteem. These latter accounts are discussed in more detail in section 'Blushing and the Expression of Embarrassment'.

Theories focusing upon self-presentation concerns suggest that embarrassment has to do with a failure to present a desired image to others whom we regard as evaluating our performance. This assumes that the individual concerned is motivated to make a particular impression on others. Falling over in front of friends is likely to cause us less concern about the impression we create than falling over just as we are about to introduce a guest of honor to a large audience at an important function. Factors that increase the negative consequences of failure, such as larger, more competent audiences, novel or ambiguous contexts, or facets of one's own personality, are likely to increase our desire to protect our image before others.

A further assumption, however, is that the prevailing circumstances during an interaction do not allow us to present a desired image to others present. The latter circumstances involve the violation, witnessed by others, of some taken-for-granted social rule. This, in turn, assumes that the person concerned has violated the rule unintentionally while at the same time being aware that a violation has occurred. Someone unaware of the rules of conduct will remain unembarrassed by their 'inappropriate' behavior no matter how concerned

they are with the evaluative reactions of others, unless others present make it clear that their behavior is inappropriate. If we are unaware of the rules of etiquette at a social function, transgressing such rules will not cause us concern unless others draw our attention to our failings. Similarly, someone aware of the rules but unconcerned with the evaluative reaction is likely to remain unembarrassed by social mishaps. Conversely, someone acutely concerned with negative audience evaluations is likely to be embarrassed by seemingly trivial events. It is only when our knowledge of, and motivation to concur with, these rules exists that embarrassment is a consequence of social failure.

Others have argued that it is not self-presentational concerns per se that cause embarrassment but flustered uncertainty about how to proceed once an unexpected or disruptive social event has occurred. Thus, forgetting someone's name or falling over in public disrupt the working consensus of identities that exist in social interaction, leaving a new consensus to be created. Until such a new consensus exists, awkwardness or flustered uncertainty predominates. Although such a reaction may well be important, flustered uncertainty is itself likely to be directly related to a concern with the evaluation of others. Appearing to be flustered or uncertain is not an image we would wish to present to others and hence may be embarrassing in its own right.

Finally, some have pointed out that anxiety and worry about whether one has actually created, or indeed will create, an undesirable impression is a central feature of self-presentational concerns. Indeed, some people seem to be so concerned about the impression they will create that they suffer extreme embarrassment in the absence of any clearly defined evoking event. Indeed, they may be so concerned that they might behave in a way which is humiliating or embarrassing that they actively seek to avoid social situations. Indeed, one of the defining features of social phobia as detailed in the Diagnostic and Statistical Manual of the American Psychiatric Association is a marked and persistent fear of social or performance situations in which embarrassment may occur.

Clearly, there are common features to the three theories described. Although flustered uncertainty and anxiety about one's social performance seem to be important aspects of embarrassment, self-presentational concerns are central. Thus, the emphasis in each theory is that embarrassment has to do with the actual, or anticipated, occurrence of an unwanted event that communicates undesired information about oneself to real, or imagined, others, whom we regard as evaluating our performance.

Causes of Embarrassment and Blushing

There have been a number of attempts to collect descriptions of, and categorize, embarrassing events on the basis of the situations involved; fewer studies have sought to classify blush-inducing rather than embarrassing circumstances. One factor illustrated by the former studies is the sheer variety of embarrassing circumstances people document. It is perhaps not surprising therefore that the various attempts to systematically categorize embarrassing acts produces a variety of different solutions. The broad categories do though correspond with

categories of situations which elicit blushing. The first two categories describe inappropriate identity (e.g., uncontrollable laughter or tears) and loss of poise. The latter includes loss of physical poise (e.g., tripping over furniture), impropriety (e.g., failure to control bodily behaviors, for example, when fainting), forgetting someone's name or introducing them by the wrong name, and awkward interactions (e.g., asking inappropriate or unfortunate questions or simply not knowing how to proceed). The third category concerns false identity (i.e., telling someone untruths about oneself and being found out), the fourth consists of breaches of privacy (e.g., unintentional exposure of bodily parts, touching or coming too close to someone, or revealing feelings that the person wished to hide), while the fifth involves being made to feel conspicuous as when over-praised (e.g., discomfort occasioned by excessive compliments). Still others have included a category of empathic or vicarious embarrassment to describe instances when we feel embarrassed for another person who is in a seemingly embarrassing situation (e.g., when an actor forgets their lines). Although there are clearly a number of ways of classifying embarrassing events, these tend to reflect the methodology used; there do not tend to be radical differences in the general descriptions of embarrassing events obtained. Thus, some categorization schemes refer to specific actions (e.g., tripping and falling) while others pinpoint dimensions (e.g., who is embarrassed, as in empathic embarrassment).

Therefore, rather than considering categories of acts, a more useful strategy for classifying embarrassing episodes is to consider psychologically meaningful dimensions. Two such dimensions appear to be of particular importance: who is embarrassed by the events and who is responsible for causing the embarrassment. The first dimension, who is embarrassed, considers whether it is an individual and/or social group, both (or all) the interactants, or the bystander/viewer. The second dimension, who is responsible for causing the embarrassment, considers whether it is the embarrassed person themselves (i.e., the actor), someone present and involved when the embarrassment occurs (i.e., the observer) and someone present but not directly interacting (i.e., person viewed). By combining these two dimensions, four broad categories of situation can be recognized: (i) those in which the individual and/or social group is responsible for their own embarrassment (individual/group behavior, actor responsible); (ii) those in which the interaction itself is embarrassing (interactive behaviors, shared responsibility); (iii) situations in which embarrassment is caused by an observer (individual/group behavior, observer responsible); and (iv) an empathic reaction of embarrassment to someone else's behavior (bystander/viewer, person viewed responsible).

The actual types of embarrassing and blush-inducing episodes described by earlier classification schemas can readily be incorporated by the dimensional categorization approach. Examples from the first category (individual/group behavior, actor responsible) include loss of poise (e.g., forgetting someone's name), impropriety (e.g., wearing the wrong clothes to a social function), and false identity (i.e., telling someone untruths about oneself and being found out). Examples from the second category (interactive behavior, shared responsibility) include any awkward interaction where neither person is sure what to say, when there are long uncomfortable silences, unsuccessful

attempts by both parties to end the conversation, and so on. Examples from the third category (individual/group behavior, observer responsible) include conspicuousness (e.g., being the 'victim' of people singing "happy birthday to you" or when being complimented or congratulated), being the victim of teasing, or when people make public our past embarrassing predicaments. Examples of the final category (bystander/viewer, person viewed responsible) include any occasion of empathic embarrassment when we feel embarrassed because of someone's or something's behavior (e.g., going to the zoo and seeing animals engage in sexual behavior).

Central to each is a desire to present oneself in a way that meets one's own standard for self-presentation and/or a desire to avoid focusing attention toward the public aspect of oneself. Thus, any event that involves the transgression of an unwritten social rule (e.g., falling over in public, dressing inappropriately for social occasions, awkward interactions), results in both the presentation of an undesired image and self-attention. Being made the centre of attention (e.g., through teasing) inevitably draws attention to the public aspect of ourselves and a concern with the image we are likely to present.

Interestingly, blushing, which is often regarded as the hallmark of embarrassment, may actually make us more self-aware and lead us to assume we are presenting an image (i.e., embarrassment) that is discrepant from the image we wish to present. We tend to assume that people feel embarrassed when they blush, although visible facial reddening also occurs with other emotional states such as anger. Thus, it is possible to make someone embarrassed simply by telling them they are blushing, even in nonembarrassing situations. Blushing may then be sufficient to generate embarrassment in the absence of specific situations that are defined as embarrassing. People who are over-attentive to internal and expressive cues may be particularly prone to generate a feeling of embarrassment from a perception of their own blushing. Because of the negative experience of embarrassment with which blushing is associated, this may, in some cases, lead to a chronic fear of blushing. This issue is developed further in the following section.

Blushing and the Expression of Embarrassment

Embarrassment is marked by a well-defined set of behaviors. Eye contact is reduced, body movements, speech dysfluencies, and smiling all increase, and blushing is likely to occur. This reaction seems nearly universal, although the intensity and relative importance of different components of the reaction seem to differ across cultures. Indeed, the display of embarrassment is readily recognizable by others. But why should an emotion we wish to hide be so evident to others? There are a number of suggestions for the functions of behaviors associated with embarrassment.

The desire to look away or hide behind one's hands when embarrassed has been studied in laboratory experiments as well as being widely referred to in people's reports of their embarrassment. A common feeling when embarrassed is a wish to disappear or escape from the situation. Unfortunately, departing the scene of an embarrassing mishap is rarely possible to achieve without attracting even more attention to oneself. Hence, as we are unable to increase our physical distance

from others, we may use avoidance of eye contact, turning away, or covering our eyes as a way of increasing our psychological distance from them. A further possible explanation is that people look away when embarrassed to avoid seeing the signs of rejection on the faces of other people. Alternatively, reduced eye contact may be a reflection of tension or anxiety associated with embarrassment. Such nervous responses may also include manipulative gestures (such as fingering one's clothes, hair, or surrounding objects), turning one's body away and stammering.

There are a number of ways in which anxiety associated with embarrassment might interfere with speaking. First, preoccupation with the reason for our embarrassment may make it difficult to pay attention to what we wish to say. Alternatively, increased anxiety may make us pay too much attention to our speech with the result that we stumble over our words. Finally, anxiety may interfere with normal breathing, with shorter, faster respiration interfering with speech output.

A 'silly' self-conscious grin and a 'strangled' laugh are also common reactions to embarrassment. The fact that, during embarrassment, smiling usually occurs while the person looks away (aversion of gaze occurs when the smile reaches its peak intensity), distinguishes it from a smile of pleasure (when looking away is more likely to occur when the smile intensity is diminishing). In addition muscular actions associated with smiling such as pressing the lips together, stretching, biting or sucking them, puffing the cheeks or bulging the tongue occur more frequently, for longer and in greater number in relation to smiling when embarrassed than when such actions occur in association with amusement. There are four possible explanations for such a reaction. First, people may use smiling in an attempt to hide or conceal their embarrassment; such attempts may occasionally succeed, as embarrassment can be mistaken for amusement. Second, smiling and laughter when embarrassed may serve as an admission of the person's inappropriate behavior, while at the same time attempting to reduce the importance of the event giving rise to the embarrassment. Third, laughter may serve to reduce the tension or anxiety engendered by the embarrassing event. Fourth, it may be a purposeful nonverbal strategy used by the embarrassed person to change the meaning and focus of the situation in an attempt to save face. By diminishing the importance of the event, the identity 'victim' can be transformed to 'co-actor' and the label 'embarrassing' transformed to 'humorous.' Finally, the 'silly grin' of embarrassment may be related to the submissive, appeasement grin which occurs in other primates when threatened. Embarrassment presents a threat to the person's sense of self and, in such circumstances, smiling may serve to conciliate a potential 'aggressor.'

Although it is possible to feel embarrassed without visibly blushing and to visibly blush without experiencing embarrassment, blushing and embarrassment have been inextricably linked by a number of authors. Although the faces of nonhuman primates redden or 'flush' with rage, blushing is a peculiarly human expression that is restricted to certain specific regions of the body. The 'blush region' is located in the face, ears, neck, and upper chest. The redness itself is caused by the bed of capillaries close to the skin filling with blood in order to allow the body to lose heat. It seems that the blood vessels in the face and upper body differ structurally from blood vessels

in other parts of the body. In addition, people seem to differ with regard to their degree of response, hence, individual differences in actual intensity of blushing. But, how might blushing and embarrassment be interlinked?

One possibility is that people use their own expressive behavior to interpret their inner feelings. Thus, skin blood-flow changes associated with blushing may play a significant part in influencing the intensity of reported embarrassment. Our attention shifts between ourselves and the environment on a continual nonrandom basis. If a social accident has occurred, attention may initially be directed toward an evaluation of the event itself. This may be followed quickly by an inward focus of attention directed specifically toward those aspects of the self that are presumed to be associated with embarrassment, most notably blushing. The subsequent environmental focus of attention may be directed toward a search for the evaluation of others, again followed by an inward focus toward our blushing. The fact that the process is rapidly repeated serves to explain why blushing and embarrassment escalate. Further, for those who are particularly sensitive to, or predisposed to attend to their bodily reactions, the sequence of reactions might be initiated internally, perhaps by a mere suspicion that one is blushing, rather than by a specific external event. Reactions to the suspicion that one might be blushing could explain why people can be made to blush by telling them that they appear to be blushing even when they are not. Such information leads them to infer that others might infer they are embarrassed, thereby leading them to blush.

Blushing is additionally curious in that it is a clearly visible sign of an emotion that, in most cases, we would prefer to conceal. Its very visibility has led some to argue that blushing is indeed communicative and acts as a 'nonverbal apology.' It is a visible statement to others that we are aware that our behavior was untoward, inappropriate, or inadequate and, because we care about other people's evaluations, our blushing is a way of seeking forgiveness from other group members. Indeed, studies indicate that those who blush after a social accident are evaluated more positively than those who do not do so.

It is also possible that blushing, like the silly grin, serves a function similar to nonhuman appeasement gestures. For non-human primates, appeasement frequently results in loss of interest in the victim by the threatening animal. One purpose of blushing may, paradoxically, be to reduce attention from observers. Although some people may deliberately embarrass or humiliate others, or deliberately draw attention to another's blushes, in general we tend to avoid focusing on people when they are blushing.

Individual Differences in Embarrassment

People differ markedly both in their tendency to blush and in their reported frequency of embarrassment experienced. Four factors related to such differences are examined here: age, gender, personality, and culture.

Age

Embarrassment is systematically built into our social system. Societies everywhere have unwritten social rules which regulate

our everyday behavior. It seems that the aversive consequences of embarrassment are such that one reason for our tendency to follow the rules, conventions, and behavior expected by others is our fear of the possibly embarrassing consequences of not doing so. Indeed, laughing at, ridiculing, or in short, embarrassing another person for rule-breaking is likely to result in attempts to avoid such rule-breaking in future. Some have argued that, via such mechanisms, embarrassment exerts a powerful influence on the acquisition of social rules in children and adolescents. Thus, children are introduced to modesty, self-control, and manners by means of teasing, laughter, and ridicule for mistakes. During adolescence there is an increasing desire to manage the impressions we create for others and hence we are increasingly motivated to avoid being singled out for laughter and ridicule. Embarrassment thus becomes a particularly powerful method by which social rules can be acquired.

Although there is limited research pertaining to developmental aspects of embarrassment, there seem to be discernible age related changes. Embarrassment seems to occur infrequently in very young children, research suggesting that the first signs seem to be around the age of 2 years. Over the next few years the tendency to experience embarrassment increases, until by the ages of 5–7 embarrassment is experienced as frequently as in adulthood. A peak period of embarrassment is during adolescence. There is then a decline in reported embarrassment in later adult life.

The experience of embarrassment is related to the emergence of the social self and associated self-consciousness. Some have argued that this occurs at about 7 years of age, an increase in self-conscious awareness then occurring during early adolescence with a peak at around 13 or 14 years of age, followed by a gradual decline. Thus, while children as young as two may show embarrassed behaviors as judged by others whether they personally experience the emotion of embarrassment is a different matter.

Central to age-related changes in felt embarrassment is the extent to which children are aware of how the impression they create is viewed by others. At a young age a child's ability to view things from someone else's perspective is limited. Their behavior is more likely to be directed by what appears to be right to him or her than by what appears to be right to others. Although they may well be aware that certain behaviors provoke ridicule or laughter they may not be aware of why such reactions occur. At this age they are thus likely to experience a fairly 'primitive' form of embarrassment. By the age of 5–7 children are more aware of the way in which the impression they create is viewed by others. They become more concerned with creating an impression appropriate to the circumstances and which will be viewed positively. Thus, for an older child, a social transgression or social accident is likely to result in 'mature' embarrassment, similar to that experienced by adults.

The peak period of embarrassment is during adolescence which parallels the peak of self-presentational concerns and self-consciousness which occurs at this time. Conformity to peer expectations, marked by a need to wear the 'right' clothes and listen to the 'right' music is especially important during adolescence. The desire to win approval from others is an important goal. In addition, adolescence is associated with marked changes in physical and psychological makeup.

No longer being a child, but not yet being an adult, the adolescent has yet to acquire the necessary repertoire of behaviors to play out an adult role. Lack of knowledge can lead to indecisiveness and lack of confidence and hence more likelihood that behaviors will be viewed negatively or have embarrassing consequences.

There is then a gradual decline in self-consciousness after adolescence which is paralleled by both a decrease in experienced embarrassment and a decrease in the tendency to blush. With increased age, novel experiences and hence the potential for embarrassment are likely to decline; this is paralleled by an apparent decrease with age in the propensity for blood vessels in the face to dilate.

Gender

The lay view is that women are more likely to blush and are more readily embarrassed than men. Certainly, within a historical context, coy, shy reactions such as exhibited by the 'blushing bride' were considered appropriate signs of modesty in women. In general, however, such stereotypical differences are not supported by research findings. Although there are some gender differences in relation to circumstances associated with embarrassment and while women in comparison with men do report experiencing more intense embarrassment and a greater propensity to blush there are few differences with regard to actual skin temperature changes in potentially blush-inducing situations. Situational differences in reported embarrassment and blushing no doubt reflect differing socialization experiences while differences in reported embarrassment and propensity to blush may merely reflect the greater propensity for women to express their feelings.

Personality

A number of research studies indicate that some individuals are more prone to experience embarrassment and more likely to report a propensity to blush than others. A central factor is the degree of concern the person has for others' impressions of them. Those concerned with projecting an image which engenders social approval, or at least avoids engendering social disapproval, are more likely to be more readily embarrassed. Furthermore, those who are more readily embarrassed tend to be intensely affected by the slightest social transgression, more likely to report enduring embarrassment even years later at the recall of the event, are more likely to feel empathic embarrassment and are more likely to report a high propensity to blush. Indeed, a proneness to embarrassment is associated with feelings of being observed and a high regard for how one is viewed by others. Indeed, this is a pattern similar to those who experience social anxiety and social phobia. It is thus perhaps not surprising that the degree to which people fear social situations in general is also related to the degree of reported blushing and embarrassment. At the extreme, people troubled by chronic fear of blushing obtain scores on measures of social anxiety similar to those clinically diagnosed as socially phobic; indeed, it is now widely recognized that for a subgroup of social phobics at least fear of blushing is their central concern.

Cultural differences

There seems to be clear evidence that blushing is universal and that embarrassment is expressed in a similar way across cultures. Blacks and other dark-skinned people experience vasodilation in the kinds of social situations that provoke blushing in whites. However, blushing in the former appears to be marked by a further darkening of the skin rather than the reddening which occurs in lighter skinned people. The occurrence of blushing is reported with greater frequency in some cultures (e.g., the United Kingdom) than in others, while averting eye contact and laughter which is reported as frequently occurring in some cultures is reported as occurring less frequently in others (e.g., Italy). These apparent differences tend to be derived from self-reports, rather than from actual observations or direct measures in the cultures concerned, and hence any variations may simply reflect reporting differences. However, if the differences are real, they may involve variations across cultures in the meaning attributed to embarrassing events. Thus, embarrassment might be a more serious matter in certain cultures and hence laughter or smiling would be less likely to occur. There may also be variations in skin thickness across cultures and hence variability in the visibility of blushing. It is also important to bear in mind that different situations are likely to elicit embarrassment and blushing across cultures.

Face Saving and Embarrassment

Because of its aversive and disruptive nature, people generally attempt to avoid embarrassing situations when possible. However, as complete avoidance is rarely possible, we often make attempts to redress the situation in order to maintain face, regain social approval, and restore the interaction following an embarrassing event. In dealing with embarrassing events four main face-saving strategies are recognized: apologies, accounts, avoidance/escape (evasive facework), and the use of humor. Two additional strategies, referred to as remediation and hostility, have also been discussed. Remediation involves offers or requests of help or comfort, expressions of concern, or offers to correct the problem, for example, clearing up after an accident. In contrast to situations inviting remediation, there are some circumstances in which anger or hostility is used as a method of coping with embarrassment. In general, however, the latter reaction is restricted to circumstances in which the person has been criticized or teased by others with the deliberate intent of causing embarrassment. In this context, the goal of intentional embarrassment is to negatively sanction the other's behavior, to establish power, or simply self-satisfaction. The embarrassed person may respond with hostility in an effort to keep the same behavior from occurring again.

The simplest way of dealing with embarrassment is to offer an apology, such as 'I'm sorry' or 'pardon me.' This serves to acknowledge blameworthiness for the undesired behavior in the hope that a minor discretion can be passed over quickly and forgotten by those concerned. Indeed, the very act of being embarrassed can itself serve as an apology, the visual sign of blushing indicating that the person accepts responsibility for the untoward act. Several theorists have stressed the functional properties of expressing embarrassment and have argued that

these expressions may help restore the person's public image after a mishap or transgression. That is, blushing or publicly conveying other signs of embarrassment can show that the person recognizes that they have committed a social or moral transgression, and that they regret having done so. Accordingly, it has been argued that blushing has appeasement-related properties which can actually positively influence observers' judgments. An interpretation of a sign of embarrassment as an apology is most likely in a situation in which the person's undesired behavior may have caused discomfort to someone else who was present. Brazening out the situation may serve to increase both parties' embarrassment, while a display of embarrassment accompanied by laughter may diffuse the situation.

While an apology offers an admission of responsibility, an account is an attempt to explain the undesired behavior. Accounts can take two forms: excuses and justifications. The former consists of attempts to play down one's own contribution to the event while at the same time admitting that the behavior was wrong. A justification similarly admits some responsibility for the event while at the same time containing an element of denial that there are any negative consequences of the behavior. Categories of accounts involve appeals to environmental circumstances, lack of intent, highlighting personal characteristics, or scapegoating. Thus, if we embarrass ourselves by tripping in front of others, we might comment 'that's the trouble with slippery floors' (environmental circumstances), 'I didn't mean to do that' (lack of intent), 'that's typical, I seem to have two left feet' (personal characteristics), 'the cleaners have polished the floor again' (scapegoating).

Categories of justification include 'self-fulfilment,' which justifies the action on the grounds that it leads to some form of enlightenment, and 'effect misrepresented,' which justifies the action because the consequences were trivial or because no harm was done. Because they add to excuses and attempt to minimize or deny the undesirability of the event, justifications may be too strong for dealing with minor transgression associated with embarrassment. An attempt to justify one's actions may serve to prolong, heighten, and add to the implications of the embarrassing event.

Although a verbal apology or account may be used frequently to deal with embarrassing events, there are occasions when they may be inappropriate or may fail to deal adequately with the situation. In addition, the person concerned may feel unable to offer a verbal apology or account for their action. In such circumstances, avoidance may be a common reaction. This may take the form of either withdrawal subsequent to the embarrassing event (escape) or attempts to avoid encounters in which embarrassment might occur (avoidance). However, physically retreating from the situation, rather than achieving the goal of averting attention, is likely to draw further attention to the embarrassed person. There are occasions, however, when averting an awkward event can be achieved by changing the topic or remaining silent rather than by escape per se. It is also clear that some people will go to extreme lengths to avoid social situation due to a fear that they will behave in a way which is embarrassing. This is particularly true for people with a chronic fear of blushing. Avoidance in this case is more an attempt to avoid *losing face* through blushing inappropriately rather than an attempt to *save face*.

A further strategy involved in coping with embarrassment involves the use of humor or laughter. Laughter serves to reduce the tension, while joking can turn a potential loss of social approval into a gain in social approval.

In order for a face-saving strategy to be successful, it must be acceptable, reasonable, and adequate. In the case of minor, nonserious events, humor and laughter may be appropriate. As events increase in their significance, the likelihood that apologies and excuses will be used with greater frequency also increases. In general, however, apologizing is the most appropriate response regardless of the type of embarrassing situation. Excuses and justifications tend to be used infrequently, except in social situations involving forgetfulness or awkwardness. In addition, research findings tend to indicate that the face-saving strategy used will depend not only on the type of embarrassing event, but also the gender and status of those involved. In terms of gender differences, women are more likely than men to offer an apology or excuses outlining mitigating circumstances. In addition, women are more likely to offer help and more likely to act on such offers, if their embarrassing actions have caused potential distress to others. When the embarrassing event is not serious, people of higher status, in comparison to those of lower status, are less likely to acknowledge responsibility for the event or to attempt to account for their actions.

Interestingly, there seems to be little variation across cultures in the type of face-saving strategy used. Both avoidance and a simple expression of embarrassment are common reactions to all types of embarrassing events across cultures. The main variation seems to be in the use of humor, which may be almost absent in those cultures which have stronger sanctions for social rule-breaking.

Observer Reactions

When someone is embarrassed, others present are likely to react to and become involved in that person's embarrassment. Each may affect the other so that embarrassment can either spiral or be mutually controlled. In seeking to offer assistance, observers may excuse or explain the embarrassed person's behavior, 'playing along' with them, for example, by the use of humor or an offer of support or empathy. Such reactions may be used alone or in combination, and seem to be relatively constant across cultures.

The most frequently reported reactions from observers are support and empathy. Indeed, these may often be used in combination, most usually with a supportive comment followed by a sign of empathy. Support includes any comment or nonverbal expression intended to reassure the person that they are still viewed positively despite the embarrassing event. A typical comment might be 'don't worry, it's not important,' while typical gestures include a warm smile or friendly touch. Empathic reactions involve comments intended to assure the embarrassed person that the event that occurred could have happened to anyone. A typical comment might be 'I know how you feel, I'm always doing the same thing.' Such a reaction can also be a useful way for the observer to show that they accept an apology offered by the embarrassed person.

Humor is also used by observers with moderate frequency. However, humor and laughter will clearly have different meaning dependent upon whether the observer laughs alone or whether both the observer and embarrassment person laugh together. There is a fine dividing line between 'laughing with,' and 'laughing at' someone. If the embarrassed person fails to join in with the observer in their attempt to help, they may well end up being the butt of the joke rather than helping to make light of the event. In such circumstances embarrassment is likely to be intensified.

A similar intensification of embarrassment is likely to occur if the observer fails to respond or responds in a manner which is interpreted negatively by the embarrassed person. As with humor, a lack of response can be interpreted as a sign of lack of support. The difference between a positive or negative reaction is often signaled by subtle behaviors such as a fleeting smile or facial expression acknowledging the event, or even an appearance of embarrassment from the observer. Assuming that the observer wishes to provide assistance in remedying the situation, their attempts can fail either because they do not know how to respond or because their attempts backfire.

There are also occasions when an observer may seek to intentionally increase another's embarrassment. For example, if they feel that the embarrassed person has not shown sufficient 'remorse,' if the embarrassing behavior has disturbed others present, or if the embarrassed person was apparently responsible for the event. Such deliberate intensification of another's embarrassment may be achieved either by drawing attention to the event or by expressing reproach. The latter may involve criticism or correction. Clearly, such reactions may well serve to further disrupt social interaction.

As well as instances when an observer may seek to intensify another's embarrassment, there are occasions when an observer may seek to intentionally initiate embarrassment in others. Intentional embarrassment is frequently used as a sanction to teach children correct or tactful behavior. Men, in comparison to women, are more likely to intentionally embarrass children and subordinates. This may reflect the fact that males are stereotypically more competitive and more likely to engage in controlling behaviors. Intentional embarrassment also occurs frequently among same sex friends, often as part of a 'game' to test each other's social poise.

Coping with Blushing

While embarrassment is a common but uncomfortable state which can disrupt social interaction, chronic blushing or fear of blushing can severely disrupt the lives of those concerned.

Blushing seems to cause most distress when it occurs in the absence of a clearly defined embarrassing event, for example, when someone fears that their red face will be taken as a sign of shyness or social anxiety. Chronic blushers are characterized by two facets of self-consciousness, they are over-concerned with both their internal sensations and thoughts, as well as observers' subsequent reactions to their blushing. Blushing causes a particular problem in social situations because we imagine others can see the blush which we assume we are displaying but which we are unable to see for ourselves. In some instances, the fear of blushing can be psychologically debilitating. For many

people such fear of blushing can have devastating effects leading to social withdrawal, friendship, and work related difficulties and a state of panic when faced with what are to other people quite ordinary social encounters. Many chronic blushers are unable to cope with their difficulty, resorting to medication or surgery. A number of authors have noted that fear of blushing is one of the core concerns for at least a subgroup of those who are socially phobic.

One of the key findings from a number of different research studies is that there does not seem to be a perfect relationship between the extent to which people report blushing or fear of blushing with actual measured changes in skin temperature or facial blood flow. In other words, fear of blushing is not necessarily to do with external signs that are visible to others but seems rather more related to our thoughts and evaluations. Thus, a fear of the prospect of blushing provokes anticipatory anxiety thereby increasing the possibility that other signs of anxiety (trembling, shaking, stammering, sweating) will be displayed during the ensuing social encounter. This further increases feelings of discomfort and anxiety which in turn is further fuelled by the assumption that others present can see the signs of our anxiety and in particular our red face. Such fears can lead to increasing avoidance of social situations.

Such findings have clear implications for treatment. If fear of blushing, or a feeling that you are blushing intensely or frequently is not necessarily related to actual blushing, then the focus of treatment should not be actual blushing but the underlying psychological parameter, that is, fear or anxiety about blushing. Appropriate cognitive behavior therapy aimed at helping the person cope more effectively with their anxiety is thus the key and has been shown to be effective. Because the negative pattern of thinking associated with blushing is sufficient to cause embarrassment in the absence of a clearly defined embarrassing event, the most effective strategy for dealing with blushing is for the person to modify their thinking pattern. This can be achieved by reevaluating and redirecting attention away from oneself and blushing.

Thus, while everyday social embarrassment may be a common but uncomfortable psychological state which can disrupt social interaction, a chronic fear of blushing can severely disrupt the lives of those concerned. While a number of strategies can be used to cope with social embarrassment, the more significant the situation and the more concern we have about our reaction the more difficult the embarrassment is to deal with. At the extreme end of the continuum are those who live in a constant fear of blushing and/or being seen as behaving in an embarrassing manner. For such people seeking appropriate therapeutic help may be the most appropriate course of action.

Glossary

Affective empathy A class of feeling states evoked by the real, implied, or imagined experiences of another person.

Altruism A motivational state with the ultimate goal of protecting or promoting the welfare of another individual.

Attitude An individual's relatively stable positive or negative evaluation of an object (e.g., person, place, or worldview).

Cognitive empathy A class of cognitive-perceptual processes oriented toward understanding the perspectives, feelings, or situations of others.

Egoism A motivational state with the ultimate goal of increasing one's own welfare.

Empathy burnout Distress and psychological distancing that result from prolonged exposure to the suffering of others.

External attribution An inference that a behavior was caused by situational factors rather than personality factors.

Internal attribution An inference that a behavior was caused by personality factors rather than situational factors.

The term empathy has been used as a label for a number of distinct psychological processes and related consequences over the past century. Most psychologists agree that understanding empathy (however it may be defined) is crucial to understanding human social behavior, yet there is much disagreement and, consequently, much confusion about what it is. Adding to the confusion is the related concept of sympathy. Although some psychologists use the terms empathy and sympathy interchangeably, others use each to refer to a distinct phenomenon. Even when each term is used to refer to a distinct phenomenon, there is little consistency among researchers in their application. At the most basic level, empathy (or sympathy) may be said to encompass processes that are responsible for, or that result from, (1) understanding what another person is thinking and feeling; (2) a broad range of perceptual, cognitive, and affective responses to negative and positive events in the lives of others; or (3) both. The term empathy may also be used to describe individual differences or a stable personality characteristic. To make sense of the many uses of the term empathy and, more importantly, to understand the role that it plays in human behavior, it is useful to differentiate the various cognitive and affective processes involved and to differentiate these processes from their effects.

Empathy as Knowing or Understanding Another's Internal States

The term empathy was coined by Titchener in the early 1900s as a translation of Lipps' concept, *emföhlung*. Both terms referred to the process by which an individual actively projects or intuitively his or her way into another person or object, thereby experiencing a situation from the other's point of view. This early conceptualization of empathy emphasized the process whereby a person deliberately steps outside of himself or herself to acquire an accurate understanding of another's psychological world.

In this respect, empathy is quite similar to the process that is sometimes labeled role taking or perspective taking.

However, there are a number of variations on this view of empathy. For example, one may actively imagine what another is thinking and feeling as a consequence of his or her situation, based solely on the perception of that person's current values, goals, resources, and the like. Alternatively, one may instead imagine how one would feel in the other's situation, given one's own current values, goals, resources, and the like. The former cognitive activity has been labeled an imagine-other perspective, and the latter, an imagine-self perspective. Although these two approaches to understanding another's internal states appear to be quite similar at first blush, research suggests that these two perspective-taking strategies have different emotional, motivational, and behavioral consequences and, as such, should remain conceptually distinct.

Further complicating the distinction between imagine-self and imagine-other perspectives are distinctions in the different aspects of another's perspective that one may seek to understand. Specifically, when attempting to understand another's perspective one may seek to understand his or her visual perspective, cognitive perspective, or affective perspective.

Visual Perspective Taking

Visual perspective taking has been defined as the ability to understand what another can visually perceive. A prototypical investigation of this form of perspective taking was provided by Piaget's Three Mountains Task. In this task, the child is seated at one of four chairs situated around a table containing three mountain-shaped objects. The child is asked to verbally describe or to select a pictorial representation of what another person, seated at a different chair, would see of these mountains.

Piaget assumed that correctly indicating what the other person could and could not see suggests an appreciation of different points of view of a visual stimulus and, by extension, a rudimentary form of decentering, an awareness that others may have access to different information about, or interpretations of, stimuli. Flavell and his colleagues extended this research by examining the active suppression of one's own

visual or conceptual perspective as a means of facilitating communication with others. Visual perspective taking is likely the initial developmental manifestation of the capacity to empathize with another person, but at least two other manifestations of this skill emerge within the first few years of life.

Cognitive Perspective Taking

Cognitive perspective taking has been defined as the ability to identify or understand what another is thinking in a specific situation. There is clearly some degree of conceptual overlap between the visual and cognitive manifestations of perspective taking in the sense that both involve the recognition of differing points of view. However, researchers tend to separate these in terms of both the focus of each skill (*viz.*, visual vs. conceptual content of the other's psychological experience of a situation) and, as noted below, the nature of the research protocols used to study them.

Building on Piaget's work, Flavell and colleagues' apple-dog story is the prototype for much of the early research on cognitive perspective taking. In this task, children are presented with a cartoon depicting a boy climbing an apple tree after being chased by a dog. The section of the story in which the dog chases the boy is removed and the child is asked to indicate what a naïve participant would think is happening in the story (*i.e.*, what caused the boy to climb the apple tree). The child's ability to suppress the privileged knowledge of the dog chase scene and to construct a story based only on the information that is physically or psychologically available to the other is taken as evidence of cognitive perspective taking.

Researchers working in the Piagetian tradition have also investigated more complex instances of cognitive perspective taking. For example, in Flavell and colleagues' nickel-dime task, one child is asked to trick a second child into choosing one of the two cups that contains the lesser amount of money (nickel) so that the first child can keep the cup that contains the greater amount of money (dime). It is assumed that successful completion of the task requires the child to engage in recursive cognitive perspective taking, whereby the child makes an inference about the other's cognitions and then adjusts his or her own in order to manipulate the other's cognitions (*e.g.*, she will believe B if I do C, so I should do Y in order to trick her into believing Z). This research has demonstrated that cognitive perspective taking is a skill that emerges relatively early in life, but one that develops and becomes more complex and flexible with age and experience.

Affective Perspective Taking

Affective perspective taking has been defined as the ability to identify and understand what another feels in a particular situation. Borke's Interpersonal Perception Test is prototypical of research on one aspect of affective perspective taking. In this task, the child is asked to indicate a hypothetical person's likely emotional responses to a series of emotion-relevant situations (*e.g.*, losing a pet). The child is typically asked to either describe or to select a pictorial depiction of the target's emotional state. Research on this aspect of affective perspective taking tends to follow the same logic as research on cognitive perspective

taking and shares its emphasis on generalized inferential strategies and cognitive processing.

A second aspect of affective perspective taking was investigated by researchers interested in participants' ability to decode a target's emotional response either in terms of feeling or displaying the same emotion that the target is depicting, or in terms of supplying the appropriate emotion label for the target's emotion expression. Thus, affective perspective taking has been conceptualized as both (1) the process of making inferences about how a generic person would feel in a certain hypothetical situation, and (2) the cognitive capacity to infer what a specific person is feeling by decoding (or feeling) the other's displayed emotion as a consequence of the other's situation. It has also been treated as a consequence of the discrepancy between the other's displayed emotion and the emotion that would be expected, given the other's situation (*e.g.*, if someone is sad at his or her birthday party).

Empathy as Feeling What Another is Feeling

Empathy has been defined as feeling the same thing that another is feeling by a number of neuropsychologists, psychologists, and philosophers. However, it was more common for research conducted prior to the 1950s to employ the term sympathy rather than empathy to describe this shared emotional response. Since that time, researchers have coined a number of phrases to emphasize the unique characteristics of this process, such as emotional contagion, or parallel emotional responding.

This view of empathy is potentially problematic in that it is unclear whether an observer must experience an emotional response that, when compared to the emotion of the other, is of either exactly the same tone, the same valence, the same intensity, or some combination of the three to qualify as empathy. For example, one researcher may define empathy as experiencing an emotional response that is similar to the emotional response of the other on one of these dimensions whereas another researcher may require similarity on all three dimensions. It is also unclear whether the observer must experience *only* the emotional response of the other, or if experiencing it in addition to other, different emotional responses still qualifies as empathy.

Empathy as Being Upset by Another's Situation

Witnessing another individual's suffering can, under certain circumstances, produce feelings of distress or anxiety. Such feelings have been labeled empathy by a number of researchers, especially in light of the strong statistical association between measures of empathy and measures of distress in certain circumstances. However, this label becomes problematic when the other's suffering is either graphic or extreme. In such cases, traditional measures of empathy and distress do not appear to assess different aspects of a unified emotional response. To be sure, distress or anxiety can be caused by witnessing another suffer, but this emotional response is not experienced for the other. Rather, it is experienced for oneself. Given the difference in focus of empathy and distress, recent

research on the topic maintains a conceptual distinction between empathy and feelings of distress that may also be produced by the same situation. This research also suggests that each of these emotional responses has distinct motivational and behavioral consequences, further highlighting the need to conceptually separate empathy from the distress that may accompany it.

Empathy as Feeling for Another

Perhaps the most common definition of empathy in modern psychology is feeling a vicarious emotion that is congruent with, but not necessarily identical to, the welfare of another. This view of empathy highlights the distinction noted above regarding distress – empathy is felt for another whereas, in some circumstances, distress is felt for oneself. Another important feature of this view of empathy is that it broadens the scope of potential empathic emotions. Specifically, empathy is typically construed as an emotion experienced when witnessing another suffering or experiencing a negative situation. However, it is also possible to respond with empathic joy when the other is experiencing positive states, with empathic anger when the other has been dealt an injustice, with empathic embarrassment when a cherished other commits a public faux pas, and so on. Thus, it may be more appropriate to view empathy as a category of emotional responses or as a way of responding emotionally rather than as a unitary, prototypical emotion.

Empathy as Matching Another's Overt Responses

Another variation on the concept of empathy views it as the process by which one matches another's overt responses to his or her current situation. Researchers have focused on various aspects of the other's responses that are to be matched, including his or her posture, emotional expressions, physiological state, and physical activities. This view of empathy has also been labeled motor mimicry or imitation to reflect its primary characteristic, some form of behavioral matching.

More recently, neuropsychological research suggests that matching in empathy goes well beyond motor mimicry or imitation. According to the Perception–Action Model of empathy, matching at the level of neural representations is central to the experience of empathy. Specifically, due to the automatic link between perception and action (*viz.*, involving the dorso-lateral prefrontal cortex and left inferior parietal region), simply perceiving another's physical activities results in a pattern of neural activation similar to what would occur if the observer were engaging in the same physical activities himself or herself. It is important to note, however, that the neural matching is far from complete, and that empathy involves a decoupling mechanism (*viz.*, involving the insula and right inferior parietal cortex) that differentiates one's own experiences and physical activities from those of the observed other.

It is important to note that response matching does not necessarily lead to an accurate understanding of the other. In many cases, matching is a goal-directed act that serves to communicate support for the other rather than an automatic and unavoidable imitative act. And it is, of course, possible that another's overt physical activities or emotional expressions

are intentionally inaccurate, so mimicking those actions or expressions would lead to an inaccurate understanding of the other. Above all, one need not match or imitate another's responses in order to understand them. Humans are quite adept at communicating what they are thinking and feeling, and one often needs to simply listen carefully to the other in a nonjudgmental manner to gain accurate knowledge of his or her internal states.

Summary

The various processes outlined above bear some conceptual overlap, but it is important to note the differences between them. The first (empathy as perspective taking) is primarily a cognitive account of empathy. In contrast, the second, third, and fourth accounts (empathy as feeling what another is feeling, empathy as feeling upset by another's situation, and empathy as feeling for another) are affective accounts of empathy, and the fifth account (empathy as matching another's overt responses) is a behavioral account of empathy.

Although the various processes labeled as empathy share similarities, it is important to note that the antecedents and consequences of these different views of empathy are not identical. Interestingly, important distinctions among these processes often result from their differential links to one another. For example, research suggests that adopting an imagine-self perspective toward another in need results in feeling a similar emotion to what one expects the other to feel, whereas adopting an imagine-other perspective toward a person in need has been shown to result in feeling for the other.

These two forms of affective empathy in turn can result in different motivational outcomes. Feeling a similar negative emotion as the other has been shown to evoke a selfish motive to reduce the emotion, resulting in attempts to escape the emotion by either escaping the situation or avoiding the other in need, both of which are involved in eliciting the unpleasant negative emotion. In contrast, feeling for the other evokes an altruistic motive to help the other, resulting in offering direct help to the other or attempting to get someone else to help him or her. The link between these two perspectives and their distinct emotional, motivational, and behavior consequences has been demonstrated numerous times in scientific literature, particularly by social psychologists. The link between being upset by another's situation and specific motivational and behavioral consequences is, however, less clear and is in need of further study.

As a further layer of complexity, research suggests that empathy as matching another's overt responses sometimes leads to cognitive empathy, affective empathy, or both. But, cognitive and affective empathy can also lead to a matching of overt responses. Thus, it is not surprising that the distinctions in various forms of empathy are often lost in the literature, given their interrelated and reciprocal nature.

Empathy as a Personality Characteristic

The research described above has sought to understand the cognitive and affective processes that have been referred to as empathy. However, other scholars have sought to describe

individual differences in either the capacity for experiencing empathy or in the tendency to use this capacity. That is, instead of thinking of empathy as a process, some scholars think of empathy as a distinct and stable aspect of one's personality that transcends situations and potential eliciting stimuli.

To this end, researchers have worked to develop valid and reliable measures of individual differences in the capacity or tendency to experience empathy for others, be it understanding what another is thinking and feeling, feeling what the other is feeling, or feeling for the other. Most of these measures are self-report in nature and, consequently, require that respondents have accurate insight into their empathic capacities or tendencies, have the means for communicating these capacities or tendencies, and are not motivated to present a distorted view of these capacities or tendencies. It is important to note that these preconditions are unlikely to be met at all times in all studies. As such, when considering various individual difference measures of empathy, one should keep in mind these potential limitations. Examples of individual difference measures of empathy include the Interpersonal Reactivity Index (IRI), developed by Davis, the Questionnaire Measure of Emotional Empathy (QMEE), developed by Mehrabian and Epstein, and the Emotional Contagion Scale (ECS) developed by Doherty.

The Interpersonal Reactivity Index

The structure of the IRI is based on the assumption that empathy consists of four related, but conceptually distinct, constructs. Specifically, the IRI consists of four subscales: perspective taking, empathic concern, personal distress, and fantasy. Taking these in turn, the perspective taking subscale measures an individual's tendency to spontaneously adopt other people's points of view. The empathic concern subscale measures an individual's tendency to feel sympathy and compassion for those in need. The personal distress subscale measures an individual's tendency to experience discomfort when in the presence of those in need. The fantasy subscale measures an individual's tendency to imagine himself or herself in fictional situations (e.g., in the scene of a movie or as a character in a book). Taken together, the IRI subscales measure empathy as various types of both cognitive processes (perspective taking and fantasy subscales) and affective processes (empathic concern and personal distress subscales).

Questionnaire Measure of Emotional Empathy

The QMEE is designed to measure a person's tendency to become emotionally aroused in response to the emotional behavior or situations of others. It includes items that measure feeling the same emotion as another, feeling upset about the situation of another, and feeling for another. Consequently, the QMEE is probably best conceptualized as a general measure of empathy as an affective process.

Emotional Contagion Scale

The ECS is a measure of one's tendency to feel the same emotions as others. It consists of five subscales that measure tendencies to 'catch' the experiences of happiness, sadness, anger,

fear, and love. Alternatively one can combine scores on all five subscales to create a general measure of the tendency to feel the emotions of others.

Sex Differences in Empathy

A commonly held belief is that women are more empathic than men, particularly in response to the needs of others. Indeed, an analysis of existing empathy research by Eisenberg and her colleagues suggests that women *report* more emotional reactivity to the plight of others in need than do men. However, a closer look across studies reveals there is little evidence of a gender difference when physiological measures of emotional intensity are used to measure empathy. This suggests that the differences found in research that employs self-report methodologies may be due to self-presentation concerns and gender role-based expectancies rather than to biological gender differences. Thus, (1) women may overreport their genuine feelings of empathy because of what they think is expected of them, (2) men may underreport their genuine feelings of empathy because of what they think is expected of them, or (3) both.

Research does suggest that women are slightly better than men at decoding visual and auditory cues from others (i.e., adopting the perspective of another individual to understand what he or she is thinking and feeling) when self-report measures of empathic accuracy are used; however, no gender differences are found when this aspect of empathy is measured using objective measures. Ironically, this difference on self-report measures of perspective taking may be due to the same self-presentation concerns and gender-role expectations as the differences found using self-report measures of affective empathy (which do not appear to reflect actual differences in the intensity of emotional response to others).

Summary

Much like the theoretical literature, studies on individual differences in the capacity or tendency to be empathic have treated the empathy concept in a variety of different ways. There are also gender-based differences in the tendency to be empathic when empathy is conceptualized as the ability to correctly infer what another person is thinking or feeling (even though objective measures do not detect this difference). Yet, there is little evidence of gender differences when physiological measures are used to assess affective empathy (even though self-report methodologies often mistakenly suggest that gender differences in affective empathy do exist).

Intrapersonal and Interpersonal Consequences of Empathy

Empathy, Prosocial Behavior, and Antisocial Behavior

One of the most widely studied consequences of empathy is its effect on prosocial behavior. The relation between empathy for a victim and an increased tendency to help him or her has been well known for several decades. However, disagreement over

the reasons for this relation has garnered much research attention of late.

According to the Empathy–Altruism Hypothesis, empathy evokes an altruistic motive with the ultimate goal of protecting or promoting the welfare of the person for whom empathy is felt. Note that, as they are used here, the term empathy refers to another-oriented emotional response to the victim’s welfare (feeling for the other), and the term altruism refers to a motivation rather than to any specific form of helping behavior. The claim that humans are capable of genuine altruism is somewhat controversial and, as a consequence, a number of egoistic explanations for the empathy–helping association have been proposed. The term egoism refers to a motivational state with the ultimate goal of protecting or promoting one’s own welfare. Among the more popular egoistic explanations for empathy-based helping are (1) the Aversive-Arousal Reduction Hypothesis, which claims that empathy is aversive and that empathically aroused individuals help in order to rid themselves of the unpleasant feeling; (2) punishment-avoidance explanations, which claim that empathically aroused individuals help because they anticipate negative social evaluations or shame and guilt for failing to help; and (3) reward-seeking explanations, which claim that empathically aroused individuals help because they anticipate praise or positive mood for helping those for whom empathy is felt. Although each of these explanations has some degree of empirical support, the Empathy–Altruism Hypothesis is considered by many researchers to have the weight of evidence on its side.

In contrast to the large body of work on the causal relation between empathy and prosocial behavior, there is relatively little research on the causal relation between empathy and antisocial behavior. Of the research that has been done, most has focused on the behaviors of deviant populations or young children, has assessed empathy as a general personality disposition rather than as a cognitive or emotional process, or used methodological designs that make it difficult to determine the causal direction of the relation (i.e., does empathy decrease antisocial behavior or does antisocial behavior decrease empathy?). As such, evidence for a negative relation between empathy and aggression has been reported, but it is largely inconsistent across populations, research paradigms, techniques for conceptualizing and measuring empathy, and for different forms of antisocial behavior. Consequently, it is difficult to generalize beyond the samples and methods employed in existing research.

Empathy, Accuracy, and Social Relationships

Empathy has long been acknowledged as an important component of social relationships. When defined as a cognitive process, empathy has been linked to conflict avoidance or management, improved communication among relationship partners, increased relationship satisfaction, and a tendency to be considerate of the partner’s wants and needs. However, research suggests a number of potential barriers to accurate perception of what another is thinking and feeling, which can mitigate the positive effects of empathy. For example, it is common for individuals to use themselves as a basis for assessing how and why another individual will react to a given

situation. Making judgments from an egocentric perspective (viz., that self and other are similar) can be useful in many cases, but accuracy is impaired when the empathizer and the other are dissimilar on situation-relevant domains. Accuracy is also impaired when the empathizer is currently experiencing strong emotion or is in a state of need, both of which tend to be unconsciously incorporated into his or her judgment of the other’s thoughts and feelings.

The role that empathy plays within the context of close relationships is even more complex. Research suggests an interesting paradox: empathic accuracy increases relationship satisfaction in certain situations, but decreases relationship satisfaction in others. Specifically, in nonthreatening contexts (e.g., discussing mundane events or planning a night out), a moderate-to-high level of motivation to accurately understand what a partner is thinking and feeling increases relationship satisfaction and stability. However, in relationship-threatening contexts (e.g., potential infidelity or disappointment with the partner’s performance), individuals tend to be motivated toward empathic inaccuracy – that is, to intentionally distort his or her perception of what the partner is thinking and feeling. In such cases, empathic inaccuracy actually increases relationship satisfaction and stability. In contrast, when the motive to be empathically accurate is strong in relationship-threatening contexts, the relationship is likely to suffer. Thus, empathy is important in social relationships in general, but inaccuracy is a common (and occasionally useful) exception, especially in close relationships when dealing with potentially threatening contexts.

Empathy and Attributions

Attributions are beliefs about the cause of an individual’s behavior. According to past research, there is a pronounced actor–observer difference when making attributions. Specifically, individuals tend to explain their own behavior as a consequence of the situation (an external attribution) whereas they tend to explain the behavior of others as a consequence of personality traits or dispositions (an internal attribution), especially when the behavior is negative or otherwise results in failure. Although the actor–observer difference is found primarily when the actor is highly idiosyncratic or when the actor and observer are in a close relationship, the effect can be reversed by simply instructing the observer to empathize with the actor. As a consequence of empathizing with the actor, the observer makes external attributions for the actor’s behavior, just as he or she would make external attributions for himself or herself. Thus, empathy promotes the evaluation of others in a relatively self-like (i.e., generous) manner.

Empathy and Attitudes

Empathy has also been shown to increase valuing of, and attitudes toward, individuals for whom empathy is felt. This is, at least in part, due to the reversal of the attributional biases noted above, especially in situations that involve some form of victimization, in that viewing another’s suffering as a result of situational factors rather than as a result of dispositional

factors reduces the likelihood that derogation and blaming the victim will occur.

The effects of empathy on valuing have important consequences for attitudes toward members of stigmatized groups (e.g., minorities or people with HIV/AIDS) and for attitudes toward social causes (e.g., animal rights or the environment). Research suggests the following three-step model of how empathy can be used strategically to improve attitudes toward such groups: (1) actively trying to understand what a stigmatized person is thinking and feeling will increase empathic feelings for him or her, (2) feeling empathy for him or her will increase valuing of his or her welfare, and (3) valuing this person will generalize to valuing the stigmatized group as a whole. Initial tests of this model demonstrated the success of this strategy by improving attitudes toward a broad range of stigmatized individuals and groups (e.g., people with AIDS, homeless individuals, and convicted murderers). Subsequent research has demonstrated the power of empathy to reduce prejudice and discrimination against members of racial or ethnic minorities, and homosexuals, and to improve attitudes toward protecting the natural environment and its nonhuman inhabitants.

Implications and Future Directions

The term empathy has been used to describe a broad range of cognitive-perceptual and emotional processes, all of which play an important role in human behavior. As noted above, empathy is potentially a powerful force not only in personal relationships, but also in an individual's interaction with social groups and with the world more generally. However, much is left to be discovered about the processes and consequences of this class of phenomena.

Perhaps the most pressing need at present is the theoretical integration of the cognitive and emotional processes involved in empathy. There is much disagreement and little consistency among researchers on exactly what empathy is, which has almost certainly slowed progress toward understanding its causes and consequences. Second, a number of important issues pertaining to empathy have received little or no empirical attention. For example, research on the neurological bases of empathy has emerged only within the last few years and much is left to be learnt about which brain processes are responsible for the various empathy phenomena and how organic brain damage can affect an individual's capacity to understand and respond to the thoughts and feelings of others. Similarly, little is known about the genetic basis or evolutionary history of empathy. Given its importance in human social functioning, it is remarkable that this topic has received so little empirical attention.

Also, much research has been conducted to understand the relation between empathy and antisocial behavior, yet the results are largely inconsistent from study to study. Future research may benefit from adopting a broader purview of the topic and by employing (1) measures of empathy as a process rather than as a general personality disposition; (2) a

representative range of antisocial behaviors rather than focusing exclusively on physical or verbal retaliation; (3) diverse populations, including normal, physically healthy adults; and (4) experimental methodology so that the causal direction of an association can be determined. A broader purview would also be useful when investigating other, socially relevant consequences of empathy, such as volunteerism and a related phenomenon, empathy burnout. Empathy burnout is an involuntary process by which empathy is transformed into feelings of distress after prolonged exposure to the suffering of others that causes caregivers (e.g., spouses, nurses, volunteers, social workers, etc.) to become callous and, potentially, disengaged from service to the victims. The majority of research on empathy and prosocial behavior has focused on single-instance forms of helping and, as a consequence, little is known about the effects of empathy in long-term care situations. Future research on these and related issues could advance both theoretical understanding and real-world application of this important and complex class of phenomena.

Glossary

Automatism Motor activity not initiated consciously.

Eidetic imagery Mental images that are almost photographically exact.

Mediumship The ability of some persons, usually in a trance or other altered state, to produce information relating to a deceased person, which they have not learned normally.

Psi A theory-neutral term designating phenomena that seem not to derive from ordinary sensorimotor processes, including phenomena such as extrasensory perception (telepathy or clairvoyance), psychokinesis ('mind over matter'), or precognition.

Introduction

Nearly all contemporary psychologists, neuroscientists, and philosophers subscribe – explicitly or implicitly – to some version of physicalism. Physicalist conceptions of the human mind and personality, contrary to traditional and everyday notions, run along roughly the following lines: We human beings are nothing but extremely complicated biological machines. Everything we are and do is in principle causally explainable from the bottom up in terms of our biology, chemistry, and physics – ultimately, that is, in terms of local contact interactions among bits of matter moving in accordance with mechanical laws under the influence of fields of force. Some of what we know and the substrate of our general capacities to learn more are built-in genetically as complex resultants of biological evolution. Everything else comes to us directly or indirectly by way of our sensory systems, through energetic exchanges with the environment of types already largely understood. Mind and consciousness are generated by – or in some mysterious way identical with – neurophysiological events and processes in the brain. Mental causation, free will, and the 'self' do not really exist; they are mere illusions, ineffectual by-products of the grinding of our neural machinery. And since mind and personality are entirely products of our bodily machinery, they are necessarily extinguished, totally and finally, by the demise and dissolution of that body.

Views of this sort unquestionably hold sway over the vast majority of contemporary scientists and they have also percolated widely through the public at large. We believe, however, that they are at best seriously incomplete, and at certain critical points, demonstrably false, empirically. In this article, we will briefly catalogue a variety of interrelated empirical phenomena that appear difficult or impossible to explain in conventional physicalist terms. We emphasize from the outset that these phenomena must be considered collectively, not piecemeal; they not only challenge the conventional physicalist picture individually, but converge in pointing to the need for a radically novel way of understanding the intimate relationship of mind and brain. We also emphasize that we are presenting here only a skeletal outline of the kinds of phenomena to which we wish to direct readers' attention. More detailed treatments of relevant empirical evidence and the issues raised can be found in works given in the Further Reading.

Extreme Psychophysiological Influence

We begin with a variety of phenomena especially suggestive of the involvement of direct mental agency in the production of physiological effects not fully explainable in terms of physiological mechanisms alone. The following examples will serve to capture their flavor.

Placebo effects and related kinds of psychosomatic phenomena have long been informally recognized and are now widely accepted, but they were accepted by modern biomedical science only grudgingly, as new mechanisms of brain–body interaction that seemed potentially capable of explaining them came to light. In particular, psychoneuroimmunology has demonstrated the existence, previously unknown, of interactions between the central nervous system and the immune system. Nevertheless, the adequacy of such explanations to account even for placebo effects remains in question, and there are many types of kindred phenomena that pose progressively greater challenges to explanation in such terms.

For example, Sigmund Freud and F. W. H. Myers were impressed by hysterical 'glove anesthetics,' in which a patient loses sensation from the skin of a hand in the absence of organic lesion, in a way that typically corresponds only to the patient's idea, in complete disregard of the underlying anatomical organization. Related phenomena have often been reported in the context of hypnosis. For example, highly suggestible persons who can vividly imagine undergoing an injurious circumstance such as receiving a burn to the skin sometimes suffer effects closely analogous to those that the physical injury itself would produce, such as a blister. More rarely, the correspondence between the hypnotic blister and its imagined source extends even to minute details of geometric shape, details too specific to account for in terms of known mechanisms of brain–body interaction. A closely related and well-documented phenomenon is that of 'stigmata,' in which fervently devout or pious believers in Christ develop wounds analogous to those inflicted during the crucifixion. The injuries are again localized and specific in form, vary in locus and character in accordance with their subjects' differing conceptions of Christ's own injuries, and appear and disappear, often suddenly and regularly, also in accordance with the subject's expectations. Similarly, dramatic phenomena have occasionally

been documented in psychiatric patients in connection with their recall of prior physical trauma.

The conventional hope, of course, is that even the most extreme of the phenomena just mentioned might ultimately be explained in terms of brain processes. Continuing allegiance to this hope, despite the indicated explanatory difficulties, is undoubtedly encouraged by the fact that the phenomena described so far all involve effects of a person's mental states on that person's own body. Still more drastic explanatory challenges are posed, however, by cases in which one person's mental state seems to have directly influenced another person's body. Such phenomena include 'maternal impressions' (birthmarks or birth defects on a newborn that correspond to an unusual and intense experience of the mother during the pregnancy), distant healing (including experimental studies of effects of prayer on healing), experimental studies of distant mental influence on living systems, and cases in which a child who claims to have memories of the life of a deceased person also displays extremely unusual birthmarks or birth defects corresponding closely with marks (usually fatal wounds) on the body of that person. In addition, there has been a considerable accumulation of spontaneous cases and experimental evidence demonstrating the reality of psychokinesis (PK), which by definition involves direct mental influence on the physical environment (see section '[Psi Phenomena](#)').

Extremes of Informational Capacity and Precision

A number of well-documented psychological phenomena involve levels of detail and precision difficult to account for in terms of a brain operating in statistical fashion with neural components of low intrinsic precision and reliability. Here are some examples.

The first involves a case of 'automatic writing' observed by William James. The subject wrote with his extended right arm on large sheets of paper, his face meanwhile buried in the crook of his left elbow. For him to see what he was doing was 'a physical impossibility.' Nevertheless, James continues: "Two or three times in my presence on one evening, after covering a sheet with writing (the pencil never being raised, so that the words ran into each other), he returned to the top of the sheet and proceeded downwards, dotting each *i* and crossing each *t* with absolute precision and great rapidity."

This episode illustrates two features that have often appeared together in the large but neglected scientific literature dealing with automatic writing: The subject is in an altered state of consciousness, and the motor performance, itself remarkable, is apparently guided by an extremely detailed memory record, an essentially photographic representation of the uncompleted page.

The latter property relates to the phenomenon of eidetic imagery, the second example, the most dramatic demonstration of which has been provided by Charles Stromeyer using Julesz stereograms. These are essentially pairs of computer-generated pictures, each of which by itself looks like a matrix of randomly placed dots, but is constructed in such a way that when viewed simultaneously (by presentation to the two eyes separately) a visual form emerges in depth. Stromeyer presented pictures of this type to the eyes of his single subject, a

gifted female eidetiker, at different times, ultimately as much as 3 days apart. Under these conditions, the subject could extract the hidden form only if she could fuse current input to one eye with an extremely detailed memory image of previous input to the other eye. Remarkably, she was able to succeed under a wide variety of increasingly demanding conditions. The original stereograms, for example, were 100×100 arrays, but she ultimately succeeded under double-blind conditions with arrays as large as 1000×1000 , or a million 'bits,' viewed up to 4 h apart.

These results were understandably shocking to many psychologists, who sought to escape their force by pointing to the dependence on a single subject and the absence of replications. At least one successful replication has subsequently occurred, however. Moreover, the literature already contains many additional examples of prodigious memory. Stromeyer mentions Luria's famous mnemonist and the case of the 'Shass Pollaks,' who memorized all 12 volumes of the Babylonian Talmud, and Oliver Sacks has reported a similar case of a person who among other things knew by heart all nine volumes and 6000 pages of Grove's *Dictionary of Music and Musicians*. Other examples could easily be cited. Prodigious memory of this sort is a real psychological phenomenon.

Third in this group is the family of 'calculating prodigies.' Of special interest is the 'savant syndrome,' often associated with autistic disorders, in which islands of spectacular ability appear in the midst of generalized mental disability. The abilities are of many types, but almost invariably involve prodigious memory. The depth of the problems they pose for brain theory is exemplified by the case of 'The Twins,' also described by Sacks. These profoundly impaired individuals, unable to perform even simple additions and subtractions with any accuracy, nonetheless proved able to generate and test prime numbers in their heads. Sacks was able to verify the primacy up to 10 digits, but only by means of published tables, while the twins themselves went on exchanging numbers of steadily greater length, eventually reaching 20 digits. Sacks makes the intriguing suggestion that they may not literally be calculating these enormous numbers, but discovering them by navigating through some vast inner iconic landscape in which the relevant numerical relations are somehow represented pictorially. The twins themselves of course cannot say how they do it.

Phenomena of these sorts look hard to explain in terms of brain processes. The most serious attempt to do so that is known to us is in fact devoid of specific neural mechanisms. Its central argument is rather that early-stage brain processes like those subserving visual perception, for example, must also be savant-like in terms of their speed, precision, and informational capacity; what is unusual about savants, therefore, may consist merely in their access to these mechanisms. This explanation of course presupposes a positive answer to the fundamental question at issue, whether the brain alone can accomplish any of these things including perceptual synthesis itself (see section '[The Unity of Conscious Experience](#)').

As proved long ago by mathematician John von Neumann, the only practical way to get increased arithmetical precision out of individually unreliable neurons is to use more of them. This biocomputational perspective clearly implies that calculating prodigies must use large portions of their brains in very abnormal ways to achieve the observed effects. The cognitive

deficits that often accompany savant-type skills could conceivably reflect such substitutions, but we must remember that comparable skills sometimes also occur in geniuses such as the mathematicians Gauss and Ampère.

Memory

The previous section focused on phenomena such as high-precision calculations and prodigious memory that appear incompatible with the physical properties of the brain considered as a kind of computing device. Problems also arise, however, in regard to memory in its more familiar and everyday forms. Here we briefly sketch some relevant issues.

Memory is central to all human cognitive and perceptual functions, yet we remain largely ignorant of where and in what forms our past experience is stored and by what means it is brought to bear upon the present. Generations of psychologists and neurobiologists have taken it as axiomatic that all stored memories must exist in the form of ‘traces,’ physical changes produced in the brain by experience, but there has been little real progress toward scientific consensus on the details of these mechanisms despite many decades of intensive research.

Significant progress has recently been made, to be sure, in regard to ‘learning’ and ‘memory’ in simple creatures such as the sea slug (*Aplysia*), and more generally in regard to what might be called ‘habit memory,’ the automatic adjustments of organisms to their physical environments. But these discoveries fall far short of providing satisfactory explanations of the most central and important characteristics of the human memory system, including in particular our supplies of general knowledge (semantic memory) and our ability to recall voluntarily and explicitly our own past experience (autobiographical or episodic memory). Furthermore, recent functional neuroimaging studies, although generating vast amounts of data, have yielded little, if any, progress toward a comprehensive and coherent account of memory based on trace theory.

Meanwhile, deep conceptual problems have been identified in trace theory itself. For example, autobiographical memory clearly involves something more than mere revival of traces of past experiences, something that allows us to interpret what is experienced now as a representation of our own past rather than a contemporary perception, dream, or hallucination. That is, traces as such only provide memory aids rather than memories per se, and it has proved extremely difficult to specify in conventional physicalist terms what that extra something is, without falling into regressive forms of explanation that presuppose and hence cannot explain the phenomenon of memory itself. Similarly, the content of a concept or semantic memory typically transcends any finite set of experienced circumstances that can plausibly be imagined as having deposited corresponding ‘traces’ in a form capable of explaining its effective deployment in an unlimited variety of novel contexts.

These conceptual problems regarding trace theories of memory have deep connections with issues discussed in section ‘The Heart of the Mind,’ and similar issues arise in relation to allied components of current cognitive theory such as ‘information’ and ‘representation.’ See also section ‘Psi Phenomena’ for an additional empirical problem.

Psychological Automatism and Secondary Centers of Consciousness

Phenomena catalogued under this heading involve what looks like multiple concurrent engagement, in potentially incompatible ways, of major cognitive skills (linguistic skills, for example) and the corresponding brain systems.

Current cognitive neuroscience pictures the mind or ‘cognitive system’ as a hierarchically ordered network of subprocessors or ‘modules,’ each specialized for some particular task and corresponding (it is hoped) to some particular brain region or regions. Leaving aside major issues regarding the details of its specification, this picture seems broadly consistent with the overall manner in which our minds normally seem to operate. That is, our basic way of consciously doing things is essentially one at a time in serial fashion. Although psychologists recognize that with suitable training people can do more things in parallel than they customarily suppose, this generalization applies mainly to relatively divergent things, and conspicuously fails as the simultaneous tasks become more complex and more similar.

Nevertheless, a large body of credible evidence, some dating back to the late nineteenth century, demonstrates that additional ‘cognitive systems,’ dissociated psychological entities indistinguishable from full-fledged conscious minds or personalities as we normally understand these terms, can sometimes occupy the same organism simultaneously, carrying on their varied existences as it were in parallel, and largely outside the awareness of the primary, everyday consciousness. In essence, the structure that cognitive psychology conventionally pictures as unitary, as instantiated within and identified with a particular organization of brain systems, can be functionally divided – divided, moreover, not ‘side to side,’ leading to isolation of the normal cognitive capacities from each other, but ‘top to bottom,’ leading to the appearance and concurrent – not alternating – operation of what seem to be two or more complete cognitive systems, each of which includes all of the relevant capacities. Emergent ‘multiple’ or ‘alter’ personalities can also differ widely, not only in demeanor, interests, and knowledge but even in regard to nonvoluntary physiological characteristics such as visual defects and susceptibilities to allergies. Even worse, it sometimes happens that one of these personalities appears to have direct access to the conscious mental activity of one or more others, but not vice versa.

Two brief examples, drawn from an enormous literature, may help convey a more concrete sense of the character of these phenomena.

The first comes from a report by Oxford philosopher F. C. S. Schiller on automatic writing produced by his brother. As is characteristic of this genre of automatism, the writer was typically unaware of the content of his writing, which went on continuously while he was fully and consciously engaged in some other activity such as reading a book or telling a story. Of particular relevance here, however, were occasions on which he wrote simultaneously with both hands and on completely different subjects, one or the other of these streams of writing also sometimes taking mirror-image form.

The second example is the case of Anna Winsor, described by William James in his report on automatic writing. The case

was protracted and bizarre, but only superficially resembles the neurological ‘alien hand’ (Dr. Strangelove) syndrome. Its central feature is that the patient, Anna, at a certain point lost voluntary control of her right arm, which was taken over by a distinctive secondary personality. This personality, whom Anna herself named ‘Old Stump,’ was benign, often protecting Anna from her pronounced tendencies toward self-injury. As in the case of Schiller’s brother, Stump typically wrote or drew while Anna was occupied with other matters. But Stump also continued writing and drawing even when Anna was asleep, and sometimes in total darkness. This secondary personality also remained calm and rational during periods when Anna was feverish and delusional, and it manifested knowledge and skills which Anna herself did not possess.

Psi Phenomena

Here we refer to experimental and field observations systematically adduced in the course of over a century of effort by workers in ‘psychical research’ and its modern descendent, ‘parapsychology.’ The phenomena in question involve, by definition, correlations occurring across physical barriers that should be sufficient, on presently accepted physicalist principles, to prevent their formation. This occurs, for example, when person A spontaneously experiences an apparition of his friend B, as B unknown to A lies dying from a fatal accident. Over a thousand detailed cases of this sort – carefully documented experiences that are not dismissible en masse as mere ‘anecdotes’ – have been published in the peer-reviewed literature. It also occurs when an experimental subject consistently succeeds in identifying randomly selected forced-choice targets displayed in a remote location. It is not difficult to set up controlled experiments of this sort and to evaluate their outcomes using rigorous statistical procedures. A large amount of careful experimental work has been carried out along these lines, with results more than sufficient, in our opinion, to demonstrate beyond reasonable doubt to open-minded persons that the sheer existence of the basic input–output phenomena – ‘extrasensory perception’ (ESP) and ‘psychokinesis’ (PK) in the popular vocabulary, or in more theory-neutral terminology, ‘psi’ – is a fact of nature with which we must somehow come to scientific terms.

Psi phenomena in general are important because they provide examples of human behavioral capacities that appear impossible to account for in terms of presently recognized computational, biological, or classical physics principles. Even more important for our purposes, however, is a further body of evidence suggestive of postmortem survival, the persistence of elements of mind and personality following bodily death. It is simply not true, as most scientists presume, that we possess no such evidence. We in fact possess a lot of such evidence, much of it of very high quality, deriving, for example, from studies of veridical apparitions, trance mediumship, and ‘cases of the reincarnation type,’ in which young children spontaneously report verifiable events from the lives of distant and ordinary persons now deceased. Ironically, the primary threat to a survivalist interpretation of this accumulated evidence arises not from considerations of evidential quality, but from the difficulty of excluding

alternative explanations based upon psi interactions involving only living persons.

Quite apart from any personal or theological interests readers may bring to this subject, it should be evident that postmortem survival, if it occurs, demonstrates dramatically the limitations of present-day reductive physicalism. If it is the case, for example, as much evidence indicates, that autobiographical, semantic, and procedural (skill) memories can survive bodily death, then memory in living persons must presumably exist at least in part outside the brain and body as conventionally understood.

Either horn of this interpretive dilemma – postmortem survival or psi among the living – is lethal to current physicalist orthodoxy, which undoubtedly explains the widespread scientific resistance to both. But as we are arguing here, and have argued in much more detail elsewhere, these phenomena cannot be isolated and quarantined, because similarly difficult explanatory challenges are posed by many other well-evidenced psychological phenomena. Evidence for the occurrence of psi phenomena in general and postmortem survival in particular must, we believe, play an important role in the formulation of an empirically adequate mind–brain theory, and our efforts here will be amply rewarded if they lead scientifically minded readers to examine these subjects more seriously than they otherwise might.

Genius-Level Creativity

Any scientific theory of personality and cognition truly worthy of the name surely must help us to understand this humanly vital topic, but by this standard we have so far made distressingly little progress. The reason, in our opinion, is that for the most part we have tried to understand the exceptional – real genius, in its fullest expressions – as an amplification of the commonplace – ‘creativity,’ as found in convenience samples of undergraduates and the like.

All of the challenging phenomena catalogued in this article – including extreme psychophysiological influence, psychological automatism and secondary centers of consciousness, flashes of inspiration involving unusual forms of thinking and symbolism, prodigious memory, spontaneous psi phenomena, and altered states of consciousness verging on the mystical realm – are inescapably bound up with genius in its fullest expressions, but these connections go virtually unmentioned in contemporary mainstream discussions. A particularly dramatic case which exemplifies our central point is that of the Indian mathematical genius Ramanujan, rated by his distinguished discoverer Hardy as standing alone at 100 atop a scale of mathematical ability on which most of us lie at or near zero, while the magnificent David Hilbert rated 80 and Hardy himself a mere 25. Replete with examples of prodigious memory, psychological automatism, mathematical discoveries presented in the form of dreams, and profound and beautiful intuitions of hidden but ultimately verifiable properties of the physical world, this astonishing case fairly beggars the theoretical apparatus currently available to cognitive science and hence could well serve as a kind of reality check and navigational aid for further investigations of genius.

Mystical Experience

Experiences of this type lie at the core of the world's major religious traditions and have continued to occur throughout history and across cultures. Their existence as a distinctive and important class of psychological phenomena can scarcely be denied, yet they have largely been ignored by mainstream psychology and neuroscience, and generations of clinical psychologists, psychiatrists, and neuroscientists have tended, with few exceptions, to devalue and pathologize them, treating them as products of malfunctioning brains. Even when acknowledging that such experiences are typically life-transforming and self-validating for those who have them, the historically standard epistemological approaches in psychology and philosophy – beginning with William James in his *Varieties of Religious Experience* – treat them as purely subjective events having authority only for those who experience them, and thus deny their objective significance and the testability of the associated truth claims. However, a large though scattered literature testifies to the common occurrence in connection with such experiences, or in individuals who have them, of genius-level creativity, spontaneous psi-type events, and many other unusual but verifiable empirical phenomena of the sorts described in this article. Mystical-type states of consciousness are also at least partially reproducible by pharmacological (psychedelic) means, and they can be induced by protracted self-discipline involving transformative practices such as the various forms of meditation. An objective and informed appraisal of mystical experience thus finds within it much additional support for an enlarged conception of human personality and many new opportunities for empirical research.

The Unity of Conscious Experience

Under this heading we briefly address two interrelated problems. The first and narrower is the so-called 'binding' problem, which emerged as a consequence of the success of contemporary neuroscientists in analyzing sensory mechanisms, particularly in the visual system. It turns out that different properties of a visual object such as its form, color, and motion in depth are handled individually by largely separate regions or mechanisms within the brain. But once the stimulus has been thus dismembered, so to speak, how does it get back together again as a unit of visual experience?

Only one thing is certain: The unification of experience is not achieved anatomically. There are no privileged places or structures in the brain where everything comes together, either for the visual system itself or for the sensory systems altogether. Some early theorists such as James and McDougall argued that the evident disparity between the multiplicity of physiological processes in the brain and the felt unity of conscious experience could only be resolved in materialist terms by anatomical convergence, and since there is no such convergence, materialism must be false. This argument, although ingenious, relied upon the faulty premise that the only possible physical means of unification must be anatomical in nature. All current neurophysiological proposals for solving the binding problem are instead functional in nature; the essential concept common to

all of them is that oscillatory electrical activity in widely distributed neural populations can be rapidly and reversibly synchronized, particularly in the 'gamma' band of EEG frequencies (roughly 30–70 Hz), thereby providing a possible mechanistic solution to the binding problem.

A great deal of sophisticated experimental and theoretical work over the past 20 years has demonstrated that such mechanisms do in fact exist in the nervous system, and that they are active in conjunction with normal perceptual synthesis. Indeed, contemporary physicalism has crystallized neurophysiologically in the form of a family of 'global workspace' theories, all of which make the central claim that conscious experience occurs specifically – and only – in conjunction with large-scale patterns of gamma-band oscillatory activity linking widely separated regions of the brain.

The neurophysiological global workspace, however, cannot be the whole story, because a large body of recent evidence demonstrates that elaborate, vivid, and life-transforming conscious experience sometimes occurs under extreme physiological conditions, such as deep general anesthesia and cardiac arrest, that categorically preclude workspace operation. In short, it appears to us that the early theorists were right after all, albeit for the wrong reason. In effect, we believe, recent progress in theoretical neuroscience, coupled with advances in our capacity to retrieve patients from the borderland of death, has provided new means for the falsification of physicalist theories of mind–brain relations.

Availability of this emerging evidence emboldens us to make some further and more speculative remarks regarding the larger problem of perceptual synthesis, and the direction in which things seem to us to be moving.

It is an historical fact that mainstream psychology has always tended on the whole to try to solve its problems in minimalist fashion and with as little reference as possible to what all of us experience every day as central features of our conscious mental life. The early workers in 'mechanical translation,' for example, imagined that they could do a decent job simply by constructing a large dictionary that would enable substitution of words in one language for words in the other. This approach failed miserably, and we were slowly driven, failed step by failed step, to the recognition that truly adequate translation presupposes understanding, or in short a full appreciation of the capacities underlying the human use of language.

A similar evolution is underway in regard to perceptual theory. Most of the work to date has taken a strongly 'bottom-up' approach, which views perceptual synthesis as a kind of exhaustive calculation from the totality of input currently present at our sensory surfaces. Machine vision and robotics, for example, necessarily took this approach, and even in neuroscience it seemed to make sense to start with the most accessible parts of the perceptual systems – the end organs and their peripheral connections – and work our way inward. The great sensory systems themselves – vision, audition, somatosensation, and so on – were also presumed to operate more or less independently, and were in fact typically studied in isolation.

A separate tradition dating back at least to Kant and the early Gestalt theorists, and carried forward into the modern era by psychologists such as Ulric Neisser and Jerome Bruner, has been sensitive to the presence of 'top-down' influences, both

within and between sensory modalities. Although a few perceptual subsystems (such as those that produce incorrigible visual illusions) may be truly autonomous or ‘cognitively impenetrable,’ these seem to be isolated and special cases. A very different overall picture of perceptual synthesis is currently emerging in which top-down influences predominate. On this view perceptual synthesis is achieved not from the input, but with its aid. This is necessarily the case for example in regard to ambiguous figures such as the Necker cube, where the stimulus information itself is insufficient to determine a uniquely correct interpretation. More generally, we routinely ignore information that is present in the input and supply information that is not, speed reading providing a characteristic example. Something within us, a sort of world-generating or virtual-reality system, is continuously updating and projecting an overall model of the perceptual environment and our position within it, guided by limited samplings of the available sensory information.

As in the case of understanding spoken or written language, an enormous amount of general knowledge is constantly mobilized in the service of this projective activity, which freely utilizes whatever information it finds relevant. Top-down and cross-modal sensory interactions have recently been recognized as the rule rather than the exception in perception, and neuroscientist Rodolfo Llinás and his coworkers have advanced the view, which we believe is profoundly correct, that dreaming, far from being an odd and incidental part of our mental life, represents the fundamental form of this world-creating activity. Ordinary perceptual synthesis, on this inverted view of things, amounts to oneiric (dreamlike) activity constrained by sensory input. Psychoanalyst Ernest Hartmann has proposed similar ideas in regard to hallucinatory activity more generally, with dreaming included. In his view such activity is again a ubiquitous and fundamental feature of our mental life, and the critical question is not ‘why do we sometimes hallucinate?’ but rather ‘what keeps us from hallucinating most of the time?’ The answer, he suggests, lies in inhibitory influences exerted by the brain activity that accompanies ongoing perceptual and cognitive functions of the ordinary waking sorts.

So far so good, but where exactly is the ‘top,’ the ultimate source of this top-down world-creating activity? The mainstream neuroscientists who have already recognized its existence invariably presume that it arises entirely within the brain itself, but evidence such as that of near-death experiences occurring under extreme physiological conditions and the more direct evidence of postmortem survival suggest that it may originate outside the brain as conventionally understood.

The Heart of the Mind

In this section we comment briefly on a hornet’s nest of issues lying at the core of mental life as all of us routinely experience it, every day. These issues have been the focus of extensive recent debates, especially in the philosophical literature, precisely because of their resistance to understanding in conventional physicalist terms. The issues are deep, individually complex, and densely interconnected, and what we can say here will necessarily amount to little more than a summary of

our own opinions. Our central point is that the prevailing a priori commitment to physicalism has rendered us systematically incapable of dealing adequately with the mind’s most central and characteristic properties. We should rethink that commitment.

Consider first the issue of semantic content, the ‘meaning’ of words and other forms of representation. Throughout our history, we have tried unsuccessfully to deal with this by ‘naturalizing’ it, reducing it to something else that seems potentially more tractable. An old favorite among psychologists was that representations work by resembling what they represent, by virtue of some sort of built-in similarity or structural isomorphism, but any hope along these lines was long ago exploded by philosophical arguments. The central move subsequently made by classical cognitive psychology is essentially the semantic counterpart of the prevailing ‘functionalist’ doctrine in the philosophy of mind: Meanings are not to be conceived as intrinsic to words or concepts, but rather as deriving from and defined by the functional role those words or concepts play in the overall linguistic system. Currently there is great interest in ‘externalist’ causal accounts of this functionalist type; in connectionism, dynamic systems theory, and neuroscience, for example, the ‘meaning’ of a given response, such as the settling of a network into one of its ‘attractors’ or firing off a volley of spikes by a neuron in the visual cortex, is typically identified with whatever it is in the organism’s environment that produces that response. But this simply cannot be right: How can such an account deal with abstract things, for example, or nonexistent things? Responses do not qualify *ipso facto* as representations, nor signs as symbols. Something essential is being left out. That something, as John Searle has so effectively argued, is precisely what matters, the semantic or mental content.

Closely related to this is the more general and abstract philosophical problem of intentionality, the ability of any and all representational forms to be ‘about’ things, events, and states of affairs in the world. Mainstream psychologists and philosophers have struggled to find ways of making intentionality intrinsic to the representations themselves, but again it just does not and cannot work, because something essential is left out. That something is the user of the representations. Intentionality is inherently a three-way relation involving users, symbols, and things symbolized, and the user cannot be eliminated. As Searle puts it in various places, the intentionality of language is secondary and derives from the intrinsic intentionality of the mind. Searle thus agrees in part with the nineteenth-century philosopher Franz Brentano, for whom intentionality was the primary distinguishing mark of the mental. At the same time, however, Searle ignores the other and more fundamental part of Brentano’s thesis, which is that intentionality cannot be obtained from any kind of purely physical system, including brains.

Talk of ‘users’ and the like raises for many contemporary psychologists and philosophers the terrifying specter of the self as a homunculus, a little being within, who embodies all the capacities we sought to explain in the first place. Such a result would clearly be disastrous, because that being would evidently need a similar though smaller being within itself, and so on without end. Cognitive modelers seeking to provide strictly physicalist accounts of mental functions must therefore

do so without invoking a homunculus, but in attempting this they routinely fail. Often the homuncular aspect is hidden, slipped into a model by its designers or builders and covertly enlisting the semantic and intentional capacities of its users or observers. Much contemporary work on computational modeling of memory, metaphor, and semantics harbors subtle problems of this sort. Sometimes, however, the homunculus is more brazenly evident. One example is David Marr's account of vision, which applies computations to the two-dimensional array of retinal input to generate a 'description' of the three-dimensional world that provided that input, but then needs someone to interpret the description. Another is Stephen Kosslyn's model of visual imagery, which essentially puts up an image on a sort of internal TV screen, but then needs somebody else to view the image.

Cognitive models cannot function without a homunculus, we believe, precisely because they lack what we have – minds, with their capacities for semantics, intentionality, and all the rest built in. No homunculus problem, however, is posed by the structure of our conscious experience itself. The efforts of Daniel Dennett and other physicalists to claim that there is such a problem, and use that to ridicule any residue of dualism, rely upon the deeply flawed metaphor of the 'Cartesian theater,' a place where mental contents get displayed and we pop in separately to view them. Descartes himself, James, and Searle, among others, all have this right; conscious experience comes to us whole and undivided, with the qualitative feels, phenomenological content, unity, and subjective point of view all built-in, intrinsic features. We and our experience cannot be separated in this way.

Finally, we wish simply to record our own deepest intuition as to where these issues lead. All of the great unsolved mysteries of the mind – semantics, intentionality, volition, the self, and consciousness – seem to us inextricably interconnected, with consciousness somehow at the root of all.

The consciousness we have in mind, however, is emphatically not that of people such as David Chalmers, irreducible but ineffectual, consisting merely of phenomenological properties or 'qualia' arbitrarily tacked on to some sort of computational intelligence that supposedly does all the cognitive work. Ordinary perception, memory, and action are saturated with conceptual understanding, and conceptual understanding is saturated with phenomenological content. Volition too has an intentionality aspect, for as Nietzsche somewhere remarked, one cannot just will, one must will something. And as William James so forcibly argued at the dawn of our science, all of this perceptual, cognitive, and volitional activity somehow emanates from a mysterious and elusive 'spiritual self,' which can often be sensed at the innermost subjective pole of our ongoing conscious experience.

We find it astonishing, and predict that it will be found so by our intellectual descendants as well, that so much of twentieth-century psychology and philosophy sought – consciously! – to slight or ignore these first-person realities of the mind, and sometimes even to deny their existence. There is perhaps no better example of the power of preexisting theoretical commitments to blind able persons to countervailing facts. The gloomy and counterintuitive modern conclusions summarized in section 'Introduction' about mind, consciousness, free will, and the self really do follow – inexorably – from the physicalism that prevails

today. But as we will next briefly explain, that kind of physicalism is itself incompatible with our deepest physical science.

Conclusion: Toward an Expanded Scientific Psychology

It cannot be emphasized too strongly that these unresolved explanatory problems concerning consciousness, the heart of the mind, and the other empirical phenomena surveyed in this article all have a common source in the narrow physicalist consensus which undergirds practically everything now going on in mainstream psychology, neuroscience, and philosophy of mind. But that consensus rests ultimately upon a classical physics-based conception of nature, deriving from people such as Descartes, Galileo, Newton, Laplace, and Kelvin, that began its career by deliberately banishing conscious human minds from its purview! Given that historical background, it should occasion little surprise that William James – like Newton and Leibniz before him, and like increasing numbers of philosophers and scientists today – clearly recognized the inherent impossibility of explaining consciousness and allied phenomena within that Procrustean framework. James himself cautioned that the physical science concepts underlying classical physicalism were 'provisional and revisable things,' but he had no good alternatives in sight. As he correctly anticipated, however, that conception of nature was soon radically undermined by a tectonic shift in the foundations of physics itself, associated especially with the rise of quantum mechanics.

The founders of quantum mechanics discovered to their horror that the fundamental ideas of classical physics were not just limited but wrong, leading repeatedly to predictions falsified by experiment. The theory they were driven to in response, quantum theory, is a more fundamental and better physical theory that explains everything explainable in classical terms and a host of additional things as well, often to extraordinary levels of accuracy. No outcome predicted by it has ever been experimentally falsified. Furthermore, in at least some of its various interpretations, quantum mechanics appears able to accommodate phenomena of the sorts surveyed here. Mathematical physicist Henry Stapp in particular has shown that a strictly orthodox interpretation derived from the mathematical formalization achieved by von Neumann leads naturally to a non-Cartesian form of dualism in which the human mind with its powers of attention and decision making plays a necessary and fundamental role in completing the quantum dynamics. As a corollary, the classical doctrine of 'causal closure of the physical,' which underlies most contemporary physicalist denials of free will, is specifically rejected. And although details remain to be supplied, many of the challenging behavioral phenomena cited above, from stigmata and hypnotic blisters to psi phenomena and even postmortem survival, seem potentially understandable within this broader framework.

The empirical challenges briefly surveyed here should be sufficient in themselves, we believe, to compel and to some extent foreshadow a radical reworking of central parts of our science of the mind. But it is also important to recognize that a scientific psychology enlarged in these ways will likely prove more compatible than present-day physicalist psychology both with everyday human experience and with our most fundamental physical science.

Glossary

Affective map Affective mapping as being the opportunity to plot on maps the feelings that particular places evoke. Feelings are shown by symbols, possibly supplemented with annotation. Where patterns of feelings can be identified on maps then areas can be shaded accordingly on drawings of the cognitive map.

Allocentric frame of reference Frameworks that are fixed to the environment itself or to the individual object.

Being lost Lost is defined as being unable to identify or orient present one's location with respect to known locations; and having no effective method for reorientating oneself. Note: one can have little accurate knowledge of where one is, but not be lost.

Cognitive map A construct which enables a person to predict the environment which is too large to be perceived at once, and to establish a matrix of environmental experience into which a new experience can be integrated, simplifying and ordering the complexity of human–environment transactions. Investigators often capture the individual's cognitive map by asking for a sketch map to be drawn.

Dead reckoning (or path integration) The process which enables a traveler to constantly update their current position

with respect to their starting point without recording details of the path already followed.

Egocentric spatial frameworks Frameworks that move with the body as it moves through the environment.

Environmental grammar The terms of reference acquired by an individual in relation to the spaces and settings around them, from which they develop the appropriate expectancies and hence, the corresponding search strategies.

Legibility The legibility of a city as "... the ease with which its parts may be recognised and can be organised into a coherent pattern" (Kevin Lynch).

Space syntax The general idea is that spaces can be broken down into components, analyzed as networks of choices, then represented as maps and graphs that describe the relative connectivity and integration of those spaces: (Originally conceived by Professor Bill Hillier, Julienne Hanson and their colleagues at The Bartlett, University College London in the late 1970s to early 1980s as a tool to help architects simulate the likely effects of their designs.)

Wayfinding The process of determining and following a path or route between an origin and a destination, as a purposive, directed, and motivated activity.

Introduction

Environmental cognition concerns the way we acquire, organize, store, and recall information about locations, distances, and arrangements in the physical environment. Other aspects of perception and cognition receive their own entries elsewhere in the encyclopedia: Why then is there an entry specific to the perception and cognition of the environment?

Most of the perception and cognition research in psychology concerns isolated objects, often studied within a laboratory, and without a broader meaningful context. In contrast, we are often surrounded by and are moving through the (hugely complex) environments that are the focus of study within environmental cognition. Theories of perception and cognition have always been central to psychology as a whole, and this is true of the relatively recent area of environmental psychology (qv), as individuals perceive, interpret, and respond appropriately to their surroundings.

Throughout our daily lives, literally hundreds of spatial decisions are made each day. These rely not on formal reference systems such as maps, but on previously gained spatial representations of the environment. Environmental psychologists define these as cognitive maps. As a result, the environment has a profound effect on human cognition, action, and well-being.

The Nature of Stored Spatial Information: Analog, Propositional, or Both?

We encode and manipulate environmental information in numerous ways. Evidence exists for two kinds of coding: propositional and analog, as in a Conventional Map. The propositional storage of environmental information, in lists and associated networks, is based on abstract representations of meaning. Analog codes, however, parallel the physical structure of information in the world, emphasizing continuity over space. Neither is sufficient alone: both are used according to need and preference.

People are able to convert propositional into analog: for example, the verbal descriptions of configurations or routes into mental representations. Thus, cognitive maps must be in effect both analog and propositional in nature.

Is configuration (or survey) knowledge metric or topological?

A metric representation would imply that distances and directions are directly encoded between environmental locations. Alternatively, if it is topological, then only the relative spatial relationships would be encoded.

Challenging any theory is the seemingly instantaneous development of configuration knowledge in certain situations as opposed to other cases where it does not seem to develop at all, even after extremely long periods of exposure.

The debate continues as to what constitutes configural knowledge as opposed to route knowledge. Most describe configural knowledge as a well-connected network of locations (or landmarks) with multiple potential paths between them. However, reasonable estimations as to the direction and distance of a remote location can often be made without creating a clear route plan.

The Way the Brain Acquires, Stores, and Handles Environmental Information. Can We Identify Key Structures?

The representation of space may be distinct from other forms of conceptual and perceptual knowledge. In many species of mammals, there have been identified specific behavioral mechanisms for locating objects, for dead reckoning, and for constructing cognitive maps. Such mechanisms probably also form the basis of human spatial cognition.

So what are the neural mechanisms supporting spatial cognition, orientation, and wayfinding? The discovery of place neurons in the hippocampus, and other evidence for the cognitive map theory of hippocampal functioning, suggest that this brain structure is the core of an extensive neural system for representing and using information about the spatial environment.

Evidence comes from lesion studies (damage invariably impairs place learning and navigation) and from neurophysiological recording studies, which show that neurons in this system code for location, direction, and distance, which are the elements needed for a mapping system.

A second brain structure involved in spatial cognition is the posterior parietal cortex, where multimodal sensory systems converge, and link to the motor cortex.

Evidence from lesion, human functional brain imaging, and human functional brain interference studies indicate that distinct areas within the posterior parietal cortex have different functional contributions.

But the core function of the parietal cortex in spatial cognition is the constitution of 'egocentric' spatial frameworks: that is, frameworks that move with the body as it moves through the environment.

In contrast, the hippocampus not only plays an important role in episodic and spatial memory but also provides a neural substrate for the representation of spatial location within an 'allocentric' frame of reference (i.e., frameworks that are fixed to the environment itself or to the individual object).

Thus, the hippocampus and the posterior parietal cortex would act differently by handling topological and metric information, respectively.

Only a close cooperation of both systems would enable the individual to 'overlay' and integrate the relevant egocentric and allocentric frameworks. This is the most important prerequisite for performing many of the complex spatial tasks successfully.

Cognitive Maps in Animals and Humans as Drivers of Action

Early psychology's account of a maze-running rat would be of a sequence of several stimulus-response connections

that formed a route to the goal. Success at getting there could not be taken as evidence that the rat had an image or cognitive map of the whole area: it might only be recalling a series of learned responses to the various choice-points in the maze.

But observations of a rat escaping from a maze and running direct to the goal (i.e., being able to integrate the various subroutes within the maze into a single direction) lead Tolman in 1948 to use the term Cognitive Map in explaining this ability.

Rather than state that animals, particularly the rats that took short cuts across his mazes, stored spatial information as a map, Tolman used the term Cognitive Map metaphorically. In other words, he suggested that the animals used in his studies appeared to be able to use spatial information as though the places they remembered were recorded in a map-like manner.

Much debate has since taken place on whether animals do have cognitive maps, or whether for example they use dead reckoning, or path integration, the process which enables a traveler to constantly update their current position with respect to their starting point without recording details of the path already followed. Without a memory trace of the path taken, exact route retrace might not be possible; but it would still be possible to return home directly with foraged food, or in the case of an emergency.

Much subsequent research has shown that birds and flying insects variously use landmarks, star and sun compasses, and magnetic compasses for their local, longer distance, and migratory travel. Are these landmarks, etc. used as a memorized sequence indicating a route to be followed or represented as a layout or survey overview? Careful and ingenious studies are needed to answer such questions.

The term cognitive maps had to wait until the early 1970s until it received wide usage in the literature about human spatial decision-making. Environmental and developmental psychologists, human geographers, and others have used the term with slightly differing implications, the broadest definition being the cognitive apparatus that underlies spatial behavior. More specifically it has been defined as a construct which enables a person to predict the environment which is too large to be perceived at once, and to establish a matrix of environmental experience into which a new experience can be integrated, simplifying and ordering the complexity of human-environment transactions.

To talk of a cognitive map is to imply that a human or animal cognizes the familiar environment as a system of interconnected places; is able to apply a set of transformation rules to this system, optimizing goal-directed movements; and is able to pilot and perform novel routes within it.

Decisions about action are not, however, purely based on knowing where resources and routes are: that is, the factual aspects of the cognitive map. They must also relate to the attributes, meanings, and values that shape behavior: we should thus talk of an affective map.

Therefore, we should see cognitive-affective maps as integrating images, information, and attitudes about an environment.

They are not isolated and contextless entities: they are formed during purposive and social activity in the person's

everyday world. Wayfinding (see below) relies on landmarks imbued with meaning.

Cognitive maps are in effect a series of knowledge (and feeling) structures which consist of different levels of detail and integration. These knowledge structures develop with age, education and experience, thus increasing the information and associations held. We in effect extract and combine information according to the task in hand: that is, there is no one cognitive map in memory but rather we construct them for specific events.

In this respect cognitive maps are dynamic, and are far from a standard cartographer's map, in that they are schematic, incomplete, distorted, simplified and idiosyncratic. The metaphor of a map in the head is so persuasive that we are tempted to believe that there is no metaphor, but rather a real 'thing.'

The main argument against such a cognitive map construct is the non-Euclidean properties discovered by some methods of investigating our knowledge structures, and the fact that we have incomplete knowledge not integrated into one single 'map' but rather disconnected components.

People's behavior in large-scale environments can be explained more completely through recourse to internal, subjective factors than by more traditional external, 'objective' factors. Ask people to plan a shopping trip round town with a map in front of them, and you may get a 'rational route'; but plot an actual trip that they make, and immediately these more subjective factors are seen to come into play.

The capacity to act and move intelligently through space may well occur before, and possibly in the absence of, the capacity to represent that space.

Very young infants can navigate in ways that demonstrate detailed spatial knowledge well before they could attempt any public representation of that knowledge by, for instance, drawing a sketch-map of a familiar area.

Sketch-mapping has nonetheless been a technique widely used by researchers trying to elicit the elusive cognitive map, despite the obvious limitations imposed by people's general ability to draw. Systematic distortions can be demonstrated in such external representations: distances become exaggerated in areas which have many features of interest, and correspondingly telescoped in less-featured areas; angles are misremembered, such that the map does not fit together; whole areas are neglected.

Some researchers have preferred instead to ask subjects to estimate a series of relative distances and angles, and thence to use multidimensional scaling to reconstruct an underlying cognitive map, thereby avoiding individual differences in drawing abilities. Other techniques have included locating points on a base map; recognizing features on aerial photographs; and obtaining think-aloud protocols.

Even within the sketch-map technique, very different impressions of the presumed underlying cognitive map can be obtained according to the particular demand that the researcher's question imposes; and how much prior spatial cueing is offered. No single test is best.

And some may indeed be misleading: consider that if humans conceive of space as collections of familiar landmarks, then the spatial representation of landmarks is thus

qualitative in the sense that it is imprecise: it does not depend on precise metric information, and therefore should not be elicited as if it were.

Direct and Indirect Sources of Information About the Person's Environment

All senses can be involved in one's direct learning about the environment; but the sense most studied is vision, justifiably so, as this sense affords one the most immediate, complete, detailed relational information about the surrounding environment. Whatever the scale, whether it be at the moment one enters an unfamiliar room, or one has a 360° view from a mountain top, vision provides an instant ordering of the elements of the room-scape or landscape, in a way that tactile exploration of a room could only slowly and partially allow. (In section 'Environmental Cognition Without Sight; and Devices for the Blind,' cognition of space without vision will be further considered, along with measures to afford the blind better awareness of space.)

Visual exploration of the space around the newborn starts from the earliest; and as soon as the infant is capable of active movement, investigation of the immediate environment leads to the integration and interrelating of multiple viewpoints when moving through. These integrative skills in developing a cognitive map of the layout of a room and then a house will be used in wider and wider contexts, from immediate neighborhood up to whole township, district, and region.

Perfect integration, however, is not easily achieved: people find it difficult to interrelate places on different floors of even a familiar house; and can often be surprised to see how close two places in different sections of town are when they are separately known from different habitual journeys, especially if they cannot be both seen at the same time. (The aerial view of a familiar place often affords surprised discoveries.)

Such an overview can also be provided by a surrogate: a map, whose *raison d'être* is to show these interrelationships and locations. We can learn relative distances and locations via such a representation, and plan efficient journeys with their aid. (As section 'Communicating and Sharing Environmental Information' will claim, there is evidence that the act of mapping is a cultural universal.)

In many cases, our knowledge of a particular area derives from both direct and indirect inputs, from exploration and map-use; and the interrelationship of these two in the cognitive map is fascinating but as yet understudied.

Cognition of more distant environments may be predominantly or entirely from indirect sources: not only maps but also television, film, photos, textbooks, travelers' tales, etc. Such sources must inevitably offer only a partial and selective view of a place and its people, and may indeed be a source of prejudices or of over-optimistic expectations.

Even the very names of distant places may convey information (sometimes misleading: think of Erik the Red's propagandizing naming of Greenland as a good place to settle and farm).

Maps may be our primary graphic source of information at the global scale, and information and impressions drawn can be influenced by the map-projection selected.

Communicating and Sharing Environmental Information

How do we communicate our environmental information to others: for example, in sharing information about the location of resources, or directing others to a destination?

Whether this is given via spoken instructions, or in graphic form, the process involves selecting a subset of the stored information, selected partly as a result of the sender's articulatory or graphicacy, and partly with regard to an appreciation of any shared understandings with the receiver of the message. An interesting insight into the selection process can be given by this simple comparison: first ask for verbal instructions; and then on another occasion, ask for them to be given graphically: subtly different subsets of information will be received.

How successful can we be in communicating route knowledge verbally? Studies indicate that remembering and following route directions can be facilitated by presenting the receiver with directions in the correct temporal-spatial order; concentrating information in statements concerned with choice points; suppressing irrelevant (decorative) detail; and by offering referents with which the listener will be familiar. Not surprisingly, navigation from good descriptions results in fewer mistakes than navigation from poor descriptions.

It has been claimed by the geographer Blaut that mapping is a universal in human culture; that it is an important ecological adaptation in all cultures (and the supportive evidence from the anthropological literature is strong); that map-like models of one sort or another have been made in all cultures since prehistoric times (again, there is strong support from the archaeological record); and that mapping ability emerges naturally (without training) in very young children of all cultures, a proposition hotly contested by conventional Piagetians.

The Piagetian position maintains that children younger than seven are 'preoperational' and therefore cannot handle or interpret the conventions involved in maps: of change of size, aerial perspective, symbolism, etc. However, many studies with much younger children show them capable of understanding such conventions and being able to use relatively simple maps to guide their own behavior.

Thus for example, 3- and 4-year-olds can use a simple map of a maze to reach their goal (i.e., a local area map); and cannot only understand that an aerial photograph can represent a familiar larger scale area, but can use it to navigate to 'hidden treasure.' At a larger scale again, young preschoolers can use an aerial photograph of a city to tell a story about imaginative journeys across it, demonstrating clear understanding that the size-reduced, aerial-perspective features on the photograph stand for real, full-scale buildings, roads, trees, etc.

These untaught (hence 'natural') mapping abilities of preschool-age children have been studied in many cultures. And confirmatory evidence comes from toy play, in which many young children have been able to use elements of a map (schematic roads, houses etc.) to describe imaginary places and journeys.

So, instead of the restricted, Piagetian, view of young children's environmental cognitive abilities, the evidence from many such studies using aerial photographs and simple maps would seem to indicate that the cognitive modeling of the environment may be an ecological necessity. Young children in every culture seem capable of modeling, in two or three dimensions, the landscape as through viewed from overhead and reduced in scale; and this is prominently assisted by toy-play and by constructing imaginary maps of what the world may look like from overhead. Do not children everywhere make model landscapes with toys on the floor or markings on the ground?

The Development of Environmental Competence

In early childhood, we have to develop our general competence in understanding and navigating environments: this will take a period of years (though probably not as many as early developmental psychologists believed). As competent individuals, we still have to develop competence with respect to places newly encountered: this will start immediately, with our first impressions, and we will rapidly acquire a survey structure, to which extra information will be added as our travels through the place continue.

The first, the development in early childhood of the basic competence, can be called the Ontogenesis of competence. The second, the application to a new place, can be called Microgenesis. Some theorists have suggested that the stages in microgenesis recapitulate those seen in the ontogenesis of competence.

Perhaps the trend in developmental psychology to stress the lack of early competence in many areas, including spatial, can be mainly attributed to Piaget. Famously, in considering the young child's failure on the 'Three Mountains' experiment, (describing what a toy figure would see in a model landscape as being what the child was seeing, regardless of the toy's position), Piaget generalized this as evidence of an inevitable egocentricity before 7 years or so.

Critics have suggested that young children find the instructions in these classic experiments confusing; and that with more careful testing, we can see nonegocentric thought evident in much younger children.

But it is clear that the youngest children are not fully competent, and do go through a number of stages in acquiring it. The account given, by Siegal and White, has become the predominant (but not unchallenged) one.

They suggest that initially, knowledge is structured around landmarks. The second stage is where such locations are linked as route knowledge; and only at the third stage can the individual be said to have survey knowledge. At first, the space between the known points or landmarks is 'empty'; and the individual cannot relate them to each other. Developing knowledge of set routes gives the individual the beginnings of a structure, but to start with it will consist of a series of local directions at decision points, with little accurate idea of distances. Survey knowledge encodes both distances and directions between landmarks, and allows more innovative route discovery.

The attractiveness of the Siegal and White sequence is that it can describe both the slow build up of the general skill during

early childhood, and the rapid acquisition of knowledge about a newly encountered place by a skilled older individual.

The original account of ontogenesis does not specify how long it takes the young child to progress through the stages, but implies early incompetence lasts several years. Does the empirical evidence bear this out? As we saw in section 'Communicating and Sharing Environmental Information,' Blaut and colleagues suggest not.

Similarly, the account of microgenesis, suggesting that the survey is dependent on accurate estimates of distances along routes and between landmarks is open to empirical challenge; and Montello has recently shown that spatial knowledge, including this metric knowledge is acquired gradually through continuing experience of the new place. And the eventual 'map' may well still include inconsistent data: a geometry of estimates which do not fully match up.

When investigators ask respondents to draw a sketch map to represent the individual's survey knowledge, the very demands of the task may produce apparent consistencies which are not borne out by that individual's actual behavior in the real world. Only a very few studies have taken the time and care to study the actual process of microgenesis over the days and weeks that it may take to develop survey knowledge of a new place; and although they give some support to the landmark-route-survey sequence, it is clear that the resultant 'map' is highly individual, relates to the pattern of the individual's exploration and interests, and will contain both highly detailed and completely ignored subareas. Adults learn some key landmarks very quickly, and start anchoring new knowledge to major, features routes and boundaries. Direction and distance estimates can develop rapidly, and then level off as habitual local travel patterns are established.

But do adults integrate newly learned routes into metrically accurate map-like survey knowledge? Could they demonstrate this by, for example, accurately navigating a novel short-cut? Experimental studies of microgenesis show that people make these short-cuts in roughly the right direction and distance; but only at a low level of accuracy, and that the implied cognitive map is not fully Euclidian. People making short-cuts are highly dependent upon visible landmarks.

Returning to the studies of ontogenesis, there are only a few studies with the time to follow the whole process through; and most are reliant on tests of the young child's competency at particular ages. These latter would be carefully controlled tests of spatial problem solving (often at table-top level) and spatial cognition, rather than studying what children are actually doing within their real world. Developmental psychology's study of children's cognition in general has placed little emphasis on the ecological or sociocultural factors supporting and developing the competencies. In contrast, from the start, environmental psychology has sought ecological validity for its studies, and sees the individual and their environment in transactions right from the start of life.

If one tests children with unfamiliar materials and in strange contexts, then they are less likely to demonstrate the skills they have developed in their everyday transactions with the world. Culturally aware field studies of children's spatial behavior by Hart, for example, have shown how independence of travel by the young directly relates to their levels of local knowledge and thence their basic spatial competences.

Wayfinding, Becoming Lost, and Signage

Environmental cognition, it could be argued, has its main role in supporting wayfinding: in the planning and carrying out of routes through the environment, in locating resources and avoiding dangers, and having an awareness of possible novel routes were the need to arise.

This involves long-term spatial memory of places and their attributes, survey knowledge of spatial interrelationships, and accessible place-tagged lists of resources: in other words, a way of linking survey with listed knowledge.

Individual differences in success in wayfinding are often anecdotally recounted, but can be borne out in part by research: factors involved include people's spatial processing abilities, as well as lifetime experience with spatial problem solving in full scale environments (often related to an individual's drive to explore and to seek novelty). Other, more situation-specific factors can include: familiarity with a particular setting (and previous experience of similar types, developing an 'environmental grammar'); the density and salience of landmarks, and the complexity and ambiguity of the layout.

All models of wayfinding distinguish between the processes of the planning of a route, and its execution via actions that are time- and place-appropriate. There will be a hierarchy of processes which unfold as route-following progresses: for example, there will be a sequence of expectancies, to find particular landmarks (maybe personal markers) at expected places. Where such expectancies are not met, the traveler will have to formulate a new plan. Where this does not work, the person may react as being lost (see below).

Routes to distant places may be planned only at a coarse level, but closer to target the planning will become much finer-detailed (in the same way that migrating birds' strategies shift from the general directional to the specific when arriving close to the familiar end of route).

Wayfinding strategies have been studied using a range of techniques. Verbal report protocols, whether given en route or in retrospect, may be vivid, but can only tell us of the processes people are aware of and can articulate. They can, however, demonstrate this two-stage process of an initial plan-formulation stage and a detailed plan execution, in which new and possibly unexpected features can be reacted to. Analysis of such protocols can also show that initially rational plans are often subverted by chance events and sightings en route.

Eye-tracking techniques will pick these attentional patterns as people travel a real or indeed a virtual route; and can be used in conjunction with protocols. Recent studies have added fMRI to this range of investigative tools; and together, they can track the moment-to-moment changes in the way environmental cognitions direct responsive wayfinding, adding to the stock of place-located knowledge as they go.

Such studies highlight individual differences in route planning and following. A small proportion of people report using cardinal directions; more use an egocentric frame of reference. Occasional individuals report planning the route back from the goal; more often, the plan is assembled from well-rehearsed segments, even if a novel route might have been more efficient. Studies of specialist wayfinders, such

as taxi-drivers, have used the full range of investigative techniques: their ability to produce highly detailed accounts of what they had been thinking during wayfinding can be corroborated by eye-tracking data.

Study of human spatial cognition should contribute to the design of buildings and local layouts which are more easily understood. Complex buildings such as hospitals and airports, which are multilevel and perhaps counter-intuitive, are likely to lead to wayfinding difficulties which good signage can only go part way to resolve, particularly if individuals are stressed or anxious at the time. Design guidelines might include architecturally unambiguous entry-points, after which there could be early open areas which enable users to survey the possible routes forward. Transitions between floors and areas should be clearly signaled, and distinctiveness planned in with a view to developing the newcomer's cognitive map of the area, perhaps with the aid of a well-designed and orientated 'You are here' map, to shape a new local cognitive map. Signage must then support and develop this information, be consistent, frequent, and comprehensible. There are implications for the signage of emergency exit routes: research indicates that under stress people do not so much panic as resort to more basic route-following strategies; and could well be better guided to safety by vocal instructions over a loud-speaker system.

'Being lost' has been studied by environmental psychologists advising police and rescue services, using case studies to show how people of different ages (and skills) are likely to react; and thereby psychology can suggest optimal search strategies. If the missing person is a child under 3-years-old in open country, for example, they may not even think of this as being lost: after a brief exploration of a small area, they are likely to find a local place in which to shelter, thus becoming hidden from searchers. In contrast, a more confident older child or adult is likely to travel much larger distances in attempting to return home, perhaps using faulty search strategies in their increasing alarm. During the preceding travel in a novel area, the landmarks may have only been sketchily encoded, and so the would-be returner may use falsely remembered cues, and travel considerable distances from their start.

The Legibility of Places

This section considers the concept of legibility and interpretability of buildings, areas, whole townscapes; and whether legibility can be a key link to the aesthetics of buildings and places.

Some environments are easier to cognize than others: the concept of legibility was introduced by the planner Kevin Lynch to describe this ease with which one can form a cognitive map of a city. Asking what makes a place legible, and analyzing the sketch maps drawn by residents, he suggested that legibility is facilitated by the presence and organization of five main elements:

Paths: the travel corridors of the city

Edges: features which limit or enclose districts (e.g., rivers)

Districts: subareas with common, distinctive features (e.g., architectural, functional)

Nodes: points of intersection of key paths

Landmarks: visible and distinct features (e.g., tall buildings)

The presence of such elements helps one to organize observations and knowledge of a city: by chunking it into districts, one can cope with possible information overload.

Cities that have a clear spatial structure and physical distinctiveness are easy to 'read,' enabling clear cognitive maps. But what of the link to aesthetic appreciation of places? Many places which are famed for their beauty do indeed have high legibility.

But there can be townscapes that are highly legible, yet which fail to engage our aesthetic or emotional response. In addition to Lynch's list, the architectural quality of the elements, the balance between simplicity and surprise, the level of visual and actual 'clutter,' and the presence of natural features, including water, have all been shown to contribute to the judgment of environmental quality. Level of upkeep, maintenance, and indications of care also contribute to the positive impression.

As an example of simplicity and surprise, a town which reveals itself straightway to the newcomer is adjudged less interesting than one which unfolds as one travels inwards; but beyond a certain level of complexity, this can become aversive and confusing. Similarly, the most positive aesthetic judgments of individual buildings can be shown to relate to an optimal middle range of complexity.

Formal aesthetics includes the idea of order and variables such as rhythm, complexity, and proportion. Symbolic aesthetics has been defined as "pleasurable connotative meanings associated with the content of the formal organization".

Many studies have shown that the presence of natural elements in a scene can evoke positive emotions, induce positive physiological conditions, facilitate cognitive functioning, evoke positive and prosocial behaviors, and help restore the individual. This is true whether the scene is experienced directly (walking through an area) or indirectly (viewed through a window, or even seen in a picture).

Restorative environments and scenic beauty may be linked. Kaplan's Attention Restoration theory states that exposure to restorative environments engages fascination or low-effort attention, promoting recovery and the opportunity to rest and reflect. In contrast, exposure to nonrestorative environments engages directed effortful attention and negatively affects mood, performance, and psychophysical well-being.

Eye movements are a way to measure attention when viewing a scene: they are unconscious adjustments to the demands of attention during visual experience.

Eye movements related to photographs low on fascination were characterized by greater exploration and a greater number of fixations compared to those rated high on fascination, though the viewing time was the same. Scenes high on fascination were viewed without really focusing on particular features. Differences in eye movements suggest that less effort is required to view nature than urban scenes, which is consistent with Kaplan's description of 'soft fascination'; which itself derives from William James' distinction between involuntary and voluntary attention.

Environmental Cognition Without Sight; and Devices for the Blind

Vision must be accepted as the most important spatial sense, for developing the cognitive map and for updating it as the individual travels. Yet blind and visually impaired people can become accomplished independent travelers using the other senses, sometimes supported by traditional and modern technological aids.

Some 30% of adults with visual impairments make no independent journeys out from their home; and many others only use a few set routes. Hence studying the cognitive maps of the blind, and their development, can have a social as well as academic purpose.

Early theories stressed Deficiency: stating that the congenitally blind would be unable to develop a general spatial understanding because they would never have experienced the necessary perceptual process: this has been experimentally discredited.

In contrast, Inefficiency theory argues that awareness from auditory and haptic cues will be less efficient than that from sight; and as a result, the blind will depend upon route-based rather than survey or map-like ideas for travel.

Much empirical evidence now supports the Difference theory, which proposes that visually impaired people possess the same abilities to process and understand spatial concepts, and that although functionally equivalent to the sighted, they are carried out in a different albeit often slower manner. Their spatial reasoning, like an internalized geographical information system, may combine image-based cognitions, which will hold relative positions of places within a frame; and language-based cognitions, which will code place a set of propositions.

For the sighted, much exploration is done visually, and a whole new scene generates a new local cognitive map, with all its implications for action. For the blind, usually much more exploration will be needed to gain information about a new place.

Mobility teachers working with blind children have described them as 'movement recallers' who have movement memories, rather than visual image memories. Their cognitive maps include the relative positions of objects (which act as local landmarks), and the routes leading to, around, or away from landmarks, are composed of movement memories.

Some individuals develop skills which enable them to achieve very accurate independent travel, using, for example, careful sensing of the position of walls. Others will rely on supports such as canes and guide dogs for their mobility. A whole range of higher technology devices are being developed: some of which are located out in the environment (e.g. acoustic beacons and 'talking signs'), others of which are handheld devices providing updatable local information. Attempts have also been made to translate visual information into haptic, to simulate the visual overview.

And tactile maps have been used for many years with great success to develop the blind traveler's spatial expectations of a new area; these can afford perhaps the most immediate sense of the layout and features of a place yet to be explored.

Individual, Specialist, and Cultural Differences in Environmental Cognition

Popular beliefs abound about differences between the sexes in spatial awareness and skills; similarly, claims have been made for special awareness among specialist groups (taxi drivers, orienteers, etc.); and for different cultural groups. What is the empirical evidence?

The most controversial is the issue of sex differences: there is evidence to support the contention that there is a relationship between some measures of spatial ability and the accuracy of cognitive maps. Males may frequently outscore females on spatial tasks which involve the mental rotation of abstract figures (and thus visualization), and on some table-top scale manipulations. But these may not translate into a real-world advantage, where wayfinding, map use, and place learning are involved. There are many spatial tasks where the sexes do not differ, or so substantially overlap that personal styles in learning and recall become more important.

How could we assess individual differences or gender differences? We should differentiate between wayfinding tasks and wayfinding means. Tasks include traveling to a previously known destination, exploration with the purpose of returning home, and traveling to a novel destination.

Means include oriented search, following a continuously marked trail, piloting (between landmarks), habitual locomotion, path integration, and reference to a cognitive map.

Truly individual differences do exist: there are a few people who perform at astonishingly high levels, and who can acquire surprisingly accurate metric knowledge relatively quickly, including relational knowledge about places between which they have not directly traveled. Could we train other people to gain a better cognitive map of the environment? What are good strategies adapted to people's existing strengths and experience?

For strategies seem to be key to understanding the acquisition of the exceptional spatial knowledge of a city by its taxi drivers and other specialists; and the heightened awareness of environmental cues developed by groups as various as prospectors, hunters, police, rescuers, hang-gliders, and divers.

The whole of the anthropological literature attests to similar sensitivities being developed in support of living in particular settings. Where these settings are especially challenging, then again a heightened awareness of subtle cues for wayfinding and resource-location can be seen as vital to survival. There are, for example, well-attested accounts of the sensitivity of Aboriginal peoples to individual rocks and plants as cues when traveling through the Outback of Australia; and of the Polynesian voyagers' heightened awareness of the significance of cues in the sea and the stars.

Electronic and Other Devices for Storing and Using Environmental Information

What impact upon the individual's environmental cognition have the various electronic devices for storing and presenting information? In-car satellite navigation and pedestrian

navigation assistance systems for wayfinding provide route-based information, generally without any survey context, and demonstrably reduce the user's spatial information processing to a minimum. Driving simulators and virtual travel via a computer screen are likely to offer something closer to real-world exploration; but still here, knowledge acquisition and the development of survey-understanding of places will be inferior, and indeed the less-realistic conventional map of a place will afford better survey and route knowledge.

Navigational assistance systems are nonetheless helpful and supportive for the newcomer, often providing a sequence of view-based (i.e., egocentric) visual images together with directions for travel. Maps, in contrast, offer an allocentric perspective, giving a survey model of place by requiring more active spatial information processing.

Navigating real spaces using devices, or navigating large virtual environments, will be optimized if we can link them to 'normal' human processing of environmental information and be aware of its limitations: virtual information environments that offer 3D representations, etc. can overwhelm many users' abilities to filter and represent. As a result, users frequently experience disorientation in navigating large digital spaces to locate and use information.

Conclusion: As we have seen, the cognition of the environment differs from the perception and cognition of objects, the usual focus of studies within psychology, in more than scale. It guides decision making about movement through space; it is linked with feelings and aesthetics, which in turn may be associated with personal well-being. Research in this area has potential benefits for professions as diverse as architecture, the design of virtual worlds, and the mobility instruction of the blind.

Glossary

Behavior setting A location that consistently evokes certain patterns of behavior in those who are present.

Crowding The experience of insufficient space; to be distinguished from density.

Density A physical measure of persons per unit area.

Personal space or interpersonal distance The physical distance component of interpersonal relations.

Place attachment, place identity A strong person–place bond that develops through long or intense association; the place becomes part of the self.

Privacy The process of regulating the amount of social interaction in which one is involved; can mean solitude-seeking but can also mean seeking company.

Programming (architectural) Planning buildings to meet the behavioral and psychological needs of those who will use them.

Postoccupancy evaluation Evaluating buildings to determine whether and how well the architectural program was executed.

Social design Architectural design that emphasizes inclusive, grassroots, democratic participation by those who will use the building; interior function and meaning are more important than exterior aesthetics and ornament.

Social dilemma A situation in which group and individual interests are in conflict, often applied to resource management situations; individuals are rewarded more for self-interest behavior than for group-interest behavior, but if most individuals choose self-interest, the resource is extinguished.

Territoriality (human) A pattern of attitudes and behaviors related to the perceived or actual control of a physical space, object, or idea; acts as a mechanism for the peaceful regulation of space use much more often than as a source of aggression.

Environmental psychology is the study of transactions between individuals and their built and natural settings. It assumes that the actions of persons change the environment and that their behavior, experience, and well-being are changed in turn by the environment. Environmental psychology includes basic scientific research aimed at understanding person–environment transactions and practice that applies this knowledge to improve human settings.

Background, Theory, and Method

As an organized discipline, environmental psychology originated in the late 1960s, but some social scientists had studied person–environment transactions for decades before that. Considering the enormous investment society makes in the construction and maintenance of the physical environment, including buildings, parks, and public outdoor settings, and its massive use of natural resources, the long delay before person–environment relations received adequate attention seems odd. However, many studies have dealt with the major topics within environmental psychology since the late 1960s. Much of this work has been stimulated by the recognition of environmental problems such as climate change, crowding, pollution, energy shortages, and unsuitable buildings.

Theories in environmental psychology are diverse. Some emphasize central psychological processes such as stimulation and control. The common occurrence of too much or too little stimulation is the focus of adaptation-level, arousal, overload, underload, and stress theories, which predict that a wide range of behaviors and experiences will be affected by one's level of stimulation. Other theories emphasize the importance of the

individual's real or perceived control over the environment (e.g., personal control, reactance, learned helplessness, and boundary regulation theories). The ecological approach asserts the importance of the behavior setting, a naturally occurring small-scale social–physical unit consisting of regular patterns of person–environment behavior (e.g., a household or a sporting event). Integral or holistic approaches (e.g., interactionism, transactionalism, and organismic theory) describe the complete interrelationship of persons and setting. Finally, the operant approach downplays abstract principles and prefers a direct problem-solving approach that employs behavior modification techniques to deal with problematic environmental behaviors.

Environmental psychologists recognize that person–environment transactions are influenced by many different factors, which has led to multiple paradigms for studying them. A strong preference for performing research in the everyday world means that field studies are common. Sometimes, laboratories and simulated settings are used, primarily when a field study is not possible. True experiments occasionally are conducted; they are desirable when a researcher seeks to isolate particular causes and effects. However, quasiexperimental research designs are much more common.

Environmental Perception

Environmental psychologists prefer to study the perception of whole, everyday scenes. In doing so, they sometimes must sacrifice a degree of experimental control, but in return they obtain data on the perception of real, complex settings through which the persons may move and feel a real connection. Perceivers select certain cues from scenes and ignore many others.

Unfortunately, some cues they ignore may be important, at least in the long run (e.g., air pollution's effect on health). Environmental perception has been studied using verbal reports, time-sampling, behavioral inference, phenomenological methods, and combinations of these.

The available evidence suggests that perceptions of qualities such as length and distance are largely dependent on the physical elements in the scene and how these elements are arranged. However, personal factors such as perceptual ability, finding a setting pleasing, culture (such as being raised in a 'carpentered' world), and training (e.g., in architecture) also affect the very way a person sees the world.

The theories of Egon Brunswik, James Gibson, and Donald Berlyne each have had major effects on the study of environmental perception. Each began as a traditional (nonenvironmental) theory, but contained the necessary seed to be fruitful for environmental psychology: an emphasis on properties of stimuli. They have provoked considerable basic research into the nature of environmental perception, but they have also been extended into the practical domains of city planning, park planning, and architecture.

Environmental Cognition

How do people think about and find their way around the space around them? They do not acquire, store, and recall information about locations, distances, and arrangements like cameras or copy machines. Yet, our ways of doing so usually are effective and rule-governed. Spatial cognition – the way we acquire, process, store, and recall information about everyday settings – is studied by examining sketch maps, model construction or manipulation, distance estimation, and naturalistic observation. It is affected by one's stage of life, familiarity or experience with the setting, and several cognitive biases. Two common biases are to envision places as more grid-like or Euclidean than they actually are, and to mistakenly employ larger geographical entities in placing smaller ones (e.g., Reno is thought to be east of Los Angeles because it is in Nevada, which is generally east of California, but Reno is west of Los Angeles).

The study of cognitive maps reveals that legible places are easier to comprehend: they have clear paths and distinct edges, districts, nodes, and landmarks. The spatial cognition of children generally develops in a sequence that progresses from egocentric to projective to abstract. The spatial cognition of older people often is limited by lowered mobility or sensory abilities, and they may perform less well. However, their memories of the environment are more personalized and are, in some respects, better than those of younger people.

Experience in a setting gives one a richer, better organized cognitive image of it. Both landmarks and paths facilitate the growth of place knowledge. Where one of these elements is more common than the other, examples of it will be learned first. Male-female differences in spatial cognition exist, but may largely reflect the different travel experiences of men and women. The environmental cognition of urban forms is improved by clear paths and visible landmarks. At the architectural level, buildings that are tall, free-standing, distinctively shaped, and used often are better recalled than others.

Environmental Appraisal

Environmental appraisals are personal, subjective judgments of places; they may or may not be consistent with most other people's assessments of the same places. Environmental appraisals take six forms: description, evaluation, aesthetics, emotional, meaning, and concern. First, environments may be verbally described in many ways; a talented writer probably is best able to describe any particular setting. However, researchers have tried to develop standard sets of descriptors to assist the average person to describe places.

Second, environmental appraisals take the form of evaluations. These are influenced by such personal factors as age, sex, and familiarity with the place and by such objective features as room design, congruity, contrast, and complexity affect evaluations.

Third, the aesthetics of environments may be appraised. Environmental beauty is the concern of activists, planners, experimentalists, and humanists. Landscape beauty has been shown to be largely a function of the prevalence of certain elements in a scene, such as bodies of water, types of vegetation, and mountains, and the apparent distance to and the placement of these elements in the scene.

Fourth, emotional response to the environment is another form of appraisal. Emotional responses to environments are usually mild, persistent, and cumulative rather than sharp and brief. Nevertheless, they are a complex mix of behavioral, cognitive, and physiological responses.

A fifth form of appraisal is the meaning assigned by a person to a place. Two kinds of this meaning are the building's communication of an architectural or philosophical concept and the communication of its purpose or function. Some buildings communicate, in this sense, to observers, more than others.

Finally, people appraise places in terms of their concern (or lack of it) for the place or the place's potential risk to themselves. This is a form of appraisal for which behavioral consequences are of particular importance.

Environmental Assessment

Environmental assessments are measurements of a place's qualities that aspire to objectivity; that is, they attempt to measure the way an entire population segment, such as visitors to a national park, experiences a place. Environmental assessments may measure a setting's physical and spatial properties, artifacts and objects, traits, behavioral occurrences, or social climate. For example, do visitors to a park as a group find the park 'natural' or 'beautiful' or 'a good place to fish'? In contrast to environmental appraisals, they are place-centered (rather than person-centered), aim to measure physical properties (rather than psychological properties), are more often policy-oriented (rather than oriented to the understanding of perceivers), and more often employ observers with an expert or frequent-user relationship to the place being assessed.

Environmental assessments may use technical or human means of observations. Each has its place; neither is necessarily more reliable or valid; each employs a variety of instruments (machines for technical environmental assessments, or TEAs), questionnaires, or rating forms for human observers.

Observer-based environmental assessments (OBEAs) have at least five purposes. They allow for comparisons between TEAs and OBEAs, assist in the development of physical measures of environmental quality, provide data on environmental quality trends from the human perspective, provide assessments of quality along dimensions with particular human relevance, and educate the staff of the assessed setting as to its strengths and weaknesses.

Environmental Personality

The study of personality may seem antithetical to environmental psychology if one assumes that environmental psychology emphasizes the effects of settings on persons. However, personality is part of environmental psychology.

Two early personality theorists are important for environmental psychology: Henry Murray and Kurt Lewin. Murray's personology introduced the concepts of alpha and beta press (the actual and perceived power of the environment to affect one's welfare), and internal and external proceedings (subjective and objective accounts of the initiation and completion of a behavior sequence). Lewin's field theory, which conceptualized persons as actively interacting with their environments in their life spaces, produced the famous formula $B = f(P, E)$. One's representation of the physical environment and some elements of the unrepresented physical environment (the foreign hull) affect one's behavior and experience. Lewin's action research concept, in which theory and application are fused, guides many environmental psychologists today.

Numerous modern systems for conceptualizing environmental personality have been described, but the most developed is the Environmental Response Inventory, created by George McKechnie. It assesses eight dispositions: pastoralism, urbanism, environmental adaptation, antiquarianism, stimulus-seeking, environmental trust, need for privacy, and mechanical orientation.

Some traditional personality measures also assist in the understanding of behavior that has environmental significance. For example, extraverts generally prefer smaller interpersonal distances and may experience less stress in higher density situations. Persons with an internal locus of control also prefer smaller interpersonal distances and tolerate high density better than those with an external locus of control.

Personal Space

Personal space refers to the interpersonal distance chosen during social interaction. It varies with and reflects the rise, current status, and decline of relationships. Alpha personal space is the objective distance between interacting individuals and beta personal space refers to the experience of that distance. Edward Hall described four zones of increasing distance that depend on the closeness of the relation between the two persons.

Personal space may be predicted in part from knowing an individual's characteristics. Males typically use larger distances than females. Young adults typically use more personal space than children. Interpersonally warm and nonanxious individuals probably have smaller personal spaces than others.

Psychological disturbance often leads to more variable or inappropriate personal space. These personal influences on personal space also have interactive effects: to predict a person's personal space choices accurately, one must know the person's age, sex, race, culture, and personality.

Social and physical features of the situation also affect interpersonal distance. Attraction, cooperation, and equal status are associated with smaller personal space; stigma and unequal status lead to larger personal space. People seem to prefer more space when the physical environment offers less room. These factors combine to produce interpersonal distances that are different from what would be expected from the consideration of each influence by itself.

Culture is a major modifier of interpersonal distance. Some evidence exists for a continuum that ranges from the closeness of Arabs and Latin Americans to the distance of English and Germans. But differences within these groups, occasional results that do not fit this neat pattern, and other factors such as the language one speaks during a particular interaction, all affect personal space.

The individual's acquisition of the rules concerning interpersonal distance are probably well characterized by social learning theory. The functions of personal space are described by numerous minimodels based on concepts such as comfort, protection, communication, stress, optimal stimulation, and affiliative equilibrium. The social penetration model emphasizes the role of personal space in the rise and fall of relationships. The limits-of-compensation model highlights the outer limits of interpersonal distance, showing that as discomfort grows, interaction becomes more difficult. The approach-avoidance model hypothesizes differences between the desire to draw close to someone and the desire to keep one's distance.

Human Territoriality

Territoriality is a pattern of behavior and attitudes held by an individual or group that is based on perceived, attempted, or actual control of a definable physical space, object, or idea. It may involve habitual occupation, defense, personalization, and marking of that space. Environmental psychologists recognize seven types of territory: primary, secondary, public, interactional, body, object, and idea. The seven types of territory may be infringed upon in at least three ways: invasion, violation, and contamination. In turn, territory-holders may utilize preventative, reaction, or social boundary defenses.

Personal factors, physical and social aspects of situations, and culture can lead to territoriality. For example, males generally manifest more territoriality than females. Defensible space theory argues that physical arrangements increase territoriality feelings and behavior and that this increase leads to a decline in territorial invasions. These physical arrangements may be at the block or neighborhood level (e.g., altering traffic flow) or at the house level (e.g., fences and plantings).

Territoriality appears to increase with three social factors: ownership compared to renting, positive social climate, and greater competition for resources. Cultures differ in their expression of territoriality, although the question whether some cultures are *more* territorial than others has not been clearly answered. Territoriality is associated with a variety of

behaviors and experiences: personalization, aggression, dominance, control, and attachment. Personalization and marking are very common, may occur with or without awareness, signal ownership but do not always lead to active defense, and seem to offer psychological benefits to the territory-holder beyond merely informing the world of a territorial claim. Popular writers have exaggerated the relation between overt aggression and territoriality in humans. Territoriality does facilitate control of spaces, but this is usually accomplished through passive means that do not involve overt bullying of others.

Place attachment is the experience of belonging to a setting. Place attachment is an important process involving some of the closest person–environment bonds that humans experience.

Theories of human territoriality remain diverse, speculative, and largely untested. Ethology, organizational behavior, behavior settings, brain structure, and conflict resolution are some of the disparate concepts that underpin theories of human territoriality. The main function of human territoriality probably is the maintenance of order and identity in everyday life.

Crowding and Population Density

Crowding is the unpleasant experience of spatial restriction, whereas density is a physical ratio of persons per unit area. Crowding and density are not always correlated with one another. The notions of social versus spatial density, indoor versus outdoor density, and proximity have been advanced as ways to refine the density ratio into a variable with more predictive power.

At the personal level, personality, expectations, and preference influence whether an individual experiences a given situation as crowded or not. Internal locus of control, high affiliative tendency, a tendency to screen unwanted stimuli, a preference for high density, and an expectation for low density upon entering a place predispose individuals to experience less crowding when density is high.

Social influences can worsen or ease crowding. Sheer numbers of others will sometimes, but not always, produce more crowding. If others are watching or touching an individual (particularly a male), or one is engaged in disliked activities, crowding is worse even when density is equivalent. Being left out produces more crowding stress than sharing space with another person who is compatible. Objective, accurate information about high-density settings reduces crowding.

Crowding is also affected by the physical surroundings. It is likely to be worse when density is higher, the building is higher, the corridors are longer, the ceiling is lower, the walls darker, and when sunlight rarely finds its way in.

High indoor density usually leads to physiological and psychological stress, at least for those who prefer larger interpersonal distances or are socially isolated. Performance may be harmed under high density when the task is complex, when others are watching, and when performers must physically interact to accomplish a task. When a person's expectations about density are unfulfilled, performance may suffer: performance may even be worse in low density if a person expected high density.

High density often has negative effects, but under some conditions – perhaps when individuals perform activities in which they are already competent – it may improve

performance, through social facilitation. Inescapable high inside density harms a wide range of social behaviors, particularly for men. Except in prison, those effects take more passive forms (e.g., lack of helpfulness) than active forms (e.g., aggression). High density may enhance humor, but it almost always creates negative emotion. High density reduces one's sense of control; as a result, a variety of coping mechanisms are used.

Privacy

A major goal of human social behavior is to regulate the amount of contact one has with others to suit one's current need for interaction, which may be high or low. Privacy essentially is about the regulation of access to oneself. This access may be interactional, as in control over who is allowed to be with whom, or informational, as in who is allowed access to archival information about whom. Privacy has four faces: solitude, intimacy, anonymity, and reserve. Conceptually, privacy may be considered as a preference, an expectation, a value, or a behavior.

Privacy is influenced by personal characteristics. For example, city-raised individuals prefer more anonymity and intimacy. Women seem to manage privacy in close groups by discussing more interpersonal and intimate matters and men often achieve privacy by removing themselves from the setting and talking less about delicate matters. Individuals who have greater-than-average privacy needs are less sure of themselves and more anxious. Members of different cultures are believed to have similar privacy needs but, depending on how the environment supports those needs, may fulfill those needs in different ways.

The physical setting also has important effects on privacy preferences, expectations, and satisfaction. For example, open space at work often breeds dissatisfaction, whereas at home it is usually preferred. Its physical influences are both immediate, such as the doors and partitions surrounding people, and less immediate, such as the distance between houses and the number of neighbors visible from one's house. Privacy attitudes and behaviors vary from setting to setting.

Those who know how to use the environment to successfully regulate their privacy may be more successful in areas of life beyond the social realm. Some individuals adapt to or accept situations that would seem to offer too much or too little social contact. Others faced with a shortage of traditional mechanisms of regulating social interaction develop creative solutions to the problem. As a key process in our dealings with others, privacy is inextricably linked to communication, autonomy, identity, emotional release, and growing up.

Irwin Altman's model of privacy as an optimizing boundary-control process dominates, but other theorists have contributed ideas. John Archea, for example, reminded us that privacy has a strong environmental component. Maxine Wolfe and her colleagues note that privacy preferences, expectations, and satisfaction vary over the life cycle. Eric Sundstrom observes that privacy needs vary as a function of status.

Home and Community Settings

'Home' is a rich personal experience that may develop in a residence, which is the physical setting. Residential satisfaction

is a function of person and residence characteristics. The more congruent the residence is with one's stage in the life cycle and role in the family, the more satisfied one is likely to be.

Moving house is one outcome of residential dissatisfaction; it is a source of stress in itself. Individuals who have little residential choice or do not enjoy new settings experience even more mobility stress. Privacy and crowding are the biggest problems, primarily as they harm child development. High-rises seem inappropriate for children.

Resident lifestyle is reflected in the physical organization of the home. Home is an important place to experience the growth and relaxation that leisure can provide. Neighborhood satisfaction is related to such physical factors as the availability of nearby green space, general upkeep, and noise. Yet, these factors interact to some extent with personal characteristics (e.g., screening tendency, perception of control, and one's residence type). Neighborhood social ties may be less important than they used to be, except for a few determined groups such as religious enclaves.

Cities are stimulating, but their impact does not constitute an overload for everyone. Individuals apparently adapt to some stressors (e.g., air pollution) more than others (e.g., noise), in the sense of no longer noticing them, although their health may suffer in the long term. Vandalism and street art are different in motive and expression: vandals destroy settings out of a sense of revenge, whereas artists enhance settings while expressing social concerns. Crime and fear of crime are also important urban problems that may be eased in part through the application of defensible space design principles.

Aggression increases with air pollution and with temperature. Sunshine combined with moderate temperatures seems to increase helping. Noise in the community reduces helping, unless the other's need is serious. Interaction among strangers on the street generally follows a minimax principle: minimize interaction, maximize order. Frequent exposure to the same strangers, however, leads to a kind of distant affection.

Environmental factors in shopping include store location and layout, the display of goods, ambient music and noise, lighting, and shopper density. Research in the retail environment has been slow to emerge. This may be because its commercial value means that researchers report their findings to corporate sponsors rather than to public-domain journals.

Most homes are threatened by one or more environmental hazards, some natural and others technological. In the precalamity phase, governments attempt to reduce risk through engineering and education, but when neither of these is effective, many lives are lost. Specific warnings and awareness-raising simulations can help, but effective personal action is often blunted by the human tendency to bounded (i.e., limited) rationality: underpreparation for impending disasters, hasty, sometimes inappropriate responses to hazard mitigation once the disaster occurs, and misperception of hazard risks.

During most disasters, individuals generally interact in relatively rational and cooperative ways; the exception is a disaster that traps people in a confined setting. The outcome of disaster is stress in many forms. Some forms of coping reduce some forms of stress better than others. Community attachment and economic factors often prevent residents from vacating high-risk areas; they would rather see governments engage in massive public works to protect their homes than leave.

Work and Travel Settings

Work begins with getting to it. Most research on this has been concerned with encouraging commuters to help save energy. Environmental psychologists have created demographic profiles of car and urban transit riders, devised models of commuter preference, provided positive information about urban transit, evaluated existing transit systems, and studied the effect of reducing fares. This research has not yet had a very large effect on society's automobile addiction, but the more promising approaches are being sorted out from the less promising ones.

Once at work, physical influences play many roles. Noise has many effects. In industrial settings, it can cause serious hearing loss. Loud noise is particularly dangerous when employees do not realize that deafness comes slowly and almost imperceptibly. Despite conventional wisdom that noise interferes with performance, research in natural settings shows how complex the issue is and that performance decrements depend on the task, the person, and the type of noise. Noise does harm performance under certain combinations of these, but not under others. For certain tasks, noise may even arouse a person enough to improve performance.

Noise is a serious problem in open-plan offices. Employees find sound a problem both coming and going: sound entering their workspace is annoying and when their own words escape over partitions too easily, their privacy is compromised. Office noise may even affect important interpersonal behavior, from mere impressions of others to important judgments regarding them. Music may improve performance of well-learned cognitively simple tasks. Employees naturally dislike noise but, for the most part, they like music on the job.

The effects of temperature are also usually moderated by access to heavier or lighter clothing. The amazing variety of temperature effects reported are due to these measurement and clothing factors, as well as many others, including the degree of acclimatization, a knowledge of coping strategies, motivation, and the type of work. Engineers have described precise 'comfort envelopes,' but environmental psychologists have discovered that comfort depends on perception as well as actual effective temperature and that optimal performance may be found outside the comfort envelope. Stress occurs when individuals are initially subjected to effective temperatures farther outside the comfort envelope, but many persons can adapt to these more extreme temperatures after a long-term exposure to them.

Lighting affects work behavior primarily when it is insufficient (leading to low productivity, accidents and eyestrain) or improperly placed (leading to glare and eyestrain). Lighting often is excessive in North American offices and many individuals dislike the newer forms of lighting, some of which distort color. European lighting standards call for lower levels of illumination. Carefully placed local lighting could resolve some of these problems. Access to natural light and views is psychologically important.

Employees are very sensitive to space and unhappy with many existing arrangements. Many open-plan arrangements reduce desirable communication and increase undesirable communication. Office arrangements lead visitors to form impressions of the office-holder's character and status.

Yet, many organizations restrict the degree to which employees may arrange or personalize their offices and fail to consult with employees when offices are planned.

The environmental psychology of travel is a new but growing area. Travelers affect destinations and are, in turn, affected by them. Anticipation, travel itself, and the recollection of travel involve environmental perception and cognition. Recreational travel is a trade-off between familiarity and risk, and between economic growth and environmental degradation, but as society is able to provide employees with more disposable incomes and time, it is a trade-off many are pursuing.

Some destinations bring relief from anxiety, others throw travelers into 'environment shock.' Travelers ruin some physical settings and enhance almost none. 'Romantic' tourism (i.e., the search for more and more unspoiled destinations) may be an undesirable luxury. A more careful planning of destination sites might spread the impact of visitors, offer more authentic experiences, and educate travelers while offering them solace from the working world.

Learning Environments

Both macro (e.g., school and campus design) and micro (e.g., desk and room design) physical features of learning settings affect learning and related activities. Students in large schools have a slight advantage in the variety of topics they can learn about but, partly because time at school is limited, students in large schools do not actually participate in more activities than students in small schools. Students in large schools more often learn and enjoy as spectators; students in small schools more often learn and enjoy as participants. In most areas of learning, students in small schools achieve more as a result of developing competence through direct involvement in activities.

If satisfied teachers are better teachers, then sensitive construction or renovations of their workplace (the classroom) should be undertaken when necessary. Students often perform better in the room where they learned the material. Noise interferes with learning both while it occurs and, if the learner is subjected to noise for long periods, even after the noise is gone. Noisy classrooms may impair the performance of girls more than boys, that of autistic children more than hyperactive children, and that of most children when the task is difficult. Noise may hinder performance by interfering with information processing, lowering the student's perception of control, and increasing blood pressure. To combat noise, instructors have changed their methods – sometimes sacrificing an otherwise good method for a quiet one – and successfully employed behavior modification techniques such as sound-activated electrical relays that control reinforcers such as radio music and extra recess time.

Incandescent lighting is preferred by many, but it is more expensive than fluorescent lighting. Fluorescent lighting has not been shown to have dramatic negative effects on the performance or health of most students, despite some claims to the contrary. As with noise, light's effects may be on specific subgroups of individuals; when studies of whole classes or schools are done, large effects on a few learners may be obscured by an absence of effects on most learners.

A few simple, direct relations exist between indoor climate and educational behavior; some combination of person and setting variables may enhance or reduce the influence of climate. Perhaps the best-supported conclusion is that student performance is best in slightly cool but not humid classrooms. Preferred environmental conditions may not be the same as conditions that facilitate performance.

The amount and arrangement of space in educational settings is important for classroom performance and behavior. High density may affect learning when the activity involves physical movement around the classroom, when learning is dependent on some classroom resource that is not increasing as fast as the number of learners, when a particular situation appears crowded to a particular learner, and when the concept to be learned is complex. Among preschoolers, high density alters the child's choice of activities. Educational benefits appear to accrue in classrooms that have the teacher's desk in a corner, carefully arrange and separate different kinds of activities, possess library corners, and are carpeted. Action zone seating (the front and central area of the room) benefits some students. All these findings depend in part on grade level and teaching style. Space in classrooms affects student and teacher feelings. Most students and teachers prefer lower density classrooms, because lower densities usually feel less crowded.

Increased social density leads to increased aggression and withdrawal when other resources, architectural features, and teaching style do not counteract it. Classroom arrangements should provide optimal stimulation. The proper amount in any given situation cannot yet be specified, but the student's need for stimulation, the type of activity, and the length of time spent in the activity must be considered.

Environmental competence involves learning about the environment. Three varieties of it include (a) one's personal style, attitudes, and awareness of physical settings, (b) knowledge of physical settings, including technical knowledge, how to unearth new information, knowledge about how social systems control space, knowledge of person–environment relations, and (c) practical environmental skills such as scouting, matching, personalization, and creative custodianship. Programs in and out of school teach many different facets of environmental competence, from basic environmental ethics to campfire starting to architectural design.

Architectural Psychology

One main purpose of environmental psychology is to use the foregoing knowledge to create more humane buildings. Some buildings are human disasters while others are merely persistent nuisances to those who occupy or use them. As described by Robert Sommer, social design is a way of creating buildings that fit occupants and users better by involving them in the planning process. It is needed in societies that have splintered the building creation process into many specialist roles. Social design is a remedy for the malady in which architects see themselves primarily as artists, ignoring the basic needs and activities of occupants. This malady is now widely recognized, yet many buildings are still constructed or renovated without significant user involvement. Social design aims to match settings to their occupants, to satisfy a variety of principal player

needs, to promote personal control in the building, and to encourage social support.

The design process includes programming, design, construction, use and adaptation, and postoccupancy evaluation. Programming consists of three phases: understanding the needs of users, involving them in the possibilities of design, and translating their needs into design guidelines, goals the actual design should achieve.

Turning these guidelines into plans and reality is the job of architects and construction companies. Later, the environmental psychologist returns to monitor user behavior and adaptation of the new building. Postoccupancy evaluation examines the effectiveness of the program and design, using a variety of social science tools. Together with programming, postoccupancy evaluation is perhaps the major activity of practicing environmental psychologists.

Resource Management

A major application of environmental psychology is to improve the management of nature and its many essential but limited resources. Each person on the planet manages a steady supply of natural resources that have been converted into products. Some of these resources come from limited sources called commons, that is, a pool of desirable materials that may be harvested by a number of individuals or organizations that share access to it. Commons *dilemmas* occur when harvesting of natural resources may proceed faster than the resource can regenerate; individuals must decide whether to maximize their own gain or the gain of the group, including themselves. The idea may sound abstract, but it applies to so many everyday situations (e.g., recycling, littering, energy conservation, endangered species, lumbering, fishing, pollution, etc.) that it is useful as a powerful general concept.

The quality of resource management depends on the resource itself, characteristics of the managers, and the rules governing the harvest. Cooperation seems to decline as the importance of the resource increases and to improve as the resource is depleted – two ominous signs.

The results of many studies suggest that when a commons dilemma exists, part of the resource should be allocated to each participant to manage, that friendship and trust should be encouraged among the harvesters, that the number of harvesters should be kept small, and that harvesters should communicate, make public choices, and be subject to punishment for selfish decisions, although positive incentives for cooperation are even more effective. Further, harvesters should be given experience operating the commons, be required to make minimal contributions where they are suitable (e.g., in commons dilemmas where the harvesters must donate to keep the resource alive), and have the altruism in the commons pointed out to them. Last but certainly not the least, payoffs for cooperation should be increased as much as possible.

Several theories of social dilemmas have been described. Limited processing theory postulates that most individuals act

selfishly, not because they are evil but because the dangers of defection simply do not occur to them. Tragic choice theory maintains that self-interest cannot be overcome except by the creation of a very strong central authority; this is unpleasant but necessary for the survival of the commons. Social trap theory applies a reinforcement perspective to social dilemmas, suggesting that better management of the commons would follow from a restructuring of reinforcements. Equity theory emphasizes the importance of perceived equity in resource allocation. Cooperation may increase if participants believe others are receiving goods in proportion to the effort invested, no more and no less. But this can still lead to the extinction of a commons: if everyone works hard and harvests equally hard, depletion will occur, so equity alone is not enough.

Two social dilemmas are pollution and energy use. Pollution is a 'give-some' form of social dilemma: individuals or organizations profit by using resources, but degrade the commons with the by-products. Energy use is a social dilemma when it is easier to waste energy, particularly from nonrenewable sources, in the service of a short-term goal than to conserve it for the future. Important savings could be achieved in ideal conditions, which would include an integration of psychological, economic, and engineering contributions. Conservers include those with enough money to purchase energy-saving devices so they can save over the long haul, those who must conserve because they cannot afford much gasoline, air conditioning, or fuel oil, those who have adopted a voluntary simplicity lifestyle and feel a personal responsibility for energy problems, those who are willing to make moderate public commitments toward energy conservation, and those whose energy use is monitored and frequently fed back to them.

Conservation may be enhanced by some appeals from authorities. Educational campaigns seem to change attitudes, priming individuals for changing behavior, but do little to change behavior by themselves. Feedback and goal-setting approaches have achieved significant savings. A housing development that integrated several design innovations with a group of ecologically oriented residents will approach the upper limit of 50% energy savings.

Episodic and Semantic Systems of Autobiographical Memory

D R Beike and J W Ransom, University of Arkansas, Fayetteville, AR, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Coherence The motivation for specific autobiographical memories to fit with abstract beliefs about the self.

Conjunction errors Memory errors in which one or a few details have mistakenly been confused with details from the memory of a different incident.

Correspondence The motivation to recollect accurate autobiographical memories that actually reflect the real state of the world.

False memory A memory that feels veridical but represents an incident that the rememberer did not in fact personally experience.

Flashbulb memory When an incident that is unexpected and highly emotional produces a memory that the rememberer feels is unusually detailed and accurate despite the passage of time.

General (or semantic) autobiographical memory A memory for either a personally experienced event that extended over several days or longer, or of a number of similar experiences summarized.

Hyperthymesia A memory syndrome characterized by extraordinary ability to recall specific incidents from one's personal experience and a tendency to spend large amounts of time thinking about such experiences.

Involuntary (intrusive) memories Specific life event memories that come to mind without volition; if their occurrence is bothersome, they are called intrusive memories.

Overgeneral memory A tendency to recall general multiday memories in response to a cue or request to produce a specific memory lasting 1 day or less.

Specific (or episodic) autobiographical memory A memory for a discrete, personally experienced event that lasted 1 day or less.

Specific autobiographical memories are memories of discrete life experiences that occurred in a specific time and place, usually lasting 1 day or less. Recollection of autobiographical memory involves a sense of reliving the experience, known as mental time travel. Autobiographical memory is used to establish a sense of personal continuity and identity, to form social bonds, to solve problems, and as the basis for projections of one's future. General knowledge of the self and acts of remembering are inextricably intertwined. This article considers both the structure of autobiographical memory as well as the processes involved in recalling them. In the first section, two theoretical frameworks for autobiographical memory structure are discussed. Second, basic memory phenomena which occur within this underlying memory structure are discussed. Third, the manner in which general knowledge about the self is maintained and updated is discussed. And finally, the failures of both general self-knowledge and specific autobiographical memories to accurately depict reality are discussed.

Episodic Versus Semantic Autobiographical Memories

Autobiographical memories and self-knowledge are two types of remembered information about the self. Most theories of autobiographical memory make reference to both of these types of self-relevant memory; that is, not only the memory for specific discrete episodes, but also larger units of self-knowledge. Two popular theories for the structural organization of broad self-knowledge and discrete autobiographical memories are addressed here.

The first theoretical approach, proposed by Endel Tulving, makes a clear distinction between semantic and episodic memories. General self-knowledge (e.g., being an introvert) is

abstracted from numerous specific memories to form a semantic memory about oneself. This semantic self-knowledge is represented in much the same way as semantic knowledge of the Civil War, which of course we never personally experienced. The recollection of semantic self-knowledge is accompanied by the experience of noetic awareness, a sense of knowing the information. Specific autobiographical memory, on the other hand, is represented with a high degree of detail as an episodic memory. The recollection of episodic memories is accompanied by the experience of autonoetic awareness, a sense of remembering in the sense of mentally reenacting the experience.

However, semantic self-knowledge might be stored in an independent semantic system or could be 'computed' from episodic memories during the recall process. Although this has been a controversial topic within certain scientific circles, research evidence has accumulated in support of the former option, showing that semantic and episodic self-knowledge are independent systems. Evidence for two independent memory systems has been provided in two veins of research: priming studies and case studies of amnesics. Klein and Loftus have demonstrated that the semantic system can be primed without affecting the episodic system and vice versa. Additionally, their research with a particular temporarily amnesic patient demonstrated that complete loss of episodic memory functioning does not impair memory for semantic self-knowledge.

In fact, this theory of distinct semantic and episodic systems is consistent with findings from multiple case studies in which patients with severe amnesia cannot remember detailed events at all, yet remain aware of general self-knowledge. Case studies with humans experiencing hippocampal damage, as well as studies with hippocampal lesions in rats, have demonstrated that the hippocampus plays a necessary role in memory.

Although memories are not actually stored in the hippocampus, it provides a sort of road map of other regions in the neocortex that must be activated to reexperience an event. Therefore, the hippocampus activates other regions to provide retrieval. Some researchers have suggested that semantic memory can be intact following hippocampal lesions because much of the information 'mapped' in the hippocampus has been overlearned and therefore represented in other brain regions surrounding the hippocampus. In short, semantic self-knowledge may be abstracted from episodic memories in the hippocampus.

Despite being distinct, these systems are believed to interact in normal memory functioning. When unique events are remembered they are stored in the episodic memory system, but as these unique event memories are joined by similar memories they may be abstracted into semantic self-knowledge. Therefore, when trying to recall an instance of behavior consistent with the self-concept, participants will often recall a broad semantic memory (e.g., 'I was always introverted in high school'). Conversely, when recalling an instance of behavior inconsistent with the self-concept, participants will often recall a detailed episodic memory (e.g., 'I remember going to a party on Halloween and being more extroverted than normal'). In theory, these separate yet interacting memory systems have evolved to allow fast, efficient recall of traits while also allowing this trait knowledge to be modified as new events demonstrate a consistent theme.

The second popular theory of autobiographical memory called the self-memory system is composed of the *working self* and the *autobiographical memory knowledge base*. The *working self* is a temporary activation of current goals which constrain the search for elements to be bound up in the memory. For example, a person trying to recollect his final exam in chemistry to help him study for an upcoming exam may be likely to include behavioral elements about his preparation before the exam. But a person trying to recollect the same memory to help him remember where he left his pen may be likely to include spatial elements about the location of the room. The self-memory system acts to construct memories consistent with current goals and the current sense of self, and to inhibit memories that are inconsistent.

These autobiographical memories are constructed by drawing from episodic (*event-specific knowledge*) and semantic (*long-term self*) components. Event-specific knowledge contains records of the microdetails of everyday experiences, which are quickly lost and become unorganized without ties to the long-term self. The long-term self is composed of a *conceptual self*, abstract beliefs about and traits of the self, and the autobiographical knowledge base, consisting of lifetime periods and general events. Unlike Klein and Loftus' distinction, however, the self-memory system posits a hierarchical arrangement of these episodic and semantic components, with lifetime periods (such as 'school years') at the most general level, general events (such as 'taking exams') at the intermediate level, and specific memories (such as 'final exam in chemistry 101') at the most specific level. Accordingly, the hierarchical arrangement must be navigated every time a specific autobiographical memory is recalled.

Based on the self-memory system theory, researchers have distinguished specific autobiographical memories, defined

as an event which occurred in a single day, from general autobiographical memories, which include events lasting longer than a day and categories of repeated types of events. Specific autobiographical memories are the result of successful generative retrieval, while general autobiographical memories are the result of a failed hierarchical progression from general memory traces to specific memories. For example, when asked to recollect a specific life experience involving the words 'ice cream,' a person may respond with 'I used to eat ice cream a lot after soccer practice' rather than the more specific 'I ate an ice cream cone during the fireworks display last fourth of July.'

The tendency to fail in attempts to recollect specific memories is known as *overgeneral memory*, and it is found in clinical populations (including those with major depressive disorder, posttraumatic stress disorder, and Parkinson's disease). However, some research has applied the same definition of specific and general autobiographical memory to the nonclinical population. Among other factors, a lack of executive resources has been shown to impede the hierarchical progression from general lifetime periods to specific autobiographical memories. In theory, people experiencing overgeneral memory are cognitively unable to move beyond the initial stages of autobiographical memory construction and therefore fail to proceed from the working self and abstract self-knowledge about lifetime periods to the specific details that will be bound to form a memory.

Therefore, one theory considers general self-knowledge to be stored independent of specific autobiographical memories, while the other considers general self-knowledge to be the first step in ultimately recalling a specific autobiographical memory. Despite the differences in terminology and research method, the need to distinguish specific autobiographical memories from some more general representations is a common thread among many theories. The conditions under which and the ways in which these two systems interact are explored. However, the basic features of remembering specific autobiographical experiences are first delineated.

Basic Phenomena in Autobiographical Remembering

Process of Construction

Like all forms of long-term memory, autobiographical memory is reconstructive rather than reproductive. The rememberer constructs a memory anew each time rather than reproducing a static representation. In the case of autobiographical memory, the process of construction involves a large number of brain areas and can extend up to 20 s in time. Most instances of autobiographical remembering begin with a voluntary search based on a cue or probe (e.g., 'When was the first time you saw your current favorite movie?'). People often begin by identifying a time period in their life during which the sought-for memory may have taken place (lifetime period, such as 'high school'), then they find generic examples of similar memories (general event memory, such as 'going to the cinema with friends'), and finally identify specific episodic memory traces that contain the elements of the desired memory (specific event memory, such as 'seeing *Titanic* with Belinda and crying at the end').

Indeed, studies using a think-aloud protocol demonstrate that people usually begin their search for a specific autobiographical memory by identifying a lifetime period or a general event type first. Brain imaging studies also verify the involvement of different regions of activation over time. The construction process begins with what appears to be the working self's activation in the left frontal lobe. The working self generates retrieval cues, then begins to activate relevant elements of the memory in the posterior temporal lobes and occipital lobes, which contain the specific features of relevant episodic memories. The elements of the autobiographical memory can include sensory (especially visual), spatial, emotional, linguistic, and narrative components. The initially activated areas in the frontal lobes and the activated sensory areas in more posterior portions of the brain are then bound together by the medial temporal (hippocampal) area. This precise pattern of neural activation is marked by the subjective experience of autobiographical recall.

Moreover, the search for elements to bind into a memory often begins by identifying an abstractly represented lifetime period in which to search. Frequent rehearsal of semantic and episodic memories is used to maintain *coherence* of the *long-term self*. Furthermore, the constant retelling of stories about the self is often biased and can lead to memory errors. Thus, both temporary and more permanent notions of the self guide autobiographical memory construction.

Amnesia and Hyperthymesia

Although virtually everyone develops the ability to recollect life experiences, there are extreme cases of those who can recollect almost nothing (amnesics) and those who can recollect almost everything (hyperthymesics) of their life experiences. The noted patient HM (Henry Molaison), for example, was unable to record any new memories of life experiences after the surgery that removed his hippocampi as well as his amygdalae and parts of the surrounding temporal cortex. Moreover, Henry Molaison was unable to recollect any autobiographical memories from several years before the surgery. Clive Wearing, who suffered hippocampal damage due to a viral infection, has similarly been unable to record memories of life experiences since his illness, and has few or no autobiographical memories from before his illness. Yet both Henry Molaison and Clive Wearing retained their knowledge, intelligence, working memory ability, and implicit memory skills, demonstrating the separation of autobiographical memory from other forms of memory.

At the opposite end of the spectrum are those whose lives are overfull of autobiographical memory. Jill Price contacted memory researchers for help understanding her inability to forget her life experiences and her obsession with remembering past events. Extensive testing revealed Price's virtually perfect autobiographical memory, but fallible memory for other types of information. Price's autobiographical memories come to mind unbidden and dominate her internal mental world. A handful of others with virtually perfect autobiographical memory have been identified, including Brad Williams, who can also provide detailed memories of his experiences for any given date. The two qualities of superior recall of autobiographical events and a great deal of time spent thinking about them define *hyperthymestic syndrome*.

Like amnesics, hyperthymesics show a disjunction in their ability to remember individual life events as compared to other forms of memory; they usually have average or even below-average working memory, memory for word lists, and so on. Moreover, there is some evidence of larger-than-average structures in the prefrontal cortex of hyperthymesics. Episodic autobiographical memory therefore seems to be distinct from other memory systems.

Involuntary Autobiographical Memories

In addition to the deliberate hierarchical process of autobiographical memory construction described earlier, there is also an unintentional and automatic process of autobiographical remembering. These *involuntary memories* tend to be more specific and more highly emotional than voluntarily retrieved memories. The best-known type of involuntary memories consists of flashbacks or *intrusive memories*, which occur in people who have experienced a traumatic event. Although bothersome intrusive memories are associated with psychopathology, most involuntary autobiographical memories are benign. They occur several times per day in the general population of adults and are twice as likely to be positive as negative in content. For example, a glance at a pond on the side of the road while driving to work might trigger an involuntary memory of swimming in a pond as a child. Such involuntary memories are especially likely during episodes of mind wandering.

Lifespan Distribution of Autobiographical Memories

The complex process of autobiographical remembering develops rather late compared to other types of memory. Infants and toddlers remember facts and procedures, but autobiographical memory ability has a later onset around age 3 or 4. The inability to remember life experiences before this age is called *childhood amnesia*. Adults do not explicitly remember life experiences that happened before age 3 or 4, even if those experiences were explicitly remembered at that time in childhood.

Autobiographical memory assumes its full adult-like form much later in adolescence, when a more complete life narrative develops. A life narrative includes themes and key scenes that express concerns central to a person's sense of self and therefore provides a sense of a coherent and unified life. The adolescent period of life during which the life story develops retains a psychological importance throughout adult life, as revealed in the *reminiscence bump*. For people of middle adulthood age or older, the retention curve for autobiographical memory is a nonmonotonic function, with no memories until about age 3, a small number of memories of the childhood years, a large number of memories from the adolescent years (the *reminiscence bump*), a moderate number of memories from the rest of adulthood, and the greatest number of memories from the most recent year of life.

Maintaining and Updating Semantic Self-Knowledge

We may gain self-knowledge by reflecting on the meaning of behaviors and experiences stored in memory. People indeed report using autobiographical memories in this way

to establish and maintain identity. Yet general autobiographical memories are more directly linked to the self than are specific autobiographical memories. For instance, those motivated to think of the self as introverted will bring to mind more general than specific memories of introversion. Therefore, general autobiographical memories and semantic self-knowledge seem to involve the same system. Specific autobiographical memories, on the other hand, may or may not feed into one's sense of self and therefore represent a separate system of knowledge.

The independence of the episodic and semantic autobiographical memory systems allows for recollection of specific autobiographical memories that may be seen as having little or no relationship to what one is like in general. After all, if one's concept of the self shifted every time a specific autobiographical memory came to mind, the results would be an unstable and therefore potentially unhealthy self-concept. One way of allowing stability in the self is to cordon off particular autobiographical memories as irrelevant for the self. A number of memory and narrative mechanisms are used to make a memory feel less central to the self. For example, the rememberer may make the memory feel distant from the self by assigning to the experience a feeling of subjective temporal distance, or a subjective sense of psychological closure, or no prominent place in his or her life story. To provide stability in the sense of self, such mechanisms may be employed regularly, or self-irrelevant memories may simply be recollected infrequently. Such 'cording off' processes do not represent an unhealthy repression; the information is explicitly remembered, but simply seen as irrelevant for the self.

When autobiographical memories do influence self-knowledge, they do so through one of two processes. One is a conscious decision process of *self-perception*. Sometimes people examine individual event or behavior memories and consider the situation in which they occurred, to come to a conclusion about what they are like in general. Such a self-perception process may explain the effectiveness of the foot-in-the-door influence technique. Starting with a small request, to which an unknowing target agrees, leads to a greater tendency to acquiesce to a large request. The target seems to reflect on his or her earlier decision to comply with the small request and to infer that he or she must be the type of person who likes such things. Thus, the large request is seen as consistent with the new view of the self.

In fact, this self-perception process may build upon itself, as memories can influence not just inferences but also behavior. For example, recollecting an autobiographical memory about donating to charity led to a greater number of charity donation behaviors than a no-memory control condition. The specific memory not only suggests an inference about the self, but may also direct behavior toward a similar inference that serves to confirm the conclusion about the self.

In addition to this conscious self-perception process, people also acquire general self-knowledge through a second process in an online fashion as informative experiences occur. Instead of a constant process of conscious self-perception, a gradual updating of self-knowledge may occur automatically with each additional episodic memory of an experience. This process feeds into an implicit rather than explicit view of the

self. Implicit self-knowledge influences behavior, but it tends to be related to specific emotional autobiographical memories that may or may not be related to explicit self-knowledge. In this way, people may maintain a fairly accurate view of the self implicitly, which may or may not accord with the way they describe the self explicitly.

Although autobiographical memory allows both conscious and automatic updating of self-knowledge, self-knowledge can survive to some degree in the absence of autobiographical memory. Amnesics usually maintain a sense of self over time, although certain aspects of it are disrupted. For example, one amnesic man claimed to be 19 years old when he was actually 49, because his brain injury occurred when he was 19 and he could not properly update his sense of self in terms of his age. Still, amnesics feel they are the same person from moment to moment rather than being in a constant state of self-redefinition. Indeed, general self-knowledge is retained despite an inability to access the specific episodes that may have originally defined that belief about the self.

On the other hand, those with a surplus of autobiographical memories may have difficulty maintaining a stable sense of self. The hyperthymic Jill Price describes her concept of herself not as a unitary and persisting entity, but as a series of separate selves nested inside one another like Russian dolls. Rather than seeing oneself as being a slightly different person in different roles and situations like most people do, Jill Price seems to see herself as being a slightly different person with each episodic memory experience. Perhaps when episodic self-knowledge is abundant and highly accessible, it overrides the usual tendency to defer to semantic self-knowledge. In summary, autobiographical memory serves as an input to self-knowledge, but only under certain conditions. In order for explicit self-knowledge to be altered by recollecting an autobiographical memory, it appears necessary for the rememberer to make a conscious inductive inference that the memory exemplifies something larger about the self. The pressure toward stability in the self makes such inferences unlikely. It is telling that people report using autobiographical memory to maintain a continuous sense of self rather than to learn new information about the self.

Coincidental and Motivated Autobiographical Memory Errors

As independent but interacting systems, episodic and semantic autobiographical memory often influence each other. As previously mentioned, the memory construction process can be biased and lead to distortions. The pressure toward *coherence* might therefore introduce error into either or both types of self-relevant memory. Indeed, research has demonstrated that semantic self-knowledge is not entirely accurate. Attempts to test the accuracy of self-knowledge have compared self-knowledge to objective behavior, self-knowledge to the perceptions of others, and perceptions of others to predictions of others' perceptions. A moderate correlation between self-reports of personality and objective real-time measures of behavior indicates that people are somewhat accurate in their self-knowledge. In fact, people's perceptions of some types of behaviors can be quite accurate, while their perceptions of

other types of behaviors are often inaccurate. For instance, people are quite accurate at reporting their behavioral patterns involving watching television and listening to music, but are relatively inaccurate at reporting their behavioral patterns involving attending class and spending time alone.

Relative to the perceptions of others, semantic self-knowledge is fairly accurate. The correlation between others' perceptions and self-knowledge is especially high for close acquaintances. Interestingly, people are quite accurate in guessing what other people think of them. Their estimates of others' perceptions accord more with reality than do their judgments of themselves.

In comparison to the evidence for accuracy of semantic self-knowledge, evidence for the accuracy of specific or episodic autobiographical memories is more impressive. In one study, 90% of small details such as location and people who were present during everyday events were accurately recalled after 3 months. In another study, 95% of everyday events recorded in a diary were recognized 6 years later, and all of them were remembered when additional prompts were given by others who were present at the time of the events. In other words, relatively few life experiences appear to be forgotten entirely, especially when reminders are provided.

But being able to remember everyday experiences does not imply that specific autobiographical memory is without errors. Because the construction process occurs anew at each time of recollection, it is not uncommon for elements that do not actually belong to that life experience to be bound into the memory. These are known as *conjunction errors*. For example, a rememberer may mistakenly bind memory features about Santa Fe into her memory of a conversation she had with her husband because she is convinced that it occurred during a vacation in that city, when in reality the conversation in question occurred in a different city entirely. Conjunction errors probably occur frequently; in one study, 44% of descriptions of events from participants' own diaries, altered to include details from other events, were accepted as true after only a month's delay.

Moreover, pressures toward coherence of memories with beliefs about the self can lead to distortions in and motivated forgetting of specific autobiographical memory. People preferentially forget and distort their memories such that individual events are seen as more positive in outcome, or events with unflattering implications for the self are poorly remembered. For instance, people remember feedback about their performance to be more flattering than it was, or may simply have a difficult time recalling such feedback. Due to shallow processing at the time of encoding, self-enhancing memories come to mind more quickly and easily than self-deprecating memories. People also report more difficulty in bringing to mind memories of incidents inconsistent with a momentarily desired view of the self. Furthermore, people psychologically push away negative memories and pull forward positive memories, by remembering them as occurring relatively further or closer in subjective time.

Memories of experiences that threaten the desired view of the self may be subject to motivated forgetting. Laboratory evidence shows that people may choose to cease retrieval of unwanted memories; with sufficient practice, this retrieval suppression leads to the desired forgetting. The mechanism

involved is similar to that used to inhibit motor responses, but is directed toward the hippocampus and amygdala. In short, knowledge of the self constrains each act of autobiographical remembering such that memories congruent with semantic self-knowledge (especially desired self-knowledge) are more accessible.

A more serious type of inaccuracy than a memory with some inaccurate details or even a forgotten experience is a *false memory*, meaning a memory that exists in the absence of an underlying actual experience. False memories are unlikely to be detected in studies of everyday autobiographical memory because researchers cannot know which of an infinite possible number of experiences that did not happen to a person might be falsely remembered. False memories may develop due to suggestions of other people. For example, one friend may convince another that he was present at a party he in fact never attended but only heard about afterward. With enough prompting, the friend may eventually come to hold a fully detailed false memory that is difficult to distinguish from a real memory.

False memories may also develop due to confusion of fictional experiences with reality. For example, former US President Ronald Reagan misremembered having made films of Nazi concentration camps during World War II, apparently confusing in memory his work on similarly themed films with a real experience. Self-knowledge derived from false autobiographical memories or from memories containing flagrant conjunction errors is therefore likely to be inaccurate. Fortunately, few autobiographical memories are completely out of line with actual experiences; instead, most exhibit a good degree of *correspondence* with objective facts.

Sources of Inaccuracy in Episodic and Semantic Autobiographical Memory

How, then, can semantic self-knowledge be only moderately accurate, but autobiographical memory be quite accurate? One answer is that semantic self-knowledge comes from sources other than autobiographical memory, some of which may be more biased than autobiographical memory (e.g., feedback from others). A second answer is that even semantic self-knowledge derived from the most factually accurate specific autobiographical memory is subject to bias and inaccuracy. Three potential sources of inaccuracy in inferring semantic self-knowledge from episodic autobiographical memory are considered here.

One source of inaccuracy is that any given autobiographical memory is but a single exemplar that occurred in a given context. Thus, it may be more a product of the situation than of the person (oneself). If the perceiver fails to acknowledge the role of the situation, he or she will come to an erroneous conclusion about the self. People sometimes simply lack information about the cause of their behavior. For example, male participants unconsciously primed to have a goal of affiliation with females were more likely to choose a female than a male tutor, but they mistakenly inferred a greater dispositional interest in the topic being taught by the female tutor rather than accurately inferring that they chose her due to a motivation to affiliate.

Another source of inaccuracy is that a rememberer may not take into account the degree of representativeness of a given autobiographical memory of the general trend of one's behavior. All of us have moments of joy and moments of sorrow, memories of success and memories of failure, and times we were in control and times we fell apart under pressure. Focusing on only one memory and using it to draw an inference about the self in general may represent a failed inductive inference. A rememberer would need to search for multiple memories of, say, a particular personality characteristic and its opposite, to determine the representativeness of a particular memory of her behavior repertoire in general. When making inductive inferences, people are unlikely to be even-handed in this way. In fact, they are influenced by the subjective ease with which autobiographical memories implying a particular trait come to mind rather than the absolute or relative number of memories they can generate. Ease of retrieval is biased by factors other than the actual frequency of memories, such as the vividness of the memory or the demands of the recall task, leading to biased interpretations of the meaning of a given memory of the self.

A final source of inaccuracy is that an autobiographical memory may be over- or underweighted as a source of self-knowledge, depending upon a variety of memory-based factors that may have little to do with its actual diagnostic value. For example, an autobiographical memory visualized from the third-person or observer perspective, in which one can see oneself in the image, is seen as more revelatory about the self than a memory visualized from the first-person or actor perspective. Yet it is not difficult to switch from one vantage point to the other in memory, and it is arguably irrelevant for the implications of that memory for the self. Is a person truly more dishonest if he visualizes himself in a memory of having lied to a coworker than if he visualizes that memory from his original first-person viewpoint? The behavior is the same, so it should be seen as having the same implications. But a structural alteration in the momentary construction of an autobiographical memory may cause a shift in self-knowledge (appropriately or inappropriately).

Are self-relevant memories immune to the distortions and errors discussed above? Generally, self-relevance increases the likelihood that information will be retained, but it also provides motivation to distort that information toward the desired view of self. Research on memory for everyday events suggests that those that involve the self to a greater degree are better remembered months later. But few such everyday events are sufficiently important or threatening to produce distortion or forgetting.

Memory for important and highly emotion-evoking life experiences has been studied in a number of different guises. One type of such memories is a *self-defining memory*, considered central to the sense of self and crucial to one's identity. Given the central role of self-defining memories in identity, one would expect them to remain fairly stable over time. However, the set of memories considered self-defining changes over time. Even across a 2-week interval, two-thirds of the participants in a particular study chose a different memory as self-defining. Moreover, the affective and motivational effects of recalling a self-defining memory are only moderately consistent over the course of several weeks to months, suggesting

some degree of flux in the components and potentially in the accuracy of such self-defining memories.

Another line of research about self-relevant experiences is that on *flashbulb memories* for surprising and upsetting major events, such as the 9/11 terrorist attacks. Flashbulb memories are vivid and feel accurate and unchanging to the rememberer. However, research on flashbulb memories demonstrates that these feelings are illusory; such memories are no more accurate or consistent over time than ordinary memories. In fact, compared to other memories, memories stored under conditions of intense emotion have been found to be more accurate in their central details but less accurate in their peripheral details. These 'tunnel memories' occur for intensely negative but not intensely positive experiences. But if an important, emotion-evoking life experience is not just negative but actually traumatic, the memory for that trauma may be more consistent over time than memories for positive experiences. Thus, it remains unclear whether autobiographical memories for self-relevant experiences would generally be more or less accurate than those for nonself-relevant experiences.

In summary, semantic self-knowledge and vivid episodic memories are relatively accurate, but are far from perfect copies of reality. Additionally, the motivation for coherence between self-knowledge and autobiographical memory tends to impair memory for experiences that challenge one's view of the self, and may distort memories toward consistency with deeply held beliefs about the self. Moreover, even perfectly accurate individual memories may not provide accurate self-knowledge, as such memories may be incorrectly recognized as unrepresentative or underweighted due to an incidental first-person perspective in the memory. More accurate self-knowledge may be gained by considering additional sources of information beyond autobiographical memories, especially the knowledge of others who know us as individuals and of psychological scientists who strive to understand us collectively as human beings.

Conclusion

The story of one's life is central to the experience of most adults. As we move through life collecting and ordering the life experiences we choose to include in that story, we also struggle to attain and to defend our self-knowledge. The two processes – remembering specific life experiences and having abstract knowledge about oneself and one's life – are tied in many ways. Yet neuropsychological and behavioral evidence demonstrates that the two processes are separable. Major differences in the two systems are that semantic self-knowledge is more stable, more accessible, and more resilient to brain trauma than are episodic autobiographical memories. Episodic autobiographical memories appear to be more veridical than self-knowledge. But it is difficult to remember life experiences without the distorting lens of self-knowledge. Semantic self-knowledge intrudes into autobiographical remembering to provide a sense of coherence between the two. However, there is a countervailing need for correspondence: accurate knowledge of the world. The two systems of autobiographical memory operate to fulfill both needs simultaneously.

Episodic Memory

G Gillund, College of Wooster, Wooster, OH, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Anoetic Not knowing. One is not aware that memory is being used. Associated with implicit memory.

Autobiographical memory Memory of the self.

Autobiographical memory is thought to overlap with episodic memory, but it additionally contains knowledge and skills related to the self which fall outside the realm of episodic memory.

Autonoetic Self-knowing. An awareness that what is being remembered has happened to the self at an earlier point in time.

Context The spatial and temporal information that is present when material is learned or remembered. The context includes both environmental and internal information.

Episodic memory A memory system that allows one to reexperience personal events.

Flashbulb memory Memory of a very emotional and surprising event.

Hemispheric encoding/retrieval asymmetry (HERA) A neurocognitive model that postulates that the right frontal lobe is used primarily for episodic retrieval and the left frontal lobe for episodic encoding.

Implicit memory Memory for how to perform skills and activities.

Noetic Knowing. The experience of knowing a fact. The type of awareness associated with semantic memory.

Semantic memory The memory system involved in the storage and retrieval of facts and general knowledge.

Source amnesia An inability to remember where one encountered or learned some information.

Working memory Immediate memory for information currently being processed.

The Episodic Memory System

The term episodic memory was coined by Endel Tulving in 1972 to refer to memory of personal experiences (i.e., episodes). Since that time, the concept has developed considerably. Although the term continues to be used to describe the contents of certain kinds of memories and certain types of memory tasks, episodic memory is also used in a theoretical sense to refer to a specific memory system, distinct from other memory systems.

The episodic memory system is designed to allow us to reexperience personal events from the past. Episodic memory is thought to be organized in brain regions that, although involved in other memory systems, are in some ways unique to this system. Retrieval of information from the episodic memory system results in a form of self-awareness. People report a sort of reexperiencing of an event.

Episodic memory is often best understood by comparison with other memory systems. The semantic memory system deals with factual information and general knowledge.

Semantic memories do not contain contextual information, unlike episodic memories. Retrieval of information from the semantic memory system results in a different subjective experience than the one experienced when retrieving from episodic memory. People *know* facts rather than remember them. The sense of self-involvement that occurs with episodic memory is replaced with a sense of knowing something, but not necessarily knowing how it was learned, where it was learned, when it was learned, or knowing how the information is related to the self. Semantic memories may result from the accumulation of episodic memories. Repeatedly learning the fact that George Washington was the first president of the United States may

result in a fact that is stored in memory distinct from the several episodes in which it was encountered.

Implicit memory is the memory system responsible for our ability to remember how to perform certain behaviors or skills. We often have no awareness of actually retrieving information from the implicit memory system. Instead, we simply perform an activity.

Episodic, semantic, and implicit memories are all thought to be forms of long-term memory. They all are capable of holding information over long periods of time. In contrast, working memory is a kind of short-term memory. The working memory system is designed to hold, rehearse, integrate, and otherwise work on information until it can be transferred to the long-term system.

Personal experiences are sometimes labeled autobiographical memories. Although autobiographical memory is often used interchangeably with episodic memory, most researchers distinguish between the two concepts. Autobiographical memory is defined as memory of the self. As such, episodic memories make up many of our autobiographical memories. However, autobiographical memories occasionally contain information that appears to be accurately described as knowledge or skills, and thus are much like semantic and implicit memories. Memory for a friend's cell phone number may be a part of one's personal history, but it may also be considered a fact. Similarly, learning to drive a car is an event in many personal histories, but driving a car is also a skill. There are reports of patients with episodic memory system impairments who remember some personal *knowledge*. One patient, K.M., could remember that his brother had died but he was not aware of when or where he had heard about the death. His personal memory in this case is autobiographical, but

it is better described as semantic memory than episodic memory. Autobiographical memory is best thought of as a variety of memories rather than a distinct memory system in and of itself.

Because episodic memory is thought to be a unique system, it is thought to differ from other systems in a variety of ways. Some of those distinctions are highlighted below.

Episodic Memory Tasks

Episodic memory is often used in a heuristic sense to refer to tasks that ask participants to retrieve personal experiences and specific events that occurred at a particular place and at a particular time. A typical episodic memory task is one in which accurate performance depends on access to the context in which an event occurred. Episodic memory is typically studied in the lab with a study phase in which a set of words would be presented to people and they would be told to try to learn them. The participants would be tested for their memory of the material with a recall or recognition test after a short break or an intervening task to allow the material to be removed from working memory. The task is called an episodic memory test because participants must retrieve a specific episode that occurred in a specific place and at a particular time. That is, they cannot recall just any words; they must recall words that were personally experienced at a particular place and at a particular time if they are to be accurate.

It is interesting to note that the typical 'episodic task' emphasizes the content, and often the semantic content of memory. That is, it emphasizes the 'what' of episodic memory. This is only a small portion of the contents of episodic memory and, theoretically, it may not be the most important component of episodic memory. Two additional important components of episodic memories have to do with the time and location of an experienced event; the when and where of memory. The role of these factors in episodic memory has often been studied under the term context.

Context is a general term that has been used in the literature to refer to factors as varied as the physical surroundings in which a set of material is studied and tested, internal moods, and drug states. A classic design for these sorts of experiments is depicted in Table 1. In an experiment such as this, a set of material is present in one of two contexts (with word A or word B, in room A or in room B, on land [A] or in water [B], while intoxicated [A] or while sober [B], while happy [A] or while sad [B], etc.). Half the participants study the material in Context A and half in Context B. Then, after a delay, half of the participants in each study condition are tested in the same context and the other half of the participants change contexts for the

test. The general finding of these studies with free recall tests is that maintaining the same context during study and test leads to better performance than changing context between study and test. Although there are exceptions to this finding, it has been replicated enough times under enough conditions that it is clear that context is associated with new material when it is learned and context plays an important role as a retrieval cue when episodic memory is probed.

It is interesting that context effects are much less robust when recognition is used as a test than when recall is used as a test. This presumably results because recognition tests include other good cues (i.e., the to-be-remembered item itself is presented and participants are simply asked whether it was previously studied or not) that are not available during free recall, where participants are simply asked to try to remember as much as they can. Context plays a bigger role when other cues are not available.

Context effects are less consistent when emotions or drug states are used as the context. These results can be at least partially explained by the difficulties in inducing emotions and by the additional effects of the drugs and emotions on cognitive functions. As an example, both depression and alcohol slow down performance on a variety of cognitive tasks and the slowed processing may make context effects more difficult to detect.

Source memory is a topic closely related to context. Poor source memory, called source amnesia in extreme cases, is indicated when a person can recognize having seen some material before (i.e., the *what* of an event is remembered) but not where or when material was originally presented. That is, memory for the source of the information is lost. If the source of the information is considered a kind of context, then this is an example of a loss of memory for context information. It is interesting that individuals who have poor memory for the source of information, such as older adults, typically also show poor episodic memory performance. In fact, older adults typically show poorer source memory than memory for items or individual events.

Outside of the psychology laboratory, episodic memory is evidenced in one's ability to answer questions such as: What did you have for dinner last night? Whom did you see at the meeting yesterday? Where were you when you received the emergency telephone call? Again, correct performance depends on one's ability to reexperience, in some sense, a personal episode that occurred at a particular place and time.

Episodic memory tasks can be contrasted with semantic tasks. A typical semantic memory task is one in which participants are asked to recall facts and definitions. How would you define 'justice'? Who was the first president of the United States? Successful performance on these questions and similar tasks does not require the recollection of a personal experience or access to a particular time and place in which the facts and definitions were encountered. In fact, such information is typically not available.

Episodic memory tasks can also be compared to implicit memory tasks. An implicit memory task rarely requires one to explicitly recall an event or fact. Instead, implicit memory is exhibited by performing a task or exhibiting a skill. Memory is shown by improved performance on the task for those who

Table 1 Typical design for a study that examines the effect of context on episodic memory

Test context	Study context	
	Context A	Context B
Context A	Context match	Context mismatch
Context B	Context mismatch	Context match

have performed the task before compared to those who have not. For example, implicit memory for riding a bicycle would be assessed by how well one rides a bicycle after a certain amount of practice. Improvement would indicate implicit memory of the task.

The sorts of tasks that are labeled as episodic are rarely purely episodic. Most of these tasks also require some access to general knowledge and facts, for example. This raises the important point that memory systems must surely interact and specifying how they interact is an important goal for any comprehensive memory theory. The fact that it is difficult to disentangle one memory system from another on the basis of the type of task employed has led to the search for other differences between systems, including the type of awareness associated with each system.

Episodic Memory Processes and Subjective Awareness

Fundamentally different operations are thought to be used by different memory systems. Each system has a unique set of processes to store, organize, and retrieve information. Episodic memory is thought to be temporally organized. In some ways it can be thought of as a movie of one's own life. Portions of one's life are organized along a temporal dimension when stored. Accurate retrieval of that information requires access to the temporal dimension. In contrast, semantic memory is stored more like a library in which related topics are stored together. Implicit memories are stored as scripts, analogous to prescriptions or recipes, for how to perform activities.

The processes used within the episodic memory system give rise to a unique subjective experience. According to Tulving, one of the most important characteristics of episodic memory is that it is associated with a reexperiencing of an event. When people recall information from episodic memory, they often report an 'I remember' sort of experience. That is, they often report experiences like 'I remember eating pizza at the party.' Tulving labels this kind of subjective experience as *autonoetic awareness*. It is a self-knowing awareness. The awareness is of a personally experienced event as having occurred. More correctly, it is a reexperiencing of a certain event.

In contrast to the reexperiencing of events associated with episodic memory, semantic memory is associated with a feeling of knowing. People are much more likely to report that they *know* that Abraham Lincoln was the 16th president of the United States than they are to report that *I remember* that Abraham Lincoln was the 16th president of the United States. The awareness associated with retrieval from semantic memory is labeled as *noetic* or 'knowing' awareness. Interestingly, retrieval from implicit memory rarely gives rise to any form of awareness at all. We are often unable to describe how we hold a pen when we write or exactly how we maintain our balance when riding a bicycle. We just do these things. Tulving labels this *anoetic awareness*, where *anoetic* is taken to mean 'not knowing.'

The type of awareness associated with episodic memory has become an important area of research partly because of the question of whether nonhuman animals have episodic memory. When Tulving first proposed the episodic memory system, it was thought that only humans had episodic memory. Over

the years, researchers have been able to demonstrate that many species can store and retrieve the *what* and *where* of experiences. More recently, several studies have shown that certain birds, for example, can retrieve the *when* of experiences. At this point in time, it is impossible to determine whether nonhumans share the *autonoetic awareness* that humans experience when retrieving episodic memories. Therefore, the question of whether nonhuman animals possess episodic memory remains open.

Although the forms of awareness associated with the episodic memory system is thought to be a defining feature of the system, little research has been conducted on this aspect of the memory system. Some researchers have used a *remember/know* procedure to address this issue. With this procedure, participants are asked at recall to indicate whether the information they recalled is known or remembered. Although interesting results have been obtained, the interpretation of the results is far from clear. A few additional studies have tried to address this issue by studying brain-damaged individuals with impaired levels of awareness/consciousness, for example, but again the results from these individuals are not clear-cut.

The Past Orientation of Episodic Memory

The episodic memory system, according to Tulving, is the only memory system whose orientation is towards the past. As has been stated above, retrieval of episodic memories is best described as a reexperiencing of one's own past. Episodic memory allows for mental time travel. It allows us to reminisce with family and recount stories of past events at reunions. Such memories surely provide a richness to our lives.

It might seem that all memories are similarly directed toward the past. Semantic and implicit memories are acquired at a certain point in time. However, their use does not depend on the fact that they were acquired at a particular time in the past. In fact, much of what we have stored in semantic and procedural memory functions to allow us to make decisions and act appropriately in the present or in the future. For example, the memory for the ability to ride a bicycle, stored in implicit memory, primarily serves us by allowing us to ride a bicycle now or in the future. Similarly, knowledge of the rules of mathematics are most useful when they allow us to solve current or future problems.

The effective use of semantic and implicit memory does not give rise to a sense of time travel. We typically do not experience a movement back in time when we use those memories. Episodic memory does involve mental time travel. It is that sense of traveling back in time that, partly, gives rise to the *autonoetic awareness*.

Emotions

Emotions are among the factors that make experiences meaningful to us. Because emotions are a meaningful part of the events we experience, they are thought to be a part of the episodic memory system. Although cognitive scientists have been slow to include the study of emotion in their memory studies, research indicates that emotions play an important role in the episodic memory system.

One's emotions can serve as a retrieval cue to access memories. Generally speaking, the more overlap between one's current emotional state and the emotional state when an event was experienced, the better the retrieval. In a general sense, emotions can be thought of as a part of context as described above. As a result, emotions, or moods, are important retrieval cues.

Other evidence suggests that emotional events are generally easier to retrieve than nonemotional events. Flashbulb memories are memories for very emotional events. People report very clear and distinct memories for events such as the Challenger explosion or the downing of the Twin Towers in New York in 2001. Although some research has indicated that such memories are not as accurate as they appear to be subjectively, the point that emotions are part of the reexperiencing of the event is indisputable.

In the case of the extremely emotional experiences that are part of traumatic events, the associated memories are often difficult to forget. Severe traumatic events such as those associated with war or severe accidents are often difficult to forget. It is not uncommon for survivors of such trauma to reexperience the events in the form of a flashback. Again, it is clear that emotions are an important component of at least some episodic memories.

Dissociations among Memory Systems

Theories of episodic memory in particular, and theories of multiple memory systems generally, have generated thousands of empirical studies. These studies have taken many forms, but among the most important studies are those that show that the characteristics of the episodic memory system are different from those of other proposed memory systems. A dissociation is said to occur when one variable influences memory systems differentially.

The stage of development is one factor that appears to dissociate episodic memory from other memory systems. Older adults typically perform much more poorly on episodic memory tasks, such as recall of a recently presented set of words, than younger adults. These same older adults often perform as well as, or better than, younger adults on semantic memory tasks such as general knowledge or vocabulary tests. Episodic memory seems to develop after semantic memory in childhood.

Similar patterns of results have been found while comparing younger and older adults on episodic and implicit memory tasks. That is, older and younger adults perform at approximately similar levels on implicit memory tasks, but older adults perform relatively poorly on episodic memory tasks. We typically show a steady decline in episodic memory as we age, starting at age 30 or even younger. The pattern is much different for semantic memory. Semantic memory performance tends to remain stable or even improve through middle age. Only in late adulthood (after age 75 or so) are declines in semantic memory substantial, and even then the declines tend to be gradual. Similarly, performance on implicit memory tasks tends to show little or no decline with increasing age.

These sorts of dissociations can be found for many variables. However, the interpretation of such dissociations is not

always clear. For example, it is possible to show dissociations within a memory system. Recall and recognition tests for episodic memory are sensitive to different variables. Therefore, a dissociation does not require the postulation of distinct memory systems. All that is required for a dissociation is that one process differs on any two tasks.

At one point in time it was thought that one could find support for the episodic memory system, as distinct from other memory systems, by examining the levels of performance across memory systems. The idea behind these studies was that memory performance based on the episodic memory system should be relatively independent of performance on tasks that primarily tap the semantic memory system, for example. That is the two tasks should show stochastic independence. A number of studies have revealed stochastic independence on episodic and semantic memory tasks. Other studies have found relatively high correlations on the two types of tasks. Because most tasks make use of more than one memory system and because in normal circumstances we would expect the memory systems to interact, it is not clear how to interpret these results. Recent attempts to show that episodic memory is distinct from other memory systems have focused on differences in the brain among the various systems.

The Neuroscience of Episodic Memory

Perhaps the most exciting research on episodic memory in the past 15 years has come from neuroscience literature. This research has attempted to find the neural correlates of the episodic memory system.

Brain-damaged individuals provide interesting case studies of the neuroscience of episodic memory. Damage to the hippocampus and surrounding areas in the medial temporal lobe can result in the loss of episodic memory. Such patients typically find it difficult to encode or store new experiences. Some old episodic memories seem to be present, but patients do not have the self-knowing or reexperiencing awareness that comes from typical episodic retrieval. Such patients have relatively intact semantic and procedural memories. It is interesting that cases of semantic amnesia can also be found. In these cases, patients lose the ability to find word meanings, but their episodic memory seems relatively intact.

The problem with studying brain-damaged individuals is that the damage is rarely neat and confined to one functional area of the brain. Careful study of brain-damaged individuals often indicates that both semantic and episodic memories are impaired to some extent.

Many imaging studies (i.e., PET and fMRI images) have suggested an important role for the hippocampus and related areas in episodic memory. Several of these studies have revealed that the hippocampus is more active during episodic memory tasks than semantic memory tasks. Studies with non-human animals have also shown that memory of location, time, and context is related to hippocampal function. Of course, the animal research has not addressed the issue of autonoetic awareness and so labeling this kind of memory performance as episodic memory must remain tentative.

The role of the hippocampus in episodic memory has become much more complicated as research has continued in

this area. Although it seems that the hippocampus plays an important role in the episodic memory system (perhaps in consolidation, forming associations, and spatial memory), it is clear that the hippocampus is just one of many structures that are important for an effective episodic memory system. Large portions of the medial temporal lobe appear to be important for a functioning episodic memory system. The hippocampus also seems to play some role in acquiring semantic memories. In addition, the hippocampus is part of several neural pathways and it may be that it is best to think about the pathways as being the seat of episodic memory.

Tulving and others have argued that there is hemispheric specialization with regard to episodic memory. Based largely on PET and fMRI studies, a consistent pattern of results has been obtained that show hemispheric specialization for episodic encoding (moving information into the system) and episodic retrieval (recovering stored information). The results indicate that the right hemisphere, and especially the right frontal lobe, is especially active during episodic retrieval. The left frontal lobe, in particular, is associated with episodic encoding. Retrieval from semantic memory is most closely associated with activation in the left frontal lobe. This pattern of results, referred to as the hemispheric encoding/retrieval asymmetry (HERA) theory, nicely isolates different areas of the brain with episodic encoding and retrieval and differentiates episodic from semantic memory.

Conclusions

Episodic memory has played, and continues to play, an important role in memory research. Over time, the emphasis in research has expanded from an emphasis on the content of personal experiences to include tasks that assess the context and awareness associated with memory retrieval. Episodic

memory continues to be used in a heuristic sense to refer to certain kinds of tasks, but the more important use of the term is theoretical, where episodic memory refers to a type of memory system. Although a good deal of cognitive research continues to explore the nature of episodic memory, the newest areas of research have added the study of the brain to cognitive tasks.

Glossary

Cross-cultural psychology The scientific study of culture's impact on human cognition, language and meaning, affect, and behavior. Cultural themes – such as the theories of mind, psychological constructs and explanatory models employed in various cultures – are investigated in order to determine the universality of various concepts.

Equity theory A theory that proposes that people are concerned about both profit and fairness in all of their relationships – from the most intimate to the most casual of interactions.

Ethnology The comparative study of the behavior of animals and humankind, typically in their natural habitats but sometimes involving experiments in both the field and in captivity.

Evolutionary psychology The field wherein human cognition, emotion, and behavior are studied in a Darwinian context. Evolutionary psychologists attempt

to explain psychological traits – such as perception, memory, or language – as the consequence of natural selection or sexual selection.

Neuroscience The scientific study of the brain and the central nervous system. This includes disciplines concerned with the structure, function, chemistry, pharmacology, and development of various attitudinal and emotional behaviors.

Primatology The branch of psychology and zoology that examines primate behavior. Generally, research involves the study of monkeys, apes, and other nonhuman primates, but sometimes nonhuman primate behavior is compared to that of humans.

Socialpsychophysiology That branch of social psychology which looks at the way that personality and situation interact in shaping physiological processes. Many scholars study the way various cognitive and emotional reactions are reflected in the subtle activity of the facial muscles.

The Nature of Equity

Saint Anselm of Canterbury (1033–1109 ACE) argued that the will is influenced by two competing inclinations: an affection for what works to a person's own advantage and an affection for justice. The first inclination is more powerful, but the second matters, too. Equity Theory, too, posits that in relationships, two concerns stand out: first, how rewarding are people's social, family, and work relationships? Second, how fair, just, and equitable are those relationships? According to Equity Theory, people feel most comfortable when their relationships are maximally profitable and they are getting exactly what they deserve from those relationships – no more but certainly no less. (People perceive a relationship to be fair and equitable when the rewards they reap from a relationship are commensurate with their contributions to that relationship.) In contrasting profit versus equity, *profit* (i.e., rewards minus costs) is generally found to be a more important determinant of satisfaction than is *equity*. In this entry, we will discuss the logic on which Equity Theory is based, discuss techniques for assessing how equitable a relationship is, and discuss the consequences of fairness (or unfairness) in both personal and work relationships.

In the past 25 years or so, social psychologists have become interested in the cognitive and emotional underpinnings of humanity's concern with social justice, fairness, and equity. Evolutionary theorists, for example, argue that for several million years, our ancestors engaged in complex social exchanges. They contend that a concern with both reward and fairness are ancient and universal concerns – wired in as part of the architecture of the human mind. Currently, most cross-cultural

investigators, neuroscientists, primatologists, ethologists, and evolutionary psychologists agree that although social definitions of equity may vary, a concern with profit, fairness and equity may, indeed, be common in many animal groups.

Equity Theory

Equity Theory as posited by Hatfield, Walster, and Berscheid (1978) consists of four propositions.

Proposition I Men and women are wired up to try to maximize pleasure and minimize pain. It follows, then, that people are concerned with the rewards and punishments they receive in their close relationships.

Proposition II Society, however, has a vested interest in persuading people to behave fairly and equitably. Groups will generally reward members who treat others equitably and punish those who treat others inequitably.

Proposition III Given societal pressures, people are most comfortable when they perceive that they are receiving roughly what they deserve from life, love, and work. If people feel overbenefited, they tend to experience pity, guilt, and shame; if underbenefited, they tend to experience anger, sadness, and resentment.

Proposition IV People in inequitable relationships will attempt to reduce their distress via a variety of techniques – namely, by restoring psychological equity (convincing themselves that an inequitable relationship is indeed fair), by restoring actual equity, or by abandoning the relationship.

A corrupt stock broker, who feels guilty about cheating his clients, may restore psychological equity by convincing himself that in business it's survival of the fittest. A woman who feels guilty about the fact that convention dictates that her poverty-stricken date ought to pay for dinner, concerts, and transportation may attempt to set things right by inviting him to dinner or pretending someone has given her free tickets to a play – thus restoring actual equity. Finally, a philanthropist who decides his charity cases are ingrates may elect to discontinue his generous gifts (and thus terminate the frustrating relationship).

Historically, different cultures and societies have possessed very different visions of what constitutes social justice. Equity, it seems, is in the eye of the beholder. Participants themselves may disagree about the equitability of their relationships; outsider observers might yet have a third view as to what is fair or unfair. In defining equity, people may focus on a wide variety of decision rules and a plethora of inputs and outcomes. Some dominant views: 'All men are created equal' (Equality). 'The more people invest in a project, the more profit they deserve to reap' (Capitalism). 'To each according to his need' (Communism). 'Winner take all' (Dog-eat-dog capitalism). 'It's a man's world' (Traditional social hierarchy). Whatever the cultural rules, social justice, fairness, and equity are deemed important in all cultures.

Social psychologists have developed a variety of scales designed to assess people's perceptions of equity. In practice, however, people's perceptions are often measured by asking: 'Considering what you put into your (dating, marital, or work) relationship (compared to what you get out of it) and what your partner puts in (compared to what he or she gets out of it), how does your relationship "stack up"?' On the basis of their answers, peoples are classified as perceiving themselves to be overbenefited (receiving more than they deserve), equitably treated (receiving exactly what they deserve), or underbenefited (receiving less than they deserve, *considering their partner's inputs and outcomes*) from a given relationship. Naturally, other scales designed to assess perceived equity exist, as well (Figure 1). In one detailed measure, for example, researchers asked men and women who were dating, living together, or married to indicate (via a 22-item scale) how fair and equitable they considered their relationships to be. The areas of interest included such personal qualities as appearance, intelligence, and social grace; emotional concerns, such as physical affection and understanding and concern, and day-

Figure 1 The relationship between perceived equity and contentment/distress.

to-day concerns, such as contributing to household expenses and helping around the house. Other scholars have developed measures to assess how fair employers/employees consider their relationships to be.

Other researchers have created 'Exchange Orientation' scales, designed to assess the concern of individuals with justice, fairness, and equity. They argue that some people are especially concerned about giving their partners and associates all that they deserve, whereas other people are primarily concerned with 'Am I getting my fair share?' Depending on their different personalities, people are predicted to respond with varying degrees of upset to injustice.

Regardless of societal definitions or one's own concern with fairness, considerations of equity have been found to be important in a wide variety of cultures and relationship types – social relationships, romantic and family relationships, friendships, helping relationships, and work relationships.

Current Research: A Multidisciplinary Approach

Currently, some of the most interesting research into the nature of social justice emanates from scholars of three different intellectual traditions (1) primatologists and evolutionary psychologists, who argue that a concern for justice arose early in humankind's evolutionary history, and who speculate about how this ancient wiring affects visions of social justice of contemporary men and women; (2) cultural researchers interested in different societal definitions as to what is fair and equitable; and (3) social psychologists, who have explored people's definitions of fairness and justice and have studied the impact of perceived fairness and equity on people's thoughts, feelings, and behaviors.

Equity: The Evolution of a Cultural Universal

In the past 25 years or so, social psychologists have become interested in the evolutionary underpinnings of a societal desire for social justice. As Cosmides and Tooby (1992) observed:

It is likely that our ancestors have engaged in social exchange for at least several million years ... Social exchange behavior is both universal and highly elaborated across all human cultures – including hunter-gatherer cultures ... as would be expected if it were an ancient and central part of human life (p. 164).

Today, paleoanthropological evidence supports the view that notions of social justice and equity are extremely ancient. Ravens, for example, have been observed to attack those who violate social norms. Dogs get jealous if their playmates get treats and they do not. Wolves who do not play fair are often ostracized – a penalty that may well lead to the wolves' death.

Primatologists have also amassed considerable evidence that primates and other animals do care about fairness. In a study with brown *Cebus apella* monkeys, researchers rewarded female monkeys with tokens after completing tasks. These tokens could be exchanged for grapes, a desired treat. However, after several trials in which completed tasks brought a grape, suddenly the situation changed. The 'fairly treated' monkeys were indeed rewarded with the expected treat – grapes. But some monkeys were deprived of their just reward: they

were given cucumbers, a nondesired food, instead. Female monkeys who were denied the grapes, that is, the rewards they deserved, became furious. They refused to 'play the game' (refused to exchange tokens for a cucumber) and disdained to eat their 'prize' – holding out for the grapes they thought they deserved. If severely provoked (the other monkeys did nothing and still got the highly prized grapes instead of the cucumber) capuchins grew so angry that they began to scream, beat their breasts, and hurl food at the experimenter. Interestingly, in a later study, the authors found that chimpanzees (*Pan troglodytes*) were most upset by injustice in casual relationships. In *chimps'* close, intimate relationships, injustice caused barely a ripple. We see, then, that different species, in different settings, may respond differently to injustice.

Potentially, this fascinating animal research may provide some insights into three questions that have intrigued equity researchers (1) when, in primates' long prehistory, did animals begin to feel guilty about receiving too much, as well as begin to feel outraged when they were deprived of their just deserts? (2) are animals more (or less) concerned about fairness in despotic, hierarchical societies than in relatively egalitarian ones? (3) are primates and other animals more (or less) concerned about inequities in close kin relationships than in more distant encounters?

Equity: Cultural Considerations

Cross-cultural theorists have long been interested in the impact of culture on perceptions of social justice. They contend that culture exerts a profound impact on how fairness is defined, how concerned men and women are with fairness, and how fair and equitable various types of relationships are judged to be.

Cultural critics point out that until very recently, social psychology was primarily 'Made in America.' Theories conceived by Western psychologists were tested in the West with Western participants and disseminated in Western scientific publications. Such ethnocentrism is a mistake, culture theorists argue, as culture exerts a profound impact on the ways in which people conceptualize the world around them, the meaning they ascribe to common life events, and the manner in which they react to those events.

Cross-cultural researchers ask: 'Is equity theory applicable to all people in all cultures and in all historical eras?' Many would say 'No.' Any number of researchers have studied cultural differences in perceptions of who ought to get what, where, when, and how. They have also studied how valuable resources are distributed within and between various societies. Some researchers argue that in individualistic cultures (such as the United States, Britain, Australia, Canada, and the countries of northern and western Europe) people tend to focus on personal goals. No surprise, then, that in such societies, people are primarily concerned with how rewarding (or punishing) their relationships are and how fairly (unfairly) they are treated. Collectivist cultures (such as China, many African and Latin American nations, Greece, southern Italy, and the Pacific Islands), on the other hand, insist that their members subordinate personal goals to those of the group: be that the family, the clan, or the tribe. It is tradition, duty, and deference to elders that matters. No surprise, then, that in such societies people are primarily concerned with fostering

good relationships with ingroup members. Along similar lines, other researchers claim that equity is of more importance in individualistic than in collectivist societies and there is some evidence that this is so.

Equity in Love Relationships

Scholars have discovered that the degree to which couples are concerned with reward and equity depends on relationship stage. When couples are first dating, they participate in a kind of dating and marriage marketplace, in which considerations of reward, fairness, and equity loom large. Once they are deeply committed to one another, however, they become less concerned about day-to-day reward and equity. Should a relationship deteriorate, however, couples – knowing (perhaps) that they will soon be back on the market – may begin to worry about 'What's in it for me?' and to ask: 'Do I deserve better?'

Mate Selection

In fairy tales, Prince Charming often falls in love with the scullery maid. In real life, however, men and women generally seek out partners who are deemed to be suitable. There is considerable evidence that when young people are attempting to decide whether or not to date or mate with someone (whether it is an arranged marriage or a love match), potential reward and equity matter. Specifically, researchers find (1) the more socially desirable men and women are – be they gay, lesbian, or heterosexual – the more social assets they will demand in a 'suitable' potential date or mate; (2) men and women tend to fall in love with partners who possess similar assets and liabilities; (3) market considerations affect men's and women's romantic and sexual choices. Dating couples generally end up with partners similar to themselves in self-esteem, attractiveness, intelligence, education, and mental and physical health (or disability), among other things; (4) profitable and equitable dating relationships are satisfying and comfortable relationships. Inequity is associated with distress, guilt, anger, and anxiety; (5) profitable and equitable dating relationships appear to be more stable (and more likely to lead to more serious relationships) than are inequitable relationships.

In conclusion, research indicates that in the early stages of a dating relationship, considerations of the marketplace prevail. Men and women will attempt to attract a socially attractive partner and they are profoundly concerned with how rewarding and how equitable their budding relationships appear to be.

Close, Intimate Relationships

Casual and intimate relationships are very different from one another. In close, intimate relationships, for example, couples feel more intensely about one another, share more of their lives, have (and expect to have) a longer time to spend together than do couples in fleeting affairs. Married and other committed couples, who assume that they will be together for a lifetime, are more likely to be sanguine about momentary injustices, confident that it will all work out in the end than are uncommitted couples. Then too, it may be difficult for

married couples to calculate whether or not relationships are fair and rewarding. (They may settle for a rough and ready definition of fair outcomes.) Only the most egregious injustices may be noticed.

Researchers argue that people participate in two kinds of relationships – exchange relationships and communal relationships – and that social norms differ markedly between these two relationships. In casual acquaintances or business relationships, exchange norms prevail. People need not feel special responsibility for others' welfare. They may invest ideas, time, and money, but it is with the expectation of receiving their fair share in return. In close, committed, intimate relationships, on the other hand, communal norms prevail. Ideally, men and women are committed to the other's welfare. They wish to please their partners, to care for and nurture them, and reject such crass considerations as score-keeping or a concern for *quid pro quo*. Such differences suggest that couples in close, intimate relationships will be less concerned about day-to-day rewards, costs, and equity than they would be in more casual friendships and work relationships.

Yet, in the end, reward (and costs) and equity do seem to matter in even the closest of relationships. This is the case for most couples – be they casually dating, living together, or married; affluent or poor; married for a few weeks or for a half-century. As we have said, people are generally far more concerned with how rewarding their relationships are than with how fair and equitable they are. Yet, in all of these groups, the degree of reward, fairness, and equity have been found to be linked to marital happiness, contentment, satisfaction, sexual satisfaction, and marital stability. Couples in fair and equitable relationships are also less likely to risk extramarital affairs than their underbenefited peers. They are also more confident that their marriages will last, and (in fact) their relationships are longer lasting than those of couples who feel less fairly treated.

In recent years, social scientists have begun to explore the perceptions of women and men concerning who does the most household work (such as preparing meals, shopping for groceries, cleaning the house, caring for children, and caring for needy or elderly relatives). They have also investigated the impact of fair or unfair divisions of labor on marital satisfaction and stability. Scholars find that for many couples, perceived fairness (in the division of housework) has a positive impact on psychological well-being and relationship happiness and stability.

Endings

Scholars agree that perceived unfairness and misery are linked. They disagree, however, as to the nature of the causal relationship: Does perceived injustice cause dissatisfaction or is the causal order reversed? Equity theorists point out that men and women who are unfairly treated for a prolonged period will begin to wonder: 'Does my partner love me? If so, why would he (she) treat me so unfairly?' They begin to ask: 'What's in it for me?' and 'Am I getting all I deserve in this relationship?' Other researchers take the opposite view, arguing that in communal relationships, couples do not keep score; they simply do not think in terms of reward and justice. Thus, if couples are concerned with such issues, it is a sure sign that their

marriages are in trouble. Misery, then, is the cause, not the consequence of perceived injustice. Regardless of the causal direction of the relationship, when men and women are at the point of separation or divorce, they sometimes become consumed with issues of fairness and equity.

A year-long longitudinal study set out to clarify this question. Researchers interviewed Dutch couples who had been married for various lengths of time. At Time 1, those who rated their marriages as inequitable were more dissatisfied than their peers. By Time 2 (a year later), these inequitable relationships were often faltering. Thus the authors concluded that inequity leads to relationship dissatisfaction and dissolution – and not the reverse. It is possible, of course, that in failing marriages, appraisal might lead to loss of commitment, separation, and then reappraisal ... the two spiraling down together.

In sum, scientists have continued to explore the impact of perceived equity on men and women's marital happiness and stability. It appears that although the concern with fairness may wax and wane during the course of a marriage, such concerns always remain there, sometimes just beneath the surface, guiding people's perceptions, happiness, and marital choices.

Equity in Work Settings

Industrial/organizational psychologists have investigated the applicability of Equity Theory to a wide variety of organizational and work settings and in a wide array of supervisor, worker, and customer relationships.

Differences in Sensitivity to Justice in Work Settings

Scholars contend that in the world of work, people differ in their 'Equity Sensitivity.' They classify people into three groups: the Benevolents (who are more concerned with what they contribute to an enterprise than with the rewards they reap), the Equity Sensitives (who are sensitive to issues of fairness, justice, and equity), and the Entitleds (who insist on extravagant rewards, regardless of their own contributions.)

The Neuroscience of a Concern with Fairness

Recently, neuroscientists have begun to explore the way that people's brains and central nervous systems respond when they are asked to make moral judgments and when they confront fairness or unfairness in the workplace. Neuroscientists have studied moral decision making, specifically moral sensitivity – the ability to detect and evaluate moral issues – major components of morality. Using fMRI (functional magnetic resonance imagery) techniques, the scientists demonstrated that sensitivity to moral issues is associated with activation of the polar medial prefrontal cortex, dorsal posterior cingulate cortex, and posterior superior temporal sulcus (STS).

In one experiment, the authors asked: Are people primarily motivated by the assumption that they will 'do well (for themselves) by doing good' or by a real, unselfish desire to 'Do unto others?' To test people's emotional reactions to various types of moral dilemmas, the scholars placed participants in an fMRI scanner. This high-tech scanner constructs an image

of the brain in which changes in blood flow (induced by brain activity) are represented as color-coded pixels. The authors then asked participants to play a series of games with real monetary stakes. How much of their own economic payoff were players willing to sacrifice to increase the payoffs of others? To find out, the authors digitally compared the scans taken while the participants decided whether to act selfishly or altruistically, to trust (or mistrust) others, to treat others fairly or unfairly, and/or to punish partners who betrayed them (by cheating them out of the outcomes they deserved from the games or to let the infraction slide). They found that people's brains were activated by the anticipation of reward, by a desire to behave fairly, and by a strong negative reaction to partners who betrayed them. Other neuroscientists and social psychophysicists have attempted to link people's self-reports of their reactions to (1) various kinds of justice or injustice; (2) various kinds of justice restoration (say, restorative justice, retributive justice (revenge), or no justice restoration); and (3) to forgiveness or a refusal to forgive, a desire for revenge, and a willingness to forgive exploiters – to their cognitive reactions to such dilemmas, as measured by patterns of fMRI responses.

Equity in Organizational and Work Settings

Scholars agree that a concern with fairness is a cultural universal and in many of the social sciences – including anthropology, psychology, sociology, politics, history, or economics – there are scholars who are primarily concerned with matters of who gets what, when, where, and how. Equity theorists, too, have focused on what participants in social exchanges perceive to be a just distribution of status and privilege, social costs and benefits, and material rewards and costs in organizational or work settings. As we observed earlier, people care about how rewarding and how fair, just, and equitable their treatment is in organizational and work settings – be they hunting and gathering societies or modern day industrial organizations.

Researchers have addressed a series of questions. Among the most important are (1) do employers and employees care about fairness and equity? (2) what do individuals and collectivities consider to be just and why? (3) is procedural justice as important as actual justice? (does it matter if the procedure for allocating reward is fair?) (4) what are considered to be valuable inputs and outcomes in work settings? (5) what are the social and behavioral consequences of perceived injustice in work settings?

There is considerable evidence that both employers and employees care deeply about equity

Researchers find that most business owners and managers are motivated to behave in an equitable way. A few follow equity rules because they are committed to abstract ideas of justice. More, however, find that they reap several payoffs from equitable behavior. In other words, it is profitable for them to conform to business world norms. Fairness allows them to attract superior workers and weed out inferior ones. They wish to motivate workers to produce, and to avoid conflict.

A more interesting question is how workers themselves feel about inequitable treatment. It is understandable that

those who feel cheated would be angry and resentful about the injustice of their situation, but what about those who are paid too much? Is it possible that those discovering they are overbenefited could really be unhappy with their good fortune? The evidence suggests they might be. Researchers find that underpaid workers show an active sense of grievance, the desire to complain, actual complaints, and an active desire to change jobs. But, more interestingly, they also find that overpaid workers are distressed too; they show a strong awareness of preferential treatment with underlying feelings of unease. More recent research has documented that justice is associated with well-being, work satisfaction, positive interpersonal and intergroup relationships, and decision acceptance. Conversely, the experience of injustice may have serious negative consequences on the individual, group, organizational, and societal levels. When faced with injustice, even the overbenefited generally feel a sense of disquiet.

Of course, this only holds true if workers perceive they are overbenefited. Humans are a creative lot and research documents that although the overbenefited might feel uneasy about their good fortune at first, it does not take long before they come up with rationalizations to justify their privileged state.

Procedural versus distributive justice

There are two general types of justice – procedural justice (i.e., the perceived fairness of the decision making process) and distributive justice (i.e., the perceived fairness of final outcomes). Researchers point out that people care about the fairness of the procedures used in allocating rewards, as well as the fairness of the rewards themselves. If the system for allocating rewards is corrupt or unjust, people feel uncomfortable, even if the actual rewards they receive are just what they deserve. In addition, the knowledge that others are receiving too much or too little is in itself unsettling.

Valuable inputs and outcomes in work settings

When considering how equitable or fair a workplace is, men and women consider a number of things to be valuable inputs in work settings. These include demographic characteristics (such as gender, age, and race), loyalty, commitment, intelligence, skill, seniority, degree of responsibility, hard work, support of colleagues, personal sacrifice, and the like. They consider a wide variety of outcomes relevant as well. These include such things as praise, recognition, a sense of achievement, respectful supervisors, friendly coworkers, opportunities for promotion, financial rewards (high pay, perks, valuable benefits), flexible scheduling, health insurance, appealing work environment, a retirement program, and the like.

Responses to perceived injustice in work settings

When faced with inequity, people try a number of techniques to set things right. These include complaining to the management, asking for a raise, and attempting to do a better (or worse) job. If all else fails, they may become absentee workers, try to sabotage production, search for better jobs, or quit their jobs.

In one classic experiment, researchers proposed the (then) unthinkable: that capitalistic American workers would be uncomfortable earning too much (as well as too little) (compared to their peers) and would actively seek to behave so as to

bring their wages in line with those of their peers. To test this notion, the researchers conducted an ingenious experiment. Logically, employees who are paid a far bigger salary than their peers versus those who are vastly overpaid on a piece-rate basis (again, compared to their peers), must utilize very different strategies if they are to restore actual equity – and end up with a ‘fair’ salary or a wage. Overpaid salary workers, for example, can restore equity by working harder or attempting to do better work than their peers. Underpaid salary workers can restore equity by doing exactly the opposite; they can take revenge on their stingy employer by slacking off (producing less work or lower quality work). Workers who are paid on a piece-rate basis, however, must follow the opposite strategy if they are to set things right. Overpaid piece-rate worker can only restore equity if they produce less work (and thus decrease their pay) or higher quality work (justifying their high pay). Underpaid piece-rate worker can restore equity by doing just the opposite; they can produce more work (thus making more) or shoddier quality work (thus justifying their poor pay). The researchers tested this notion in a real-life work setting and found that they were right. Workers did indeed vary their production as the researchers suggested they would.

Of course, as we observed earlier, individuals may respond to inequitable payment not by actually working to make things fairer but by a mental sleight of hand: they can distort reality and convince themselves that they deserve what they are getting. There is considerable evidence that, given adequate time, workers do tend to convince themselves that what is, is right.

Finally, people who are offered a wage that is inappropriate can ‘leave the field.’ Applicants can refuse to accept a job that they think is providing inappropriate rewards. Employees who feel unfairly treated can take up a job that pays more fairly. Naturally, this strategy is preferred by those who are cheated rather than those who are offered a windfall. As we observed earlier, given time, it is usually fairly easy for the overbenefited to alter reality and convince themselves that they deserve to make far more than their peers, given their intelligence, productivity, or charm.

Conclusions

It appears that people in all cultures, settings, and relationships are concerned with being treated fairly. However, what is considered equitable, how considerations are made, and how individuals attempt to restore equity does vary by location, setting and relationship type. Even across these different situations four trends emerge. First, people everywhere are concerned with the punishments and rewards they receive. Second, societies use punishments and rewards to encourage people to behave equitably. Third, people feel uncomfortable when they

receive more or less than they deserve, and feel best when they receive no more and no less than they deserve; and fourth, individuals who overbenefit or underbenefit will to restore the balance somehow. As such, equity remains an interesting and important research topic.

Glossary

Cerebral cortex The outermost layer of the brain (1.5–5 mm thick in humans), often called ‘gray matter’ because it contains nerve cells (neurons) that lack the white-looking insulating layers of myelin.

Component A deflection in the brain electric waveform that can be reliably related to a specific experimental manipulation, paradigm, or task.

Dipole In electrical systems, a separation of positive and negative charges.

Electroencephalography (EEG) The measurement of the ongoing electrical activity of the human brain using scalp electrodes. The electroencephalogram reflects the synchronized electric activity of hundreds of thousands of nerve cells.

Event-related potential (ERP) The sequence of voltage deflections from the EEG that are time-locked to the beginning (or end) of a specific event, such as a stimulus presentation or behavioral action.

Microvolt The millionth part of a volt; abbreviated as μV . The range of the ERP voltages is typically between 1 μV and tens of microvolts.

Pyramidal cells Neurons in the cerebral cortex with a cell body (soma) that is roughly shaped like a pyramid with two distinct structures of dendrites, which are the tree-like projections through which the cell body receives information.

Scalp topography The spatial distribution of the ERP voltage at a specific time, often illustrated using color maps to code the amplitude of voltages at different locations.

Introduction

Measuring brain activity in humans is critical to answering questions regarding the relationship between brain and behavior. Neural activity originates in specialized cells in the brain called neurons that have electrical properties. When neurons fire, a change occurs in their electric status, which generates voltages that can be measured on the scalp as negative and positive voltage deflections. Measuring the electrical activity of the brain by placing sensors on the scalp is referred to as electroencephalography (EEG). During both waking and sleep states, the ongoing EEG results in waveforms with distinct frequency characteristics, including slow wave activity during some sleep stages and fast oscillations during mental work. EEG is usually measured at very fine temporal resolution, typically sampling the voltage measured at the scalp every thousandth of a second (i.e., 1 ms).

Event-related potentials (ERPs) are derived from the ongoing EEG activity, and specifically measure neural activity following (or preceding) the onset of a target event – a word, picture, sound, or other visual, auditory, or somatosensory sensory stimulus; following the onset of a stimulus that cues preparation for, or execution of, motor activity; and even following a cue to perform covert mental operations (e.g., imagery, retrieval, anticipation). Historically, ERPs have been used as indices of psychological phenomena ranging from perception and attention to emotion, action, and memory.

An ERP is typically obtained by averaging several temporal segments (trials) extracted from the ongoing scalp-recorded EEG. Each trial is defined with respect to the event of interest, containing a baseline segment (prior to the event) and a post-event segment. By averaging the EEG activity over many trials, a representative temporal waveform of brain voltage changes is obtained, which characterizes the event of interest. Trial averaging is essential both because the ongoing EEG is noisy and

because the amplitude of changes to specific events are normally on the scale of several microvolts (μV), whereas the EEG involves voltage fluctuations that can be hundreds of volts in magnitude.

The peaks and troughs in the averaged ERP are presumed to reflect latent components or mental processes that contribute to its shape, and the sequence of observed components that characterizes an ERP for a given event is often divided into early mandatory components and later components. Early ‘evoked’ deflections are strongly affected by physical stimulus properties, such as stimulus intensity or duration. Researchers often referred to these early deflections as ‘exogenous’ or ‘evoked potentials’ in order to describe neural activity strongly tied to stimulus properties, compared to ‘endogenous’ psychological processes, which more strongly affect later ERP components. Currently, rather than making a strong distinction between exogenous and endogenous potentials, ERPs are taken to reflect processes that can occur from early to late in the processing cascade that follows the onset of a critical event.

Because ERPs reflect the activity of a large set of synchronously active neurons and can be measured in near-real time, they are often informative when testing hypotheses about the timing of neural activity in behavior and cognition. For instance, studies of visual selective attention to locations in space have shown that attending to a particular area in the visual field will lead to an ERP enhancement as early as 80 ms after the presentation of a stimulus in the attended, compared to a nonattended, location. This information was instrumental in the testing theories of early versus late models of selective attention. Given the versatility of the ERP, which can be measured in almost every experimental or clinical research context, there are a plethora of applications for ERPs and the reader is directed to the bibliography at the end of this article for excellent recent review articles on the topic.

The Neurophysiological and Physical Origins of ERPs

Because ERPs are based on EEG recordings, it is helpful to consider what is known about the neurophysiological and physical processes that underlie the scalp-recorded EEG. Most neurophysiological studies concur in the supposition that EEG reflects the synchronized activity of millions of cortical pyramidal cells. Pyramidal cells make up the majority (80–90%) of cortical neurons, with some differences in their density in different cortical regions. Their elongated shape and parallel orientation within the cerebral cortex, the outermost mantle of brain cells, makes them ideal generators of well-oriented electric fields: although electric field changes of a single pyramidal neuron cannot be detected through the layers of cerebral spinal fluid, skin, and scalp that separate the neural tissue from the electrodes, it is possible to measure the electric activity that is evoked at a given point in time by millions of such pyramidal neurons if they are oriented in the same direction. Thus, the dipolar (i.e., positive or negative) voltage changes induced by either excitatory or inhibitory postsynaptic activity at the apical dendrites are measurable outside the brain. This implies that the EEG measures neural activity in large areas of tissue.

In order to arrive at the scalp electrodes, currents generated by the cortical processes need to travel through the tissue of the human head. Thus, relatively strong currents traveling smaller distances on their way to the sensor electrode are well represented in the human EEG. This favors electrocortical activity in near-surface cortical neurons that are oriented parallel to the scalp, rather than deep brain regions with less favorable orientation. Because the different types of tissue through which the current passes (e.g., brain, cerebrospinal fluid, skull, skin) have different electric properties, volume conduction leads to blurring and distortion of the original electric field. Effects of volume conduction can also vary across the recording period, thus posing constraints on the spatial specificity of the voltage measured by EEG electrodes.

Measurement and Analysis of ERPs

ERP measurements are usually performed in an experimental chamber or room that is shielded from outer electrical fields. During the recording procedure, participants are encouraged to avoid ocular and body movements, as these lead to large nuisance signals (artifacts). A typical recording session involves the following steps: (1) a participant gives informed consent to being part of the study; (2) sensors are then placed on the scalp, and impedances (a measure of the resistance between the sensor and the neural activity) measured; (3) parameters are chosen for the filtering, digitization, and, ultimately, recording of the data; (4) artifacts are removed offline (i.e., after the recording session) from the data; (5) meaningful time segments are chosen from the data and averaged to yield ERPs.

Information critical to these steps include the following.

Sensors and Recording Reference

EEG is a safe and noninvasive procedure with minimum discomfort to the human participant. Over the last few decades,

the application of sensors on the scalp has become more comfortable with technical innovations such as all-in-one electrode caps, which can hold hundreds of sensors and are placed on the head using a cap or net structure (**Figure 1(a)**). In general, specialized sensors (electrodes) that are able to monitor voltage changes are placed over different scalp locations. The most frequently used sensors involve a silver–silver chloride contact that is filled with conductive paste, but other technologies are now available that provide excellent electric contact between the scalp and the amplifier. For instance, **Figure 1(a)** illustrates a dense-array net in which the sensors consist of an electrical contact that is placed in a sponge and is able to conduct current if it is dipped in a saline solution prior to recording.

Originally, the use of a three-sensor montage (sensor array) to measure voltage changes over midline frontal (Fz), central (Cz), and parietal (Pz) sites was common, but larger arrays were soon developed, prompting the formalization of a method for describing and applying sensors on the scalp called the 10–20 system (**Figure 1(b)**). This system labels sensors that are placed over the frontal pole (Fp), frontal (F), central (C), temporal (T), parietal (P), or occipital (O) cortex, with even numbers labeling sensors over the right hemisphere and odd numbers labeling sensors over the left hemisphere; ‘z’ labels midline locations. The numbers attached to sensors provide information regarding their distance from specific landmarks. The 10–20 system provides a common terminology for describing sensor locations across different researchers and laboratory sites and has been expanded to describe sensor locations for up to 257 sensors.

Because voltage is only a relative measure, that is, a difference in electrical potential that exists between two sites, EEG voltage at any specific sensor is always measured with respect to a reference site. One reference montage often used in ERP research is the common reference, in which each of the recording electrodes measures the voltage gradient against a common reference electrode. The location of the common reference electrode is critical to the interpretation of the resulting scalp distribution of the measured voltage, with normal recommendation to place the reference at a site that is electrocortically silent, allowing an estimate of the neural activity at each of the recorded sensor locations. Thus, distant and presumably electrically ‘quiet’ regions have been used as reference sites, such as a sensor mounted on the tip of the nose, the front of the forehead, or on the earlobes. Nonetheless, both cranial currents and extracranial sources (e.g., muscle activity) can affect flow at those sites and distort the measured voltage. Alternatively, the EEG may be recorded using one of the sensors on the scalp itself (for instance the vertex electrode at the top of the head) as the reference site during recording, and then computing an average reference offline (i.e., after recording) as the mean differences across all electrodes. Use of this reference avoids biases due to the specific reference location, but requires extensive coverage over the entire head for accurate estimates. Whichever reference is used, it is important to realize that it can greatly affect the timing and shape of the final ERP waveform, which will always represent the voltage measured over a particular sensor with regard to the reference montage.

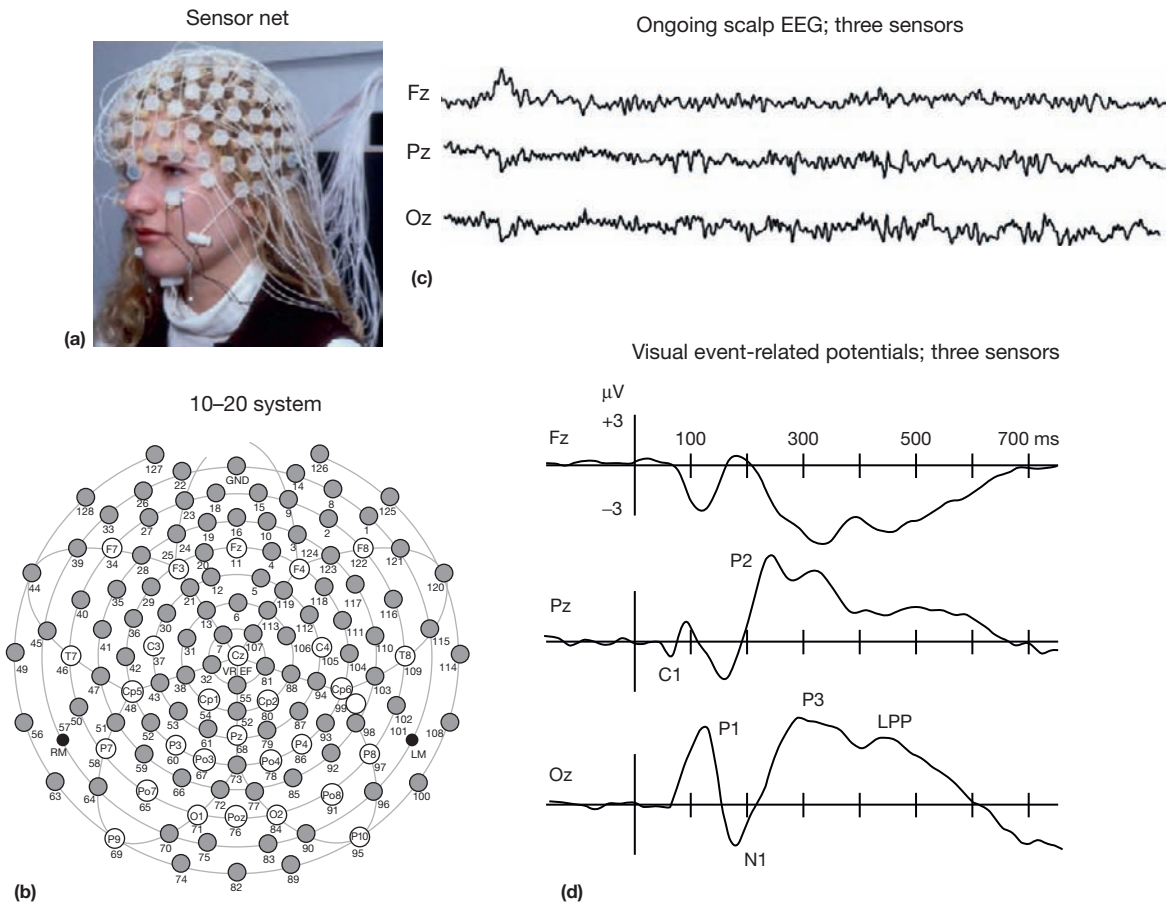

Figure 1 (a) An example of a dense sensor array used to measure EEG. (b) Layout of the 10–20 system and labeling of other sensors in a dense sensor array. (c) Ongoing EEG measured over a frontal (Fz), parietal (Pz), or occipital (Oz) midline sensor. (d) When the EEG in (c) is averaged across trials and deviated from the baseline, an event-related potential with peaks and troughs is produced for each sensor.

Amplifiers, Filters, and Sampling Rate

In addition to the selection of a reference site, other variables affect the quality and appearance of ERP during (and after) recording. The measured voltage at each sensor is typically amplified by appropriate hardware which can increase the amplitude of the EEG by factors of several thousands, making it highly sensitive to both scalp noise and high impedance, which is a measure of the factors that impede the flow of current. Traditional recordings of EEG have attempted to keep the scalp impedance below 5000Ω , which can be measured after the sensors are applied to the head. Recent developments in EEG technology include the creation of very high-input-impedance amplifiers, which allow clean recordings even when scalp impedances are ten times higher than the traditional threshold.

Filters are also used (both during recording and after recording) to further suppress unwanted noise that is not eliminated by signal averaging. Filtering is particularly effective if the desired (or the unwanted) signals are characterized by a certain frequency, for example, AC line noise at 60 Hz. The selection of filters for reducing noise in specific frequency bands will greatly affect the resulting ERP, as low-pass filters (e.g., those that pass frequencies below a certain level) will allow slow changes to remain in the EEG recording, and

high-pass (e.g., those that pass frequencies above a certain value) filters will allow fast changes to remain in the signal. Thus, filters that constrain the spectral content of the signal affect the resulting presence or absence of slow- or fast-going deflections in the final ERP.

The sampling rate at which the analog voltage fluctuations at the scalp are digitized into a numeric representation (using an analog-to-digital converter) will also influence to what extent slow- or fast-going deflections are visible in the averaged ERP. For most applications, sample rates of 250 Hz (i.e., 250 samples per second) will allow veridical reconstruction of the ERP. Using a sample rate of 250 Hz also means that the brain process under consideration will be monitored every 4 ms, affording exquisite time resolution.

Artifact Control and Rejection

After the EEG is recorded, several sources of noise may still be present in the signal, regardless of filtering. Extraneous electrical activity that leads to artifacts in the measured EEG include eyeblinks, eye movements, muscular activity, external electromagnetic noise, sweating, and heart rate potentials. Such artifacts can often be identified in a process of visual inspection, and

discarded or corrected by appropriate algorithms. In traditional approaches to artifact correction, EEG segments (or sensors) containing artifacts or contaminated sensors were completely removed from the data, leading to data attrition.

More recent methods try to retain as much of the recorded data as possible by mathematically modeling certain types of artifacts (e.g., eye blinks), and then correcting (i.e., recalculating) a version of the original EEG that estimates the true signal without the targeted artifact. Often borrowing from methods used in geophysics, signal detection, and engineering, these computational algorithms use advanced interpolation and artifact correction techniques, in which bad data segments or sensors are estimated using statistically weighted spherical interpolation from the full sensor set. To result in accurate estimates, these techniques rely on the use of a moderate to large sensor montage at recording.

Segmenting and Averaging

The positive and negative deflections associated with a specific ERP are typically quite small, and are embedded in ongoing EEG activity that is not time-locked to the event of interest (**Figure 1(c)**). As noted earlier, a simple way of reducing the contribution of nonrelated EEG activity is by averaging activity that is time-locked to the event of interest (**Figure 1(d)**). Random activity not related to the event will cancel out (i.e., positive and negative deflections that occur randomly in time) as the number of trials included in the average increases, leading to greater suppression of the nonstimulus-related EEG activity. Depending on the size of the ERP of interest, recommendations for the number of trials necessary for extracting meaningful ERPs range between 15 and 20 trials (e.g., for extracting large responses to salient visual target stimuli) to thousands of trials (e.g., for extracting the brainstem's response to specific sounds).

When averaging trials, the selected segments from the EEG typically includes a baseline period that occurs just before the event of interest (e.g., often 100–200 ms) and a variable amount of time following event onset (e.g., 1000–2000 ms is fairly typical postbaseline interval). After averaging over multiple trials, the ERP represents the part of the signal in each trial that is time-locked and phase-locked to the event, which means that the peaks and troughs in the resulting waveform tend to occur at the same time and with the same voltage (positive or negative) on most trials. Once the baseline is subtracted from each timepoint following event onset, the resulting ERP waveform will typically consist of a sequence of positive- and negative-going voltage deflections, which vary in their latency, amplitude, and topographical distribution across the scalp.

ERP Components

The pronounced positive and negative deflections in the ERP that are reliably present in a specific experimental context are often called components, and are typically labeled by letter-number pairs indicating their polarity and temporal position in the sequence of deflections. For instance, N1 refers to the first negative deflection, whereas P2 is the second positive deflection. Historically, the numerical index reflected the

temporal latency of a component in milliseconds rather than its temporal position but in recent years labeling an ERP component by its temporal position (e.g., 1, 2, 3) is preferred, as the specific timing of a component can vary broadly, depending upon the experimental context. Thus, for instance a classical ERP component originally labeled 'P300' (i.e., a positive deflection at 300 ms after stimulus onset) is often also referred to as a 'P3' component. Whereas the P3 typically tends to be the third positive peak in studies of visual attention and perception, its temporal maximum is not always at 300 ms. Slower components in the ERP are longer lasting deflections that often lack a clear peak, and are typically labeled, depending upon their polarity, as positive or negative slow waves or potentials. Occasionally, an ERP component that occurs very reliably in a specific paradigm is named, such as the LRP – the lateralized readiness potential – which is an ERP that is maximal over contralateral sensors when preparing to make a motor movement on one side of the body.

Statistical Analysis and Interpretation

Positive and negative components are generally taken as indices of neural activation that reflect underlying latent processes, with a greater amplitude suggesting stronger neural activity at the time point selected. In general, extraction of dependent variable from a spatial-temporal array such as the ERP waveform recorded at many electrode sites is nontrivial. Multivariate statistical approaches such as principal component analysis (PCA) have been used to reduce the many time points included in the averaged waveform to specific time intervals and scalp regions that are sensitive to the experimental question. Then, either averaging over the specified time interval or scoring the peak activity in that time interval results in the dependent measure of interest. PCA can also be used to reduce the spatial information and combine electrodes into groups showing similar time course and/or sensitivity to the experimental manipulations. Difference waveforms between two experimental conditions are also sometimes used to highlight a neural difference between experimental events that are identical except for a variable of interest that was manipulated in the experiment.

In addition to amplitude measures, the latency at which specific components occur is of interest in some experimental studies. Although determining component latency (the point in time at which the peak of the deflection occurs) can be used as an estimate for the point in time at which neural activation occurs, its implementation is variable and, because analysis of single trials is difficult in ERP studies, relies on the average latency across all the trials going into the average.

In addition to the amplitude and latency of different ERP components, ERP studies also result in topographical information that specifies the sensor locations at which selected positive and negative voltage deflections are maximal. Because the EEG records activity from large cell assemblies whose original locus is spatially smeared by conductance properties of the scalp and other brain matter, the topographical information associated with a measured ERP component does not specify the original source of the neural activity. Moreover, because any specific scalp topography can be generated by many different configurations of potential sources of neural activity, the

topography of any voltage distribution measured at the scalp does not uniquely identify the underlying sources. Thus, the topographical information in an ERP study primarily allows more precise labeling of the ERP component, which is useful both for comparison across paradigms as well as for differentiation from other components that may occur in the same time interval but measured at other sites.

Statistical analyses of ERP amplitude, for instance, will often include not only the key experimental manipulations, but also the electrode site (as a factor) to statistically identify its topography (e.g., larger over parietal than frontal; larger left than right, etc.). Depending upon the size of the sensor array, this can lead to conducting a very large number of statistical tests, particularly when dense arrays (e.g., up to 256 sensors) are used, prompting problems associated with alpha error accumulation: How many of the significant test results can be attributed to chance, given that a high number of statistical tests were conducted? Recently, procedures to control alpha error accumulation have been newly developed or adopted from neuroimaging work, in which this issue also arises.

ERPs and Psychological Processes

ERPs are a powerful tool in identifying neural correlates of mental processes associated with information processing and behavior in human participants, as well as in understanding individual differences due to psychopathology, brain insult, aging, and other clinically relevant phenomena. They are used to make inferences about the presence or absence of processes in a specific experimental context, as well to draw conclusions about the timing and ordering of these processes. Nonetheless, it is important to emphasize that an ERP component does not exist independently of the specific experimental context in which it is measured. For example, a 'P1' obtained during visual perception does not necessarily identify the same underlying process as a possible 'P1' that might be measured in olfaction. The interpretation of specific ERP components (either punctate deflections or slow waves) always needs to be tied, at least initially, to the experimental context in which they arise. When an ERP component with a similar timing and topography is found in a different experimental context, careful experimentation is needed to conclude that the same latent process is responsible. Such experimentation will involve systematic comparisons of the contexts prompting that ERP component within the same participants.

Secondly, even when an ERP component appears to consistently vary with a specific experimental manipulation, this does not confirm that the inferred process was actually measured by that component. For instance, if a study finds that the amplitude of a visual P1 component is enhanced in a study of spatial selective attention, this cannot be taken to conclude that an increase in P1 amplitude always indicates that spatial attention was paid to a stimulus. Rather, P1 amplitude can be affected by whether the stimulus is brighter, closer, or more salient in a context, have greater spatial frequency, or has other properties that may lead to the observed change. Again, careful experimental scrutiny is needed to strongly infer that a specific ERP component indexes a specific mental activity.

The critical dependence of the interpretation of ERPs on the specific paradigm of its investigation can be demonstrated for the P3 component, one of the most investigated ERP deflections in psychological research. As its name implies, the P3 is a positive ERP component, often occurring as the third positive deflection in the ERP. It was originally measured in the context of an 'oddball' task in which a tone of the same frequency was played over and over (i.e., 'the standard') and subjects were instructed to count or otherwise respond to rare presentations of a different tone (i.e., the 'oddball'). A P3 component (often occurring 300 ms after stimulus presentation) was larger (over parietal sensors) for the oddball, compared to the standard stimulus, and later studies found that P3 amplitude was generally heightened for any task-relevant stimulus.

Extensive work using both visual and auditory stimuli in the oddball task has yielded a complex database regarding this ERP component, which suggests that the P3 consists of several overlapping subcomponents that depend both on features of the stimulus (e.g., a novel or rare stimulus) and features of the task. For instance, a more frontally oriented and somewhat earlier P3 component, often called the novelty P3 or P3a, describes P3 amplitude enhancement over frontal sensors when novel stimuli appear as nontargets in a stream of events. Task relevance is not critical for measuring this component. In a similar but slightly longer time range, a P3 enhancement over posterior regions has been observed for stimuli that are task-relevant, even if they are not novel, often called P3b. Experiments have investigated the contribution of active motor responses, type of task, modality of target and nontarget, probability, and frequency to the amplitude of the P3 component. Current theoretical interpretations of the P3 suggest that it indexes allocation of attentional resources during perception and mentation.

The database of ERP research is dense, comprised of many thousands of studies conducted since the technology first became widely used in the 1960s. Consistent with the goal of psychological science, certain reliable components have been identified and hypotheses regarding their functional significance advanced. Because both vision and hearing are critical in human information processing, much of the research has measured ERPs in experimental contexts which prompt perception, attention, and action following visual or acoustic stimulation, which is briefly reviewed below.

Visual ERPs

The presentation of a visual stimulus, or even the induction of a simple brightness change in the environment, leads to a characteristic ERP waveform whose components are maximal over sensors located on the posterior part of the scalp. Because the visual system in humans is highly parallel and complex as well as widespread, visual ERPs tend to extend over longer time ranges than auditory or somatosensory potentials. [Table 1](#) (top panel) lists a sequence of potentials together with their latency, neurophysiological interpretation, and factors that impact their amplitude.

Auditory ERPs

The human auditory system is more confined in space and more time sensitive than the visual system. Most auditory

Table 1 Common ERPs measured when processing visual and acoustic events

	<i>Peak latency (ms)</i>	<i>Neurophysiology</i>	<i>Varies with</i>
Visual ERP			
C1	40–80	Response in the calcarine fissure (= lower tier visual cortex)	Physical stimulus features, some forms of spatial selective attention
P1	80–120	Arrival of cortical activation in extrastriate cortex	Spatial selective attention, some forms of feature-based attention
N1	140–190	Spread across the visual system, reentry from frontal cortices	Feature-based attention, match or mismatch with expected semantic content, priming, face processing
P2/N2	200–280	Engagement of wide cortical areas, occipitoparietal focus of activity	Perceptual novelty; stimulus mismatch; response inhibition
P3	300–500	Contributions from widely distributed cortical and subcortical regions	Stimulus probability; attention allocation; task relevance
Late positive potential (LPP)	>400	Contributions from widely distributed cortical and subcortical regions	Sustained attention; motivational relevance; memory retrieval
Auditory ERP			
Brain stem auditory evoked potential (AEP)	1–10	Responses in the deep nuclei in the brain stem; require thousands of averages (stimulus repetitions). Labeled I, II, III, IV, V	Physical stimulus features; temporal properties of the acoustic sequence
Middle latency components: No, Po, Na, Pa, Nb, and P1, Pb, P50	10–40	Subcortical and primary auditory cortical neural activity; require several hundreds of averages	Physical stimulus features; temporal properties of the acoustic sequence
N1	50	First pronounced response of (primary) auditory cortex	Stimulus detection and encoding
	70–110	Primary and secondary auditory cortex	Interstimulus interval; changes in stimulus frequency; rate of presentation; predictability
P2	120–200	Contributions from widely distributed cortical and subcortical regions	Similar to N1
N2, N2a, N2b, N2c	200–250	Contributions from widely distributed cortical and subcortical regions	Stimulus deviance; novelty; task relevance
P3	>250	Contributions from widely distributed cortical and subcortical regions	Stimulus probability, attention allocation, task difficulty

ERP components are generated in the temporal lobe of the cerebral cortex, located bilaterally above the ears and are best recorded from the top of the scalp. A particular feature of auditory recordings is a very early response to sound that can be recorded from the brainstem, if sufficient numbers of trials are available (see [Table 1](#), bottom panel).

Source Analysis

As noted previously, knowing the topography of a specific ERP component does not provide specific information regarding the original sources of the electrical activity that have been measured over the scalp. Nonetheless, there have been several computational efforts in recent years that attempt to estimate the sources contributing to the ERP measured over the scalp. A number of issues are critical in this work.

The Inverse Problem

Both the size of the sensor arrays and their location outside the brain limit the ability to spatially sample the neural generators presumed to underlie the measured scalp voltage. EEG provides a two-dimensional (2D) projection of a three-dimensional (3D) reality, and it has long been known that an infinite number of

3D source configurations exist that can produce a given 2D projection. This is referred to as the inverse problem: It is difficult to go backwards from the 2D signal to generate the sources in 3D space. In practice, this means that there is no mathematically unambiguous way to calculate the neural sources of an ERP voltage distribution. Nonetheless, several methods have been developed that use additional knowledge to constrain the infinite solution space, or to infer gross source configurations by means of simple data transformations.

Mapping Techniques

The extent of the spatial sampling of scalp voltages affects the ability of researchers to use topographical information of the ERP distribution over the scalp to infer sources. With the advent of dense-array EEG/ERP recordings (with up to 257 sensors), the possibility of more accurate source localization of the underlying the scalp-recorded EEG has dramatically risen. By taking into account the physics of current flow in a conducting volume together with sufficient spatial sampling, transformations of the topographical map are available that highlight the current flow on the scalp and allow one to infer possible sources of brain-electric activity. Among the most widely used techniques is the current source density (CSD) mapping approach, which is mathematically based on

the Laplace operator. The Laplacian can be conceived of as the second spatial derivative of the voltage map, thus showing the change of the voltage gradient across the scalp. Assuming no sources in the scalp, the CSD map will be proportional to the radial current flow in or out of the skull at a given site. Because it is reasonable to assume that most generators of the ERP are located in near-surface cortex, this type of measure allows a first approximation of the underlying electrocortical sources.

Source Estimation Techniques

A more elaborate source analysis technique harnesses the spatial information inherent in multichannel ERP recordings using appropriate algorithms to guide estimates as to their cerebral origin. Historically, one of the first techniques used tried to fit the surface potential distribution by assuming it was generated by a single equivalent current dipole. In this procedure, the assumption is that the voltage map at the scalp reflects the activity of a single neural source with a positive and negative pole. The procedure uses knowledge about the possible distortion of this signal together with the current flow in the head to systematically fit a source dipole that is most similar to the measured voltage distribution. To this end, a forward calculation is performed many times, which generates various voltage distributions based on many different dipole locations and orientations, and the one location, strength, and orientation that leads to the distribution most similar to the measured signal is assumed to be the source. This procedure is called inverse modeling.

An alternative distributed source modeling procedure has been proposed as a means for enhancing the resolution of electrophysiological data without constraining the inferred

electric activity to point sources or single dipoles. In this procedure, hundreds of potential dipoles at various locations in a 3D volume are included in the model which estimates the scalp voltage distribution. Several different procedures have been suggested and are in current use. Efforts are also under way to obtain more accurate 3D representations of voltage sources in the brain, although the basic issues inherent in the inverse problem remain to be solved.

Glossary

Empirically supported treatments A term used by psychologists to designate behavioral health interventions that are supported by evidence from either clinical trials or single case experimental designs.

Evidence-based behavioral practice (EBBP) EBBP applies the concepts and methods of EBP to behavioral health practices that address mental health and health risk behaviors.

Evidence-based practice (EBP) EBP is both a conceptual model and a process. The conceptual model, depicts 'three circles' or data streams to be integrated via decision making: research, client characteristics (including values and preferences), and resources (including practitioner expertise or skills). Performing the EBP process entails carrying out a sequence of five steps. After assessing the presenting problem, the practitioner: (1) asks key questions, (2) acquires evidence to answer them, (3) appraises its quality and contextual relevance, (4) applies the evidence via shared decision making that integrates client characteristics and

resources, and, after reassessing, (5) analyzes outcomes and adjusts practice accordingly.

Evidence consumers Those who apply evidence, usually for the purposes of implementing clinical or public health practice or policy, or for educational purposes.

Evidence creators Researchers who perform studies to produce data that tests a hypothesis or answers a question.

Randomized controlled trial (RCT) A study in which participants are assigned to different intervention conditions at random and the groups' outcomes are compared for the purpose of determining whether one intervention is more effective than another.

Systematic evidence review A structured review of research that addresses a well-formulated question and applies comprehensive, rigorous, systematic, and transparent methods to minimize bias in the results. The review protocol follows predetermined inclusion and exclusion criteria, critical appraisal of the relevant research, and extraction and synthesis of data from the evidence to formulate findings.

Introduction

Evidence-based practice (EBP) is both a conceptual model and a process of patient-centered decision making. Originally introduced in medicine, the EBP framework has now been endorsed by all major health professions. Here we describe how the concepts and methods of EBP can be understood and implemented by mental and behavioral health care professionals in support of integrated patient care. The conceptual model, elaborated below, depicts 'three circles' or data streams to be integrated when making practical decisions to promote health. One circle represents best available research evidence; the second is client characteristics (including preferences and values); the third is resources (including practitioner expertise or skills). Performing the EBP process entails carrying out a sequence of steps. The practitioner frames clinical questions, locates and contextualizes evidence to answer them, assesses outcomes, and adjusts practice accordingly. By understanding the EBP framework, behavioral health care providers are better able to communicate with other health professionals in a manner that integrates care for mental and physical health.

Terminology, Rationale, and Tools for EBP

Since its first emergence in medicine a century ago, the evidence-based movement has been about finding ways to distinguish quackery from valid health practices. EBP now has become recognized as a core competence for all health professions. Here we address EBP's implications for psychologists, social

workers, physicians, nurses, public health practitioners, and others who implement nonmedical interventions to address the mental health needs and health risk behaviors of clients.

We call the relevant class of interventions behavioral health treatments, while acknowledging that this phrase is sometimes used more narrowly to designate only mental health interventions. In our usage, behavioral health treatments are non-medical interventions that address psychosocial or behavioral problems such as depression, anxiety, obesity, and substance abuse that have documented adverse effects on health and health care costs. Relevant research-supported treatments are sometimes called evidence-based *behavioral* practices (EBBP) because they do not entail medical components: drugs, surgery, medical devices. Psychologists in the United States sometimes call behavioral health interventions empirically supported treatments (EST) if they are supported by results from one or more clinical trials or single case experimental studies. Ironically, though, usage of the phrase 'empirically supported' can cause confusion when used in the context of an interprofessional team. EST connotes positive features to psychologists by suggesting that a treatment has research support. In medicine, by contrast, the phrase 'empirically supported treatment' has negative connotations. The wording suggests use of an intervention in a trial-and-error, exploratory fashion to see if a good effect can be produced, despite the fact that the treatment lacks a basis in clinical trial evidence or pathophysiology.

Many date the onset of the evidence-based movement to the 1910 publication of the Flexner report that challenged the quality of that era's medical training. The Flexner report, a work commissioned by the American Medical Association and

the Carnegie Foundation, set out to ground medical education on a firm scientific foundation.

The EBP movement has continued to press for rational, systematic provision of high-quality care. To achieve that objective, the first problem that needed to be resolved was to find a basis on which to judge the quality of alternative care options. Randomized controlled trials (RCTs), first championed by Archibald Cochrane in the early 1970s, have become accepted as the most valid method to determine treatment effectiveness. Cochrane proposed that the value of a treatment should be determined by high-quality RCTs because this method provides the most valid, least biased estimate of treatment effectiveness. However, it is widely recognized that uptake of best practices supported by RCTs is abysmally slow and incomplete and that many clinical practices have little or no research support. To address these criticisms, it was necessary to develop concise and far-reaching ways to disseminate findings about EBP.

The systematic review is one tool that was introduced to help bridge the research to practice gap. Systematic reviews are literature reviews that employ rigorous, thorough, and transparent methods to minimize bias in the results. Systematic reviews provide a vehicle to synthesize evidence across numerous clinical trials. The Cochrane Collaboration, founded in 1992 and now grown into an international network, prioritizes, performs, and regularly updates systematic reviews, and disseminates them to end users via the worldwide web.

Practice guidelines are sets of recommendations or principles to help health professionals and patients make decisions about screening, prevention, and treatment of specific health conditions. Federal agencies or professional organizations are usually the entities that undertake preparation of practice guidelines. To be considered evidence-based, a guideline must be demonstrably derived from a systematic literature search and review of existing scientific evidence published in peer reviewed journals. However, the systematic review itself only summarizes the evidence; it is silent about practical applications. The job of extrapolating from evidence to clinical recommendations is the task of guidelines creation.

High-quality guidelines explain very explicitly the logic that was applied to derive recommendations from the evidence. The guidelines created by the United Kingdom's (UK) National Institute of Clinical Excellence (NICE) offer an excellent example. NICE guidelines serve as a link in the chain of the UK's EBP policy. They are formulated on the basis of systematic evidence reviews that the National Health Service (NHS) commissions in order to determine which health care procedures to fund. Other evidence-based guidelines can be found by searching the National Guidelines Clearinghouse website. Sponsored by the US Agency for Health Research and Quality, the National Guideline Clearinghouse posts more than 2000 evidence-based guidelines.

Growth of the Evidence Base

One of the greatest challenges EBP faces stems from gaps in the research literature. Insufficiencies are especially stark in the areas of nonpharmacological treatments for mental health conditions and for health promotion, preventive care. On the one hand, there is a great abundance of high-quality evidence

demonstrating adverse effects of poor behavioral health on quality of life, chronic disease risk, and costs. On the other hand, the evidence base evaluating the efficacy and cost impact of interventions to modify behavioral risk factors is relatively meager and of modest quality.

A consequence is that policy makers often find too little high-quality evidence to recommend for or against the delivery of many behavioral health interventions. Of course, absence of evidence is not the same as evidence of absence of an effect. Nevertheless, guideline panels are often compelled to assign a grade of 'I' ('insufficient evidence') for behavioral health interventions. A grade of 'I' renders a policy-making body unable to advise for or against the intervention because the available evidence is of insufficient quality or quantity to support a recommendation.

There is a critical need for a high-quality base of clinical trials that evaluate behavioral health treatments. The fact that creators of evidence-based guidelines apply the same evaluative criteria to trials of medical and nonmedical treatments levels the playing field for psychological and psychosocial interventions. Patients often express a preference for nondrug treatments. Strengthening and disseminating the evidence base for behavioral health interventions supports patient-centered care by helping the public to access and benefit from all effective health treatments. To strengthen the needed evidence base, the US Congress recently authorized new research on comparative effectiveness. In a comparative effectiveness trial, two or more efficacious treatments are contrasted in a head-to-head comparison that tests which one works best and at what relative costs. It is to be hoped that a body of evidence comparing alternative behavioral health treatments to each other and to medical alternatives will support evidence-based policies that expand the effective behavioral health treatments available to patients.

Transdisciplinary collaboration

The start of the twenty-first century has ushered in calls for increased collaboration and teamwork among scientists from different disciplines and practitioners from different professions. Scientific funding agencies encourage transdisciplinary collaboration based on recognition that scientific progress is often made at the interface of preexisting disciplines. Thought leaders and policy makers call for greater collaboration in the education of health professionals based on the expectation that future health care teams will be increasingly interprofessional. The US Institute of Medicine endorses cross-training among the health professions to help care delivery transition toward a 'patient-centered health home' that provides coordinated, accessible team-based care that addresses all of an individual's health care needs.

Yet, despite the advantages that accompany professional boundary spanning, vast differences between disciplines in vocabularies and frames of reference can impede progress. That EBP has come to provide a shared vocabulary and perspective across health disciplines offers tremendous advantages for communication. Learning EBP vocabulary and methods affords behavioral interventionists invaluable opportunities to participate in interprofessional collaboration. The shared EBP framework supports jointly held foundational assumptions, vocabulary, and practice principles for behavioral health practitioners who participate in interprofessional teams.

Lifelong learning

The methods of evidence-based behavioral practice were developed as a way to close the research to practice gap and foster lifelong learning. A well-documented chasm exists between what research shows to be effective and what is done in usual clinical practice. Often, practitioners continue to implement practices they learned during training, even when few of those practices were ever based upon evidence and some have been supplanted by new evidence.

The research evidence base relevant to health professionals proliferates at an astonishing rate. There exist ~23 000 clinical journals that publish more than 2 million articles annually. It is difficult to imagine how a practitioner could keep up-to-date with this primary literature.

At McMaster University in Canada in the early 1980s, there developed a critical mass of faculty with an ambitious agenda to close the research to practice gap. The group wrote many journal articles and books about how to keep up with and understand the research literature. They wanted to develop a method that let practitioners find and apply evidence that answered their questions in real time, during the actual clinical encounter. The idea was to make it a habit to routinely ask questions, consult research, and integrate knowledge from three data strands (research, clinical experience, and the patient) when making clinical decisions. The rationale was that routinely performing such integration would overcome old, automatic, decision-making biases and cultivate new learning. Gordon Guyatt coined the phrase 'evidence-based medicine' to describe the EBP process. The new name represented a departure from the older term, 'scientific medicine,' which omitted the clinician's and patient's contribution to decision making and overemphasized making inferences based on pathophysiology. The basic premise of EBP is that there should be no learning disjuncture between graduate school and subsequent professional life. While in school, just as afterward, engaging in evidence-based behavioral practice involves finding and implementing the practices that are supported by best available current research evidence. It is to be hoped that scientific progress supplants older best practices with newer and better ones, and that the evidence-based practitioner will continue to find the best evidence and upgrade respectively.

One can only marvel at the McMaster group's audacity. Just imagine trying to train practitioners to do library searching and critical appraisal of research at the bedside in real time before the advent of the internet. Having rapid access to the research evidence base at the point of care became critically important. Such access became feasible as the emergence of large electronic data sets brought library resources to the desktop. Perhaps not surprisingly, the McMaster group has played a key role in developing the health informatics that are needed to store, retrieve, manage, and use health information at the time and place that decisions need to be made.

The science of informatics addresses resources, devices, and structures (e.g., treatment algorithms, practice guidelines, systematic evidence reviews, and electronic medical records) that are needed to store, retrieve, manage, and use evidence at the point of care. A growing set of databases of secondary, synthesized literature has evolved to meet practitioners' needs. One important resource already mentioned is the Cochrane Collaboration's online database of Systematic Reviews of

health care practices. Other more clinically oriented resources to address practical questions are available online and/or on a hand-held device. These tools, based upon continually updated evidence reviews, offer pithy evidence synopses, clinical practice guidelines, and structured abstracts. Examples of online resources are UpToDate, MD Consult, ACP Journal Club, Clinical Evidence, InfoPOEMS, and Clin-eguide. The phrase, 'evidence-based capitulation' is sometimes used pejoratively to describe practitioner reliance on filtered, synthesized evidence resources rather than primary research studies. However, use of such infrastructure is in keeping with the voluminous realities of contemporary science and practice.

Conceptual Model of EBP: Three Circles

The root conceptual model for evidence-based behavioral practice depicts three interlinked circles (i.e., data strands) that need to be integrated in order to determine optimal client care. Research evidence has consistently remained a circle as EBP models evolved over time. In 2006, the National Institutes of Health's Office of Behavioral and Social Science Research commissioned the first author to undertake a 5-year project to create 'Resources for Training in EBBP' that harmonize the EBP approach to behavioral health interventions and support communication and collaboration across health disciplines. The resulting interprofessional Council and Scientific and Practitioner Advisory Boards for Training in Evidence-Based Behavioral Practice, include EBP experts from medicine, nursing, psychology, social work, public health, and library sciences. The Council's transdisciplinary model of EBP, depicted in [Figure 1](#), incorporates the most important conceptual advances made by each profession and reflects an emphasis on shared decision making. Additional information and online tutorials about EBP can be accessed free of charge or for continuing education credits via the EBBP Project website.

The transdisciplinary EBP model depicts three data streams to be integrated when deciding upon a course of action: evidence, client characteristics, and resources. Best available scientific evidence remains one of the three circles. Client values, preferences, and characteristics remain a second circle. Reflecting a conceptual advance from public health, the third circle is resources, which includes practitioner skills. Decision making is the central concept of the model and the action that ties the three data streams together in EBP. The interprofessional EBP model is grounded in an ecological framework that suggests a need to understand a problem in context and address influences at multiple levels. Consequently, the model depicts decision making in the environmental and institutional surrounding context that frames it.

Best Research Evidence

Evidence comprises research findings derived from the systematic collection of data through observation and experiment and the formulation of questions and testing of hypotheses. What constitutes best research evidence depends upon the question needing to be addressed. For example, for questions about etiology or prognosis, the optimum research design is often a longitudinal cohort study. For questions concerning the efficacy and effectiveness of treatments, the research design least prone to bias or error is the RCT. Topping the evidence

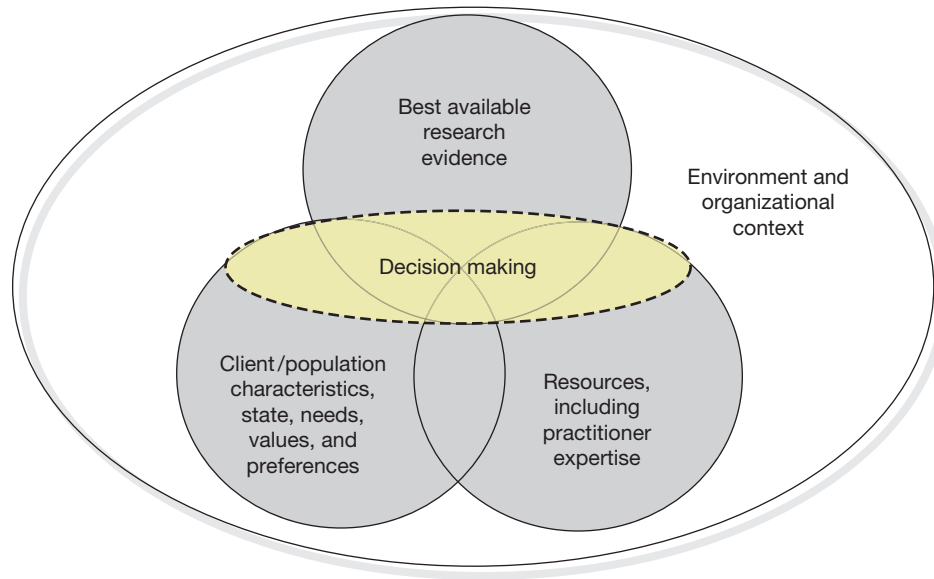

Figure 1 Elements that need integration in EBP. Reprinted with permission from Spring B and Hitchcock K (2009) Evidence-based practice in psychology. In: Weiner IB and Craighead WE (eds.) *Corsini's Encyclopedia of Psychology*, 4th edn., pp. 603–607. New York: Wiley.

pyramid for a question about treatment is the systematic review, which synthesizes the findings from many treatment trials. Recently there have been renewed calls for contextualized research evidence that is directly relevant to the specific patient and practice context. Accordingly, some presentations of the evidence hierarchy place at the apex of the evidence pyramid an $N = 1$, single case study using an experimental design that tests the treatment of interest with the target patient.

Resources

The resources circle depicts the skills and infrastructure support that are needed to offer EBPs. Resources include the physical, technological, personnel, and financial assets needed to deliver treatments (e.g., space, time, technological support, finances including insurance reimbursement, and expert practitioners trained in the EBP). Unless they are fully automated (e.g., internet delivered treatments), all evidence-based behavioral health interventions require practitioner competence in communication, assessment, and counseling skills (e.g., building a therapeutic alliance). Many evidence-based behavioral health treatments also require that the interventionist possess complex clinical skills that require substantial supervised training to develop. Other needed resources may involve institutional endorsement by higher administration and agreement from other system components.

Universally, resources are a variable that factors into evidence-based decisions. The most efficacious treatment is irrelevant to any but theoretical EBP if there is no trained practitioner accessible to deliver treatment or no resources to pay. The creation of resource-sensitive practice guidelines is a new development in EBP. Such guidelines review the quality of evidence supporting alternative practice recommendations that fit the resources available. Decision makers can use the guideline to gage the level of intervention intensity that makes best use of accessible infrastructure, human capital, and financial wherewithal.

The transdisciplinary EBP model incorporates practitioner expertise within the broader circle that depicts needed resources. In earlier models of EBP, the circle named practitioner expertise generated the greatest controversy and underwent several revisions. The problem, in part, reflected ambiguity in medicine's original EBP model, which sometimes led practitioner expertise to be misconstrued as opinion or unquestioned intuition. Later versions of the EBP model in medicine operationalized expertise as skill in performing the steps of the EBP process (e.g., asking questions, acquiring evidence, critically appraising research), etc. In the transdisciplinary EBP model, practitioner expertise entails four categories of skills: (1) assessment skills; (2) EBP practice process skills; (3) communication and collaboration skills; and (4) engagement and intervention skills.

Client Characteristics, State, Needs, Values, and Preferences

Except for single case studies, research evidence describes the average responses of individuals or groups. The core challenge addressed by EBP is how to apply the averaged data to a particular individual or community. The evidence needs to be appraised in relation to the particular circumstances at hand. Client characteristics are one key set of contextualizing factors that need to be taken into account. Relevant client attributes include state and trait variation in condition, needs, history of treatment response, values, and preferences. To decide whether available research evidence is truly relevant to the client, a judgment needs to be made about the comparability between the study population and the client. Some tailoring (e.g., literacy level of materials) can often enhance treatment feasibility and acceptability, without undermining fidelity to the core treatment elements that make a treatment effective.

Client preferences warrant special mention as a contextualizing variable. Patient preferences are the lynchpin of shared decision making, but are also the least developed aspect of the

EBP model. The rationale for shared decision making is to engage patients more fully in self-managing their own wellness and health care. For shared decision making to become a reality, there are two needed preconditions. One is departure from an authoritarian model of care in which the provider makes decisions on the patient's behalf. The other is progress toward a more culturally informed shared model of care. The idea is for providers to respect and help patients clarify their own values and treatment preferences so that patients can behave in ways that will enhance their personal health and well-being.

The need to systematize an approach to client preferences is inescapable and complex. How individuals weigh out the relative risks and benefits of treatment alternatives is personally distinctive, subjective, and often not previously considered by the patient. The issues are no less complex when a community deliberates how to invest resources in order to curtail a public health problem. Effective deliberation also requires information that may be unknown to the clients, such as the range of intervention alternatives, including watchful waiting, and their potential inconveniences and risks. For many psychological conditions, patients need to determine whether they prefer

to be treated pharmacologically, psychosocially, or both. The availability of insurance coverage for specific treatments factors in, as do such logistical considerations as geographic access to trained therapists, scheduling, transportation, and child care. For public health problems (e.g., obesity), there may be trade-offs between investing resources in prevention or treatment, physical infrastructure, program staffing, or policy outreach.

EBP has done much to highlight the importance of shared decision making in the health service delivery process. Engaging clients in decision making that acknowledges their preferences is justifiable on sociopolitical grounds of equity. Shared decision making is also justified on evidentiary grounds because shared decision making has been found to be associated with improved health outcomes.

Roles in EBP

As depicted in [Figure 2](#), behavioral health professionals have three main roles in relation to EBP. First, as primary researchers, behavioral health professionals contribute directly

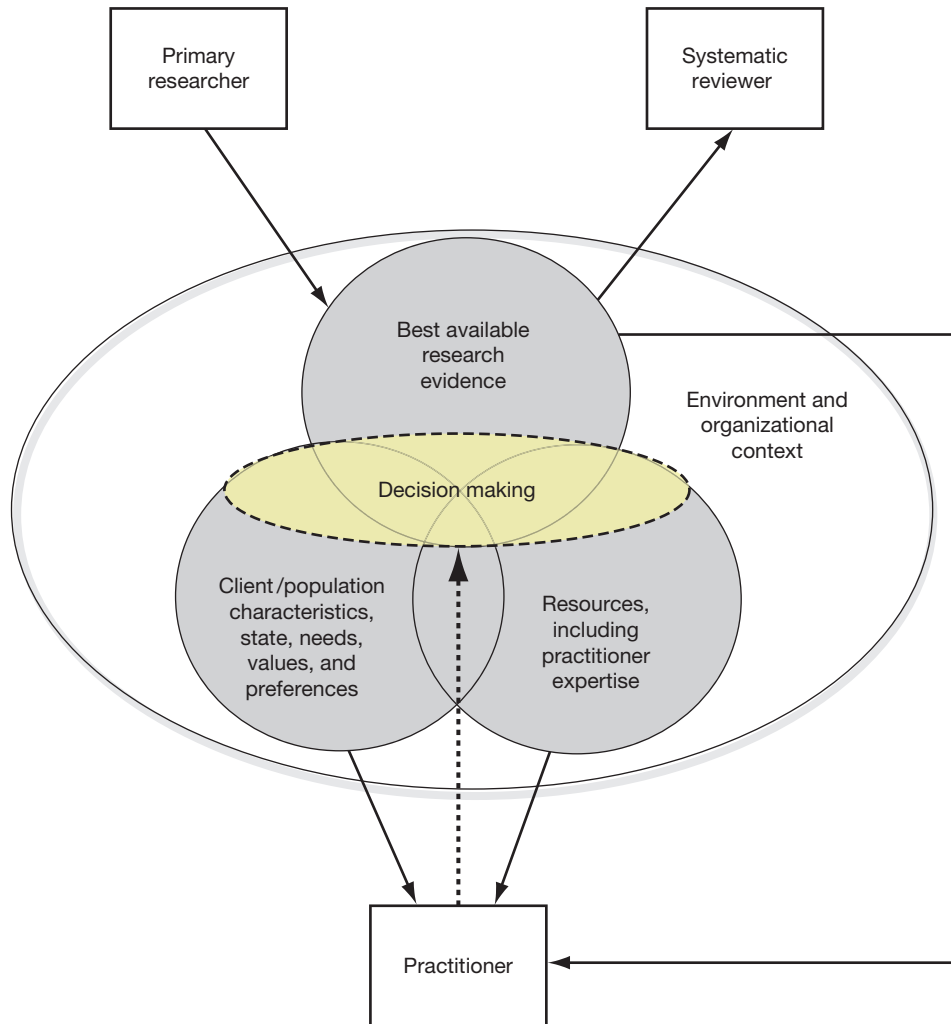

Figure 2 Practitioners' roles in evidence-based practice. Reprinted from Oxford University Press. Spring B and Neville K (2010) Evidence-based practice in clinical psychology. In: Barlow D (ed.) *The Oxford Handbook of Clinical Psychology*. New York: Oxford University Press, with permission from Oxford University Press.

to creating the evidence base. They design, conduct, analyze, and report research that characterizes the risk factors, course, and causal influences on a wide range of mental health problems and health risk behaviors. They validate instruments to assess mental health conditions and unhealthy behaviors, and they develop and test interventions to improve behavioral health outcomes. The evidence that primary researchers create is used by both systematic reviewers and practitioners.

Second, as systematic reviewers, behavioral health professionals use primary research that has been created by others in order to create syntheses that are used by practitioners and policy makers. They locate the primary research that addresses a practical question, and they critically appraise, extract, and synthesize the information to provide an answer. Systematic reviewing is itself a sophisticated and evolving form of research methodology that is increasingly becoming the basis for health policies.

Finally, as practitioners, behavioral health professionals have the most challenging role in EBP. The practitioner extracts and uses data from each of the three circles of EBP. In the assessor role, the clinician acquires and parses data about client characteristics, including developmental course, response to prior interventions, needs, core values, and treatment preferences. She or he collaborates with the client to identify the most pressing behavioral health problem that needs to be addressed. Next the clinician assumes the role of a research consumer, formulating the clinical question in a manner that will efficiently cull the best relevant research. Having found the literature, the clinician turns to critical appraisal, evaluating the research's quality and relevance for the client and context. Then the clinician engages in shared decision making with the client. In that process, the clinician is the authority on best practices; the client is the authority on personal preferences; and both collaborate to determine available resources. Part of the practitioner's resource assessment concerns her own personal training and skill in delivering the optimal evidence-based behavioral health practice and that of other clinicians in her referral network.

The EBP Process

The five steps of the EBP process are depicted in [Table 1](#). After assessing the problem, the practitioner performs the following sequence: (1) Ask a question, (2) Acquire the evidence, (3) Appraise the evidence, (4) Apply the evidence, and (5) Analyze and Adjust practice. Each step, described in greater detail below, is an integral component of the EBP process and represents a competency or skill to be mastered by the practitioner. Note that, rather than being considered a formal step in the EBP process, assessment is assumed to precede the onset of the process and to recur throughout it.

Ask: Asking Questions

After assessing the client, the practitioner poses key questions about optimal management of the presenting condition. Asking effective practical questions involves formulating them in a manner that allows them to be readily answerable. Skill at framing 'well-built' questions is an acquired competency.

Table 1 Steps in the EBP process

Step 1	Ask client-oriented, relevant, answerable questions about the health status and context of individuals or communities
Step 2	Acquire the best available evidence to answer the question
Step 3	Appraise the evidence critically for validity and applicability to the problem at hand
Step 4	Apply the evidence by engaging in collaborative health decision making with the affected client(s). Appropriate decision making integrates the context, values and preferences of the recipient of the health intervention, as well as consideration of available resources, including professional expertise. Implement the health practice
Step 5	Analyze the effects of the health practice and adjust practice. Evaluate implications for future decision making, disseminate the results, and identify new informational needs

Numerous important questions arise in practice. The major kinds concern: (1) assessment – questions about best ways of measuring, describing, or diagnosing a condition; (2) treatment – questions that address interventions to prevent, contain, or improve biopsychosocial or socioecological difficulties; (3) etiology – questions about influences that cause or contribute to the onset of a health problem; (4) prognosis – questions about the probable course and outcome of a health condition; (5) harm – questions that concern potential adverse effects of interventions; and (6) cost-effectiveness – questions about the expenditures relative to outcomes yielded by alternative courses of action. Because many questions will be generated for each client, prioritization of the most important ones needs to proceed in an efficient fashion. Criteria for prioritization usually concerns the impact of potential courses of action on the client's functioning or quality of life, or the perceived significance of an issue to the client.

Trainees learning to practice EBP are taught to differentiate two formats of question: background (general) and foreground (specific). Background questions aim to acquire general information about a condition, class of treatments, etc. A well-formulated background question comprises two parts: (1) a question root (What, Who, How, etc.) including a verb and (2) a disorder, treatment, or other health issue. Training in evidence-based medicine devotes almost no attention to background questions. Such questions are too diffuse and yield too many citations to be used efficiently in the very brief time that the physician has available for each patient. Behavioral health interventionists usually have longer to spend with each client. The authors' experience is that many psychologists, psychiatrists, or social workers ask background questions in order to update their knowledge when first preparing to see a client. Subsequently, after having assessed the client in context, the clinician proceeds to pose more focused and efficient foreground questions.

An example of a background question is: 'What are effective treatments for binge eating disorder (BED)?' A clinical psychologist preparing to see a new client with BED might pose such a question in order to ensure that her knowledge of current best treatment options is up to date. A subsequent foreground question takes the PICOT format because the query specifies

the Patient population, Intervention, Comparison condition, Outcome, and Time frame of interest. An example might be, 'In adults with BED (*P*), does interpersonal therapy (*I*) compared to cognitive-behavioral therapy (*C*) reduce the frequency of binge episodes (*O*) at 1-year follow-up (*T*). The better focused foreground question will yield citations that specifically inform a decision about whether to proceed with interpersonal or cognitive-behavioral therapy, assuming the clinician is trained to provide both and both are acceptable to the client.

Acquire: Acquisition of Evidence

Once a well-built question has been formulated, the next step is to acquire the evidence to answer it. This step requires the practitioner to translate the question into an efficient search plan. Help can be found in the EBBP project's online learning module about searching, or via consultation from a librarian or other information scientist. Navigating the sheer bulk of existing primary research can be daunting and time-consuming. Consequently, it is expected and advantageous that busy practitioners will turn first to the secondary synthesized literature to answer their questions. Practice guidelines based on systematic reviews can be found online via the US Government's National Guidelines Clearinghouse or the UK's NICE. Useful search strategies for retrieving systematic reviews have also been published. The authors of a systematic review or evidence-based guideline will already have compiled and critically appraised the quality of the primary research literature to answer many frequently asked questions. However, the clinician will still need to appraise the quality and relevance of the secondary resource.

Appraise: Critical Appraisal of Quality and Relevance

The next step in the EBP process is to critically appraise two aspects of the obtained evidence: its quality and its applicability to the client and circumstances at hand. In evaluating research on interventions, the key parameter to be appraised is internal validity: whether the research was designed and conducted in a manner that allows behavioral change to be attributed causally to the intervention rather than to extraneous influences. Applicability or relevance refers to the practitioner's judgment about whether the research results can be generalized to the specific client, interventionist, and circumstances at hand.

The appraisal of relevance is challenging. Applying either overly stringent or overly lax criteria to judge applicability may have adverse consequences. If the body of evidence is seen as having no relevance to new groups and circumstances, then old, untested practices could continue to constitute usual care for understudied and underserved populations. On the other hand, if interventions are assumed to be universally applicable, then the need to adapt treatment to attain client acceptance may be ignored. Given the limited body of research for psychosocial and behavioral interventions, few interventions have been evaluated fully to determine their efficacy across demographic and cultural groups.

What should the practitioner do when considering the prospect of delivering a well-established intervention to a client from a demographic subgroup whose response to the intervention has not been fully characterized? One possibility

is to search the primary research literature for evidence of subgroup interactions indicative of differential benefit or harm. Finding no evidence of interaction and assuming the client finds the treatment acceptable, the best available evidence suggests going ahead to implement the intervention. Of course, the essential next step is to assess the results and adjust treatment accordingly. That 'analyze and adjust' step, to be discussed shortly, is no less necessary when treating someone from a well-studied population (because no individual or community's responsivity can be assumed).

Apply: Decision Making and Action

The apply step is at the heart of the EBP process. Apply is also the most complex and least-described step in the EBP process model. During the apply phase, the practitioner integrates knowledge from best available, relevant research with consideration of client characteristics and resources to arrive at an action decision. After finding and appraising the evidence, the interventionist assesses the resources available to offer what research shows to be the intervention best supported by evidence. The considered resources include finances, linguistically appropriate materials, trained practitioners, client's ability to access the intervention, etc. The practitioner also considers the likely acceptability and uptake of the best supported treatment by the client. She proactively engages the client, and in some instances other stakeholders (e.g., family members), in a process of collaborative decision making because the hardest work of changing behavior will fall squarely on the client's shoulders. Resource appraisal usually requires the practitioner to self-assess whether locally available training and skills are adequate to implement best practices. A challenge for EBP in behavioral health interventions is that once an evidence-based treatment is identified, practitioners may not have the skills needed to implement the intervention. A decision then needs to be made, collaboratively, about whether to implement an alternative EBP in which the clinician is trained, or whether to refer (if a clinician skilled in the best practice is available and amenable).

For EBPs to be disseminated and implemented, practitioners need to know how to search for training resources. In addition to supervised training offered by a skilled professional, in-person trainings are offered at professional conferences. Some materials are also available on internet sites. For example, kits to support the implementation of evidence-based mental health practices are available from Substance Abuse and Mental Health Services Administration's National Registry of Evidence-Based Practices and Programs. Comparable material to support health promotion and behavioral risk factor reduction are available online at the National Cancer Institute's Cancer Control Planet.

Analyze and Adjust: Evaluation, Dissemination, and Follow-Up

A practitioner engaging in evidence-based behavioral health practice performs continuous practice-based quality improvement. During and after applying an evidence-based intervention, the clinician analyzes outcomes and adjusts practice accordingly. The clinician also engages the client and

sometimes other stakeholders (e.g., family members) in the process of evaluation and quality improvement. Results are then used to refine local decision-making policies, generate new questions, and identify needed research.

The analyze and adjust step makes EBP an iterative process. Performing the step requires ongoing assessment, followed by realignment of intervention based upon local data from the client. It is usually possible to perform such realignments within the scope of an evidence-based behavioral health treatment without compromising the core features integral to the intervention. Analyze and adjust simply reminds the practitioner of the need to monitor progress. In some instances, however, the practice appraised as having highest quality research support and relevance may fail to help a particular client. To continue administering the originally chosen intervention after the client's condition has continued to deteriorate would no longer constitute EBP. The EBP clinician, who would be continuing to assess client outcomes, would analyze the deterioration and adjust course, perhaps by offering an alternative evidence-based intervention.

The EBBP Project website offers a number of online learning modules about EBP. Tutorials are available on systematic evidence reviews, critical appraisal, RCTs, and evidence search strategies. Of particular relevance is the interactive, experiential EBP process module, which presents two cases in which a practitioner addresses tobacco use with a client. In one case, the client is an individual. In the other case, the client is a community. Also valuable are two experiential modules on shared client-centered decision making. In those modules, practitioners encounter scenarios in which best EBPs, client preferences, and available resources are at variance. By making a series of care decisions, the learner is able to detect personal biases toward overemphasizing evidence, client preferences, or resources when making decisions. The learner also can experience and revisit the consequences of choosing to pursue different decisions.

Conclusion

Engaging in EBP entails a process of lifelong learning as the evidence about effective practices continues to evolve. Attaining mastery of the skills needed to perform EBP is a process and not an event with an endpoint. The complexities of real world practice, the proliferation of the research evidence base, the changing sociocultural and healthcare contexts, and rapidly evolving health information technologies require ongoing engagement in the EBP process. Ultimately, the goal of EBP is the provision of best-tested, most effective care to the public in a manner that reflects shared decision making and mutual involvement in continuing to enrich the evidence base.

Glossary

Adaptation The result of selection, in this case mental mechanisms evolved to solve survival or reproductive challenges by processing information according to selected mental rules.

Environment of evolutionary adaptedness (EEA) The relevant adaptive challenges and selection forces in the species' evolutionary past that have designed the specific adaptation one is studying.

Evolutionary function The increased inclusive fitness generated by the adaptation in the EEA.

Harmful dysfunction Wakefield's definition of psychopathology, a state that both is considered by evolutionary psychology to not be functioning as selected.

Mismatch theory As the current environment may deviate significantly from the EEA, this may cause maladaptive behavior or detrimental environmental effects.

Schizophrenia paradox The question of how a disorder that seems to reduce inclusive fitness has not been selected out of the gene pool, given that it probably has been around since before the human species migrated from North East Africa 70 000 years ago.

Introduction

Our species' phylogeny has influenced our mental health, not just our mental capacities. While mainstream evolutionary psychology approaches the species' universal normal psychology, evolutionary psychopathology focuses on the breakdown of normal mental function. These two approaches provide important complimentary approaches to the study of human nature.

One of the earliest evolutionary approaches to psychopathology was offered by Sigmund Freud – whose fundamental Oedipal conflict was based on evolutionary (albeit flawed) reasoning. Although Bowlby's attachment theory was explicitly evolutionary and most phobia theory has acknowledged an evolutionary logic, the evolutionary perspective has generally not been focused explicitly on, within clinical psychology. Despite this, the last decades have seen a surge of new interest in evolutionary, biological, and genetic insights within many different disciplines of psychology – including clinical psychology.

The major contribution of evolutionary approaches to clinical psychology, psychiatry, and mental health care in general is often thought to be a conceptual tool. The evolutionary approach is systemic, ecological, multilevel of analysis oriented. It is a truly biopsychosocial, integrative, and multidisciplinary approach. But it would be most strange if an understanding of function or an analysis of dysfunction did not provide clinical theorists with insights that may lead to treatment interventions.

This article will attempt to describe some of the most important contributions within evolutionary clinical psychology thus far. Despite being a part of clinical thinking since the dawn of psychotherapy, evolutionary approaches have never become very common, and there is a limit to how much empirical data and treatment interventions the evolutionary approach has been able to offer so far.

Defining Psychopathology

There is currently no general definition of psychopathology. Many different approaches based on theories of mental health

(e.g., psychodynamic theory, humanistic-existential theory, neurotransmitter theory) focus on different aspects of what constitutes mental health or mental well-being, and also suggest what may be considered pathology. Further, there is a more descriptive tradition of the diagnostic manuals, with a continuous attempt to remove theoretical and mere expert consensus, and move toward an empirical scientific description. But even this approach begs the question of what to actually describe; dustbowl empiricism will never answer that question.

Troisi and McGuire have pointed out that it is not possible to define mental disorder merely due to sequelae, statistical deviancy, or subjective suffering. They claim that a definition of psychopathology must be based on an analysis of the individual's ability to achieve biological goals in the individual's specific environment (lack of such would constitute biological dysfunction).

Kennair suggested that we have three categories of disorder in current diagnostic manuals: (a) The fundamental biological disorder category: mechanism dysfunction, that is, breakdown of the adaptation. (b) Subjective suffering caused by evolved mechanisms that are evolved to produce mental pain. (c) Socially undesirable behavior, caused yet again by mechanisms evolved through selection to produce that behavior. But all of these categories would not typically be considered pathological from an evolutionary perspective. To understand further how these three categories still are the focus of clinicians, we need to consider two analyses: harmful dysfunction and treatable conditions.

Harmful Dysfunction

One of the most debated and influential general definitions of psychopathology is Jerome Wakefield's harmful dysfunction analysis of psychopathology. According to Wakefield, harmful dysfunction analysis considers psychopathology on the basis of two concepts. (1) Harmful is a value term. This means that a category of psychopathology will be defined based upon social and cultural values – there has to be a perception of the state as

harmful. (2) Dysfunction is a scientific factual term. The basis of identifying dysfunction needs to be that the mental mechanism is not functioning the way it evolved to function through selection.

There is broad consensus among evolutionists that a dysfunction – a nonfunctioning adaptation – may be considered a hallmark of pathology. Many natural scientists would similarly disagree with the addition of a value term, and would prefer to see that one could base the whole definition on dysfunction. The phenomenon of mental disorder is not that simple, though. We have a tendency to define conditions that we deem harmful as disorder, thus dysfunctions that are not perceived to be harmful will not be considered necessary to treat or as signs of disorder. A lot of our modern mental functioning is not similar to that of our pleistocene ancestors. If any part of our mind not functioning as it was selected to function was defined to be pathological, then we would have a strange perspective on modern human culture.

But the fascinating aspect of the harmful dysfunction analysis from an evolutionary psychology perspective is that it demands a catalog of research from a functional, modular, evolutionary perspective on the normal mind. We need a taxonomy of functions to be able to develop the nosology of harmful dysfunction.

A last important point is that the dysfunction analysis defines many undesirable behaviors out of pathology. Many mental states and behaviors that may be considered pathological are actually the result of mental mechanisms functioning exactly as they evolved to function through selection. Thus, it would be unreasonable to call those states pathological. Despite this, one might want to treat these conditions, which may be considered harmful functions.

Treatable Conditions

Cosmides and Tooby introduced the concept ‘treatable conditions.’ While not really defining psychopathology, this concept is an insightful specification of a large portion of mainstream clinical practice. Rather than consider whether a condition really is harmful or a dysfunction, clinicians in general treat what is believed treatable. Thus, one treats what is considered to be a nuisance from either a societal, theoretical, or individual perspective without concern for potential function.

The fact that treatment may be desirable even for functioning adaptations suggests that there may be reason to know when this is the case. If we are naïve about the fact that we are attempting to subdue a functioning aspect of human nature, this ought to call for both ethical reflection as well as limited optimism about the ease with which the behavior may be modulated. But an important question is also what the systemic consequences of altering the mental mechanisms workings will be.

Potential Iatrogenic Consequences

Nesse and Williams warn against the iatrogenic consequences of not understanding the evolved organisms’ adaptive defenses. Treating the defense as if it were the symptom of a disorder, and not the body’s attempt to combat the disorder, may create further problems – quite simply because one is attacking the

organism, not the disorder. This is why we need to understand the functions, dysfunctions, and evolution of disorders.

Imagine a depressive state that actually is not a brain disorder but a condition that is meant to help solve a specific problem, by regulating mood. This is the case for most emotions we have. The fact that it is painful is not a convincing argument for this state being unhelpful. Not having physical pain receptors is a lot less helpful than having them – as individuals without pain receptors may have a shortened life span, and endure continuous injuries due to not receiving feedback from their bodies when they are being compromised in a harmful manner. Anyone who has bitten themselves after being to the dentist knows this.

Several functions of adaptive depressive states have been suggested (see below) – but in this instance, let us hypothesize that the function of low mood merely is a signal to both the organism and to kin that one is suffering. If this is the case, then treating the low mood, rather than changing behavior or social conditions, might actually cause the organism more suffering, by reducing the motivational forces for both her close kin and herself.

If symptoms of fear are supposed to make us avoid a potential real threat, merely reducing fear might be lethal. This has been Nesse’s most important message, from a Darwinian Medicine approach, to health professionals in general: we need to understand the nature of disorder, as well as evolved defenses, so that we do not aid the pathological agent by attacking the organism’s defense mechanisms.

Etiology of Psychopathology

We do not really know the etiology of any disorder – all of the explanations in this volume are at best considered tentative. The same holds for the development of personality traits and almost all normal development. The general finding from behavioral genetics is that environments cause differences between members of the same family, while genes cause similarities – and that both genes and environments influence the development of most phenotypes. All human traits, abilities, symptoms, and behaviors seem to be influenced by both genes and environmental input – even though we currently may claim that random effects are more likely than any specific environmental explanation. Currently, only very few genes seem to provide relatively replicable connections with disorder phenotypes and almost no specific environmental stimuli are known.

Etiological research needs not only theories of development, individual differences, and genetic influences but also function and selection. Evolutionary psychology focuses on what we know about relevant features of the species’ evolutionary past, and combining this with middle-level evolutionary theories, to suggest hypotheses of functions that probably evolved, and then testing these in empirical studies.

Principles such as the Belsky–Draper hypothesis (an observation and theory of how the lack of paternal investment in early years may shape specific features of girls’ physical maturation and sexual behavior; specifically, increasing likelihood of early menarche, sexual debut, and pregnancy) may help us understand the etiology of specific disorders. Perhaps other relevant childhood contexts would have specific evolutionary

predictions of later life functioning based on functional analysis of ecological demands.

But before addressing the questions of 'how?' evolutionary approaches start by addressing questions of 'why?'

Why Does Psychopathology Exist?

Evolution does not design perfect organisms, and the process is often more comparable to tinkering rather than industrial design. Our vision has blind spots, we can develop cancer, and we do not live forever. Obviously, there also are arms races between different pathogens and us, which cause infectious diseases. At the same time, this does not answer why a disorder such as social anxiety or schizophrenia may exist in all human populations. Both of these disorders will seemingly cause reduced fitness. The schizophrenia paradox points out that a clearly debilitating disorder is similarly prevalent in all human cultures, and must therefore have been present since the species migrated in different directions from North East Africa. Why has not the disorder been selected out of the gene pool? This and several other questions concerning other disorders need to be addressed.

From an adaptive perspective, it is obviously tempting to suggest that what clinicians consider to be maladaptive really is adaptive. In some cases, this may be true; in many cases, this is an original perspective that at least challenges clinical consensus. At the same time, it is important to note that few disorders are clearly due to proven dysfunction.

Why Do Individual Differences Exist?

An even more fundamental question is why individual differences exist at all. Evolutionary personality psychology and evolutionary clinical psychology both struggle with this – and both address both adaptive and maladaptive variation. Typically, sources of individual differences are considered to be genetic, developmental, and cultural–environmental. Some of these are considered to calibrate mechanisms differently; a few may cause adaptive variation; others will damage the organism in some manner. It is important to add random effects as an explanation, as we currently cannot provide evidence that the individual differences are due to systematic effects of the environment: on the basis of data from behavioral genetics, most psychological theories of such systematic effects have been ruled false or unlikely.

Mismatch: An Important Evolutionary 'How?'

A general idea – even before the invention of evolutionary theory, and even as early as the brink of the industrial revolution – has been to suggest that our modern style of living has a detrimental effect on our well-being, including our mental health. From an evolutionary perspective, one would contrast our modern lifestyle and ecology with that of our Pleistocene (or earlier) ancestors.

This would, for example, be relevant in an analysis of our current increased intake of calories, our lower levels of physical activity and dental caries, diabetes II in children, obesity, heart and coronary disorders, and other lifestyle disorders. We probably evolved to be interested in consuming sugar

and fat – which is probably why livestock has higher levels of fat than game and why we produce large amounts of sugar. And why supermarkets are designed so that the counters – where we stand waiting – are stocked with brightly colored wrappings containing nothing but empty calories waiting to be purchased by primates acting on impulse.

Typically, evolutionary analysis considers whether a specific state or trait could have been adaptive in our species' past. Thus, if something seems maladaptive in a modern setting, it might still be due to an adaptation functioning exactly as it was selected to do in the environment of evolutionary adaptedness (EEA, i.e., the adaptation's relevant past evolutionary ecology, consisting of the selection forces that caused the design of the specific mechanism).

Mismatch may cause negative interactions between the modern environment (toxins, nutrition, technology, social systems, etc.) and our adaptations, resulting in poor mental and somatic health for the individual. This may be due to the adaptation functioning, and the stimulation being excessive and thus harmful. Or it may be due to mismatch causing an adaptation to dysfunction.

Some mismatch, such as easy access to calories and individualizing child rearing practices, may also cause some benefits – such as a better social functioning in western societies, and the Flynn effect (the rise, until recently, of general IQ scores through the last 100 years), which may be due to more stable brain growth (and maybe a result of the increased intake of sugar). Most types of mismatch would cause the developing adaptations to be stimulated in incompatible manners, or cause adaptations to dysfunction. But our omnivore nature and general behavioral flexibility have made us very versatile organisms. Also, our most important ecological feature – other people – has been kept in the form of relatively closely knit small bands until very recently.

A cautionary note is needed: we do not really have as much evidence for mental disorder as for tooth decay, obesity, and diabetes being results of mismatch. Although some studies show an increase in depression or other mental disorders, not all studies point in that direction.

Examples of mental disorders resulting from mismatch are therefore few. Some disorders such as anorexia seem to increase consistently in Westernized, that is, modernized, cultures – including the most modernized subcultures or urban areas in developing nations. Despite the seemingly clear pattern of this disorder, we are still not certain of what causes the disorder. Young women seem to be the group with the greatest increase of depression. Life history-relevant changes (lack of close extended family, less support around pregnancy, and relationship instability) in their ecology *might* be a cause. I would argue that some anxiety disorders may be on the rise due to less stimulation and possibilities for experiencing coping with hazardous environmental features during development, due to modern society's fear of harm, and our safety regulations and lack of experience with nonurban environments. It is also suggested the dietary changes, especially a lack of fish and fatty acids, will influence rates of attention deficit hypersensitivity disorder (ADHD), depression, and schizophrenia. The problem with all of these explanations is that there is very little evidence to back them up. Despite this, mismatch needs to be considered.

A specific type of 'mismatch' warrants further note: what Cosmides and Tooby call Value-Condition Divergence. This is the mismatch between what society today finds acceptable or desirable, and the natural function of the evolved mental mechanism. For example, despite the mental mechanism, potentially motivating cuckolded men to wish to avenge themselves, functioning violently as it evolved, such violence is not accepted in many societies and will result in criminal charges against the violent husband. As such, many kinds of behavior may be considered mismatched as different cultures sanction evolved expressions of human nature in different ways, and some of these will describe undesirable behavior as psychopathology (but that only covers the value-half of the Harmful Dysfunction definition).

Evolutionary Constraints on the Mind and Mental Well-Being

The evolutionary process operates with certain constraints – this is true. Despite this, most modern evolutionists are wary of placing too much emphasis on this limitation of evolution's potential for design. But in considering different design aspects of our bodies, we will soon notice that there are parts and mechanisms that could have been safer and more efficient. But evolution is more a process of tinkering than engineering.

Further, an important reminder, the evolutionary process is based on reproductive success, not happiness, well-being, or painlessness. But this must not be taken to mean that poor mental health would not have been selected against – if poor mental health is taken to mean that the function of the individual is compromised due to suffering, or if the mental health causes a reduction of inclusive fitness.

Many mainstream psychological theories of etiology have described humans as such frail organisms that a normal life in the EEA would have caused poorly functioning bands (if indeed the individuals still could form bands) huddled quivering together riddled with psychosis, posttraumatic stress disorder, and every other disorder of the diagnostic manuals. This frail species would not have conquered the world. Resilience had to be part of our nature. And mostly, we must have been functioning well enough to survive and reproduce, and our mental well-being and mental disturbances had to be limited to a level that did not end in extinction.

Psychological Theories of Etiology

Poulton, Menzies, and coworkers have challenged the existing knowledge of how anxiety disorders develop. Further, Kendler and coworkers have challenged the stress–diathesis model of phobia acquisition. In many of this volume's articles, the most typical psychological explanations are learning-based or stress–diathesis-type explanations. These have for a long time been considered the most scientific – not least because exposure and habituation models of treatment have proven efficacious. Two important cautions need mentioning: (a) there is some disagreement within clinical psychology that habituation really is the mechanism that brings about change, and (b) even though a condition appears due to maturational processes (rather than environmental conditioning), an environmental conditioning intervention may change the condition.

The challenges to mainstream clinical consensus mentioned above suggest that evolutionary, innate, or genetic

models are better explanations than many of the environmental or stress models of etiology. A simple example: I work and teach in Norway, where there are no harmful spiders, and one would have to go abroad to have a painful conditioning experience with a spider. Despite this, I have patients with spider phobias, and I can always rely on someone in the audience having this condition in order to demonstrate the swift effect of exposure and cognitive behavioral therapy for phobias.

Less scientific theories of etiology and development have come under fire from behavioral genetics. It would seem that to understand the causes of mental disorder, one needs to consider our species' evolutionary history. If psychopathology is defined as harmful dysfunction, we further need to understand the functions of the mechanisms that are dysfunctioning. This calls for a general evolutionary psychology of the function of mental mechanisms, of individual differences, and of development.

Viral Causes, Environmental and Nutritional Causes

Work by sociologist Roger Masters and coworkers has provided us with insights on the importance of environmental toxins (e.g., lead) and metabolic, nutritional, ethnic, and social interactions and aggression. Evolutionary biologist Paul Ewald has championed the role of viral agents in almost all conditions. Horrobin and coworkers advocated the effects of nutritional shifts through our species' evolution – and the effects of modern diets on brain function.

One has to agree that a purely psychosocial approach to mental health and mental disorder is too limited and not fully in the spirit of evolutionary psychology. Despite being a psychological discipline, evolutionary psychology is based on an anti-dualistic foundation. But it is also important to analyze critically all suggestions – and thus many of these viral and nutritional ideas have not garnered enough support to be considered mainstream or very relevant for our understanding or treatment. At this point, it is important to keep both an open and a critical mind as we continue to consider these causes.

Biopsychosocial Integration

Many explanations of the etiology of mental disorders are offered as universal – they are supposedly the explanation of all cases, and are therefore considered to be competing explanations. This is obviously a rather premature position to take for any of these explanations. The lack of understanding of how to define psychopathology creates some problems, but as mentioned below the mere uncertainty of what phenotypes are relevant causes problems for any explanation.

It is important to consider how several different causes may be integrated, and how many explanations might be relevant for subcategories of disorders. Multidisciplinary, integrative meta-theories should be exceptionally well suited for multi-causal phenomena such as psychopathology.

Specific Disorders

The following section will attempt to highlight different evolutionary approaches to the specific disorders. It is important to

point out that a comprehensive evolutionary approach would have to start by critiquing the phenotypes of the diagnostic manuals – as these to a large degree are the result of traditional theory and dustbowl empiricist description, with little evolutionary functional analysis or basic biological knowledge. Thus, most conditions are extremely heterogeneous, and any attempt to explain a condition will probably not be able to cover all facets. Despite these shortcomings, the following section will consider major diagnostic categories, as these are how we currently categorize the relevant states.

Anxiety

It may be helpful to first differentiate between fear and anxiety disorders. Fear is an adaptive emotional response to real threats – and the fight, flight, or freeze responses that this emotional state causes will help the organism avoid or prevent danger in a manner that increases fitness through the species' evolutionary past. Within the domain of fear, one will have species-specific defenses of different types – from defensive burying in rats and freeze behavior in grouse to species-specific avoidance behavior. Anxiety is defined by having a fear response when there is no real present threat or danger. Anxiety is therefore an exaggerated or maladaptive fear response, in which none of the safety behaviors that the individual uses to defend himself with is necessary – as no catastrophe or harm would come about even if the safety behavior was discontinued.

One may also differ between what Marks and Nesse call hypophobia – a maladaptive lack of fear – and hyperphobia, maladaptive hypervigilance, or fear activation. But what seems to be maladaptive needs to be considered in terms of mismatch. Also, we need to consider whether what seems to be maladaptive due to discomfort or limitations for an individual might be adaptive for the individual's genes in the long run. Thus, hypophobia, as in the young male syndrome described by Daly and Wilson, might cause an increase in deaths among young males, as found by Nesse, but at the same time the males that are chosen by females due to displays of recklessness would have increased their fitness. Currently, hypophobia is not considered a disorder, although lack of consideration of consequences might be a symptom of manic disorders.

The anxiety disorders have benefited from the functional (and evolutionary) understanding of fear. This approach suggests that anxiety attempts to protect, or at least that the underlying fear mechanism is activated in a general attempt to protect the organism. Considering what the individual is attempting to protect from or avoid therefore informs the clinician of cognitive, emotional, and behavioral processes. It also differentiates between different anxiety disorders.

Panic disorder and agoraphobia

These two conditions co-occur to such a degree that they usually are considered together. Agoraphobia is often due to a fear of having a panic attack and not being able to return home to 'safety.' There are two points worth considering about this: (a) the panic attacks occur at home as well, so the patient is not really escaping the panic, but is seeking surroundings in which the patient feels safer, usually due to freely being able to perform safety behaviors; and (b) the panic attack is not dangerous. Usually, panic attacks are considered to indicate one

(or more) of four major catastrophes: that one is going mad, that one is having a heart attack, that one is choking, or that one is going to faint. These are due to misinterpretations of anxiety symptoms such as: depersonalization or a sense of unreality or other cognitive anxiety symptoms (giving a sense of going mad), increased heart rate and blood pressure and other bodily sensations (interpreted as symptoms of heart attack), tightening of the chest and sensation of a lump in the throat (a choking sensation), and dizziness and hyperventilation (interpreted as precursors of fainting). But none of these will occur due to anxiety – increased blood pressure and fainting are simply incompatible, so even the most 'likely' event in the opinion of many clinicians is actually not possible. Thus, there are problems when considering these conditions from an adaptive perspective – panic does not make you flee danger, it makes you focus on the nonreal threat of the anxiety symptoms. Actually, there seems to be a necessary higher level conceptualization in order to develop panic disorder. In some cultures, the patient rather than believing that one is choking, believes that an evil entity is sitting on one's chest, a djinn. This interpretation of bodily sensations suggests that panic has no evolved function, and is merely due to our increased intelligence and attributions (often cultural) about bodily sensations.

Social anxiety disorder

Social anxiety disorder (SAD) is often conceptualized, from an evolutionary, perspective to be a fully understandable condition. Baumeister's seminal works on the normal need for social belonging of humans, the obvious threats to fitness of being ostracized, group processes such as conformity, and the fitness benefits of being considered attractive all suggest that we *should* fear negative evaluations from others. The major problem is to explain what socially anxious patients specifically are threatened by – because what they fear is that intermediate acquaintances (rather than close family and friends – the group from which being ostracized is most relevant) should notice that they are anxious. For example, they fear blushing in public, and due to introception (perceiving the heat on their cheeks to be an indicator of degree of blushing) they often have an exaggerated belief about the degree of blushing. But there are no typical negative appraisals of or sanctions toward people who blush. Males witnessing blushing females might even find them more attractive. Actually, the most typical fitness-reducing consequence of SAD is the patient's own safety behaviors – which include social avoidance, and in some cases more noticeable deviant behavior (in attempts to not show signs of anxiety – and these signs are often not perceived by onlookers). In general, patients with SAD are less likely to seek promotions or extra attention in the workplace, less likely to enter romantic relationships, and thus the disorder itself is causing what many believe is the threat that the anxiety is protecting against. The very good reasons for caring about social evaluation suggest that an evolutionary approach is very relevant – although the conceptualization needs to consider the actual negative consequences of SAD.

Specific phobias

It is quite obvious to anyone working with phobias how stimuli such as heights, darkness, strangers, water, snakes,

spiders, rodents, insects, germs, and social settings are the typical sources of anxiety. But to most people in the Western world, these stimuli (apart from maybe the social setting) are not dangerous. At the same time, modern societies attempt to install fear in populations: fear of smoking, driving too fast, drugs, not using seat belts, getting STDs, getting pregnant, sugar, fat, exposure to too much sun. Generally this has little or no effect. Teaching someone to fear truly dangerous or culturally undesirable phenomena is much harder than any learning theory or psychosocial theory of anxiety acquisition suggests. Without an evolutionary understanding of the evolved susceptibility of specific evolutionary relevant stimuli, we would not have understood the nature of specific phobias.

Blood phobia

This very specific and different phobia is the only anxiety disorder where the patient may faint. Marks pointed out the adaptive logic: in all the other anxiety disorders, the fear mechanisms motivate the organism for a fight-or-flight response – with an increased need for energy, and therefore increased adrenalin and blood pressure. In the case of severe bleeding, a sudden drop in blood pressure would be a lot more helpful to the organism.

Generalized anxiety disorder and health anxiety

These seem to be specific human conditions. While one may consider social anxiousness and even specific phobias in other species, it would seem that the verbal problem-solving cognition involved in worry suggests a very species-typical disorder. In health anxiety, the worry is mainly focused on different threats to health – and mostly lethal diseases known from media. In GAD, it is a diagnostic criterion that the patient worries about more than one topic. An important question is whether this continued anticipation of catastrophes is beneficial in any way. In our current society, the loss of function due to generalized anxiety disorder (GAD) is obviously maladaptive. But everyone worries – thus the ability to plan for contingencies and imagine situations where bad things may happen might be beneficial in some way. Even if this maybe true, although something that needs investigation, such positive metacognitions (worry keeps me prepared/worry protects me) are exaggerated in GAD patients, where continuous worry about catastrophes that do not occur is causing them distress and limiting function. Changing these metacognitions is often the focus of treatment.

It would seem reasonable to claim that anxiety in general is not currently adaptive – and that the disorders do not have specific adaptive functions. On the other hand, it is relevant to note that hypophobia – too little fear of real threats and dangers – also is maladaptive to the individual. Fear of specific features of our past ecology was adaptive, and some psychological mechanisms involved in these processes are present in current anxiety disorders. Understanding the functions of fear and other emotional responses and evolved psychological mechanisms may further improve our ability to prevent the development of anxiety disorders. (*Note: treatment of anxiety disorders with CBT and exposure is currently that effective that the aim is not presently improved treatment for anxiety disorders, with the possible exception of GAD.*)

Autism

Autism is usually not considered a mental health condition – rather it is, together with most examples of mechanism failure, typically considered a neuropsychological disorder. Despite this, it warrants mention in this article. There are two reasons: it is a prime example of mental mechanism failure. Further, it is an example of how a modular adaptive evolutionary psychology framework may inform researchers seeking to understand both normal and pathological development.

Baron-Cohen's research into theory of mind (ToM) and the evolved ability for 'mindreading' has informed us of many of the mental mechanisms that are involved in both normal mental processing of social interactions as well as autism. This has been a prime case of how the lack of specific abilities, such as taking the intentional stance, as Dennett calls it, toward other humans when attempting to understand their behavior impairs behavior in a specific set of ways. This research has thus highlighted the role of mechanisms for theory of mind both in autism and also in schizophrenia.

Depression

Depression is one of the most debilitating health conditions worldwide. The anhedonia, lack of energy, low mood, and negative appraisal of oneself and the future, has obvious consequences for fitness and function. At the same time, it is one of the most common disorders. How can something as widespread and debilitating as depression exist? An evolutionary approach is necessary to address the nature of depression.

There are two basic views within evolutionary perspectives to unipolar depression: (a) the involuntary behavior inhibition approach and (b) the social bargaining or social problem-solving approach.

The involuntary behavior inhibition approach may be formulated from foraging theory and social hierarchy theory. In both cases, the inhibition is involuntary or elicited by ecological cues. From a foraging perspective, there is a more general consideration of when spending energy ought to be suspended. Focusing primarily on the demotivating aspects of depression, this approach predicts that depression will occur in any context where increased effort would have been fitness reducing in the EEA. The social hierarchy perspective is more specific, suggesting that under socially threatening conditions, subordinate behavior may reduce threats. Thus, the behavior that is inhibited would be subdominant challenges toward dominants.

These approaches, formulated by both Nesse and Gilbert, focus mainly on the processes and mechanisms behind depression being adaptive. The syndrome of major depressive disorder is not considered to be adaptive. Rather, this is a condition that occurs due to the adaptive processes being disturbed in some manner. This is probably the most accepted approach among clinicians with an interest in evolutionary theory.

On the other hand, more adaptationist approaches draw on the possibility that just because we subjectively deem depression undesirable, does not mean it is maladaptive. Watson and Andrews suggest that depression in general improves social cognitive problem-solving. The depressed state of mind will

be less vulnerable to the biases of a nondepressed mind, and focus more on specific social information. While many clinicians are critical of this approach, it is a highly original and thus interesting contribution to the investigation of possible facets of depression.

Hagen suggests that depression is functional, and uses a specific subtype of depression, postpartum depression (depression with an onset tied to childbirth), as a model of how depression in general may have been adaptive in our past. The parents are codependent of each other's investment in the child. Therefore, a suboptimal investment by the father may elicit a depressive response in the mother, which reduces her caretaking behavior, which in turn forces the father to put more effort into parenting.

An extreme example of depression-relevant theorizing from an adaptationist perspective is the work on suicidal ideation by de Catanzaro. There are obvious cases where suicide could be fitness-enhancing – the mathematics of selection predict that if one is a burden to one's family, and thus reducing one's inclusive fitness more than one can hope to compensate by having further offspring, then suicide is adaptive – from a gene/inclusive fitness perspective. Also the functional approaches of Hagen and Watson and Andrews to depression provide evolutionary explanations of suicide and self harm.

Unipolar depression is a prime example of a lack of evolutionary functional analysis of phenotypes considered psychopathology. This category should probably be plural: depressions. Within the same category, one will find certain bipolar conditions; conditions that are better explained by ongoing life stressors or events; deregulated biochemistry of the brains neurotransmitters, but also more endocrinological disruptions or gastrointestinal disturbances; evolved adaptive responses or brain malfunction; agitated, atypical, anxious, physiological, psychological, social, female, or male types, etc. It is clear that this causes a large array of possible explanations – but also it does call for a better analysis of phenotypes, and an integrative approach. Thus, the evolutionary approach is warranted.

While depression is the disorder that has been given most attention within the evolutionary psychopathology literature, too little work has attempted to differentiate different types of depression. A modular approach might be helpful.

The general lack of subdivisions of depression suggests that many evolutionary attempts at explaining 'depression' will fail due to a lack of specificity. Two interesting subdivisions that intuitively make for evolutionary analyses are seasonal affective disorder and postpartum depression. But while seasonal effects on behavior and mood have been found, the diagnosis of 'winter depression' seems less certain. In Norway, there are effects of seasonality and latitude, but the peaks of pathology are found in April, with a smaller peak in October. And while women may get depressed after birth, they may get depressed at other times, too – and there is little to substantiate a specific link between birth and depression. There is therefore a need for more work on specifying phenotypes. Evolutionary clinical psychologists need to ascertain that what one is attempting to analyze from an evolutionary perspective actually is a relevant evolutionary phenomenon and phenotype. This would be a great contribution to mental health science.

Eating Disorders

It is obvious to most of us that we should eat fewer calories (despite the fact that many calories taste delicious); that we eat more fruit, vegetables, and fish (while it is still safe); and that we ought to exercise more (not merely pay the annual gym fee). We have constructed our society and industry in order to save ourselves effort and still provide us with what were scarce resources in the EEA, but which now are found in abundance ripe for the picking in our supermarkets. Obviously, this will cause a general increase of body fat in the general population of all countries that reach a certain standard of living – and for many there does not have to be anything wrong with the metabolism to gain excessive weight. An evolutionary understanding is fundamental to understanding this aspect of our modern health hazards and lifestyle diseases.

Evolutionary approaches have also offered some correction to theories of the puzzling disorders where patients starve themselves. Early psychoanalytical approaches suggested that one of the effects of anorexia – delaying onset of menarche – was the function of the behavior: the sexually repressed girl wishing to put off adulthood and adult sexuality through starving her body.

This creates an interesting reverse image compared with the most empirically researched evolutionary approaches to disordered eating, where different life history strategies and female intrasexual competition is considered to be fundamental. Here initial findings suggest that a slow life history is linked to greater executive control and protects against disordered eating or extreme low weight.

Obsessive Compulsive Disorder

Several different evolutionary approaches to understanding obsessive compulsive disorder (OCD) have been suggested – including general threat monitoring mechanisms, group selection models, and animal models focusing on ritualized behavior. This is one of the disorders where the viral explanation is most often mentioned. Swedo and colleagues suggested that pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) may explain OCD symptoms. This is still a controversial explanation, and mainly considered an explanation of recurring and remitting cases or sudden onset cases. The treatment of choice of cases where a viral explanation seems relevant is the same as other OCD: cognitive behavior therapy (CBT) and exposure with response prevention. Why this should work for viral throat infections is so unclear that many are critical of the explanation.

OCD is, as the other anxiety and disgust disorders, efficiently treated with CBT and exposure. But the nature of OCD is still not very well understood – and certain subcategories may demand special attention. From an evolutionary and modular perspective, it is important to differ between normal and extreme hygiene and grooming behavior, hoarding, and magical thinking/ritualistic behavior. Yet again, specifying the phenotypes and subcategories of the diagnostic category may currently be important, rather than attempting to explain the whole disorder.

Personality Disorders

Personality disorders are sometimes considered to be extreme versions of normal personality traits, such as the traits of the big-five model of personality (openness, agreeableness, conscientiousness, neuroticism, and extroversion). Linda Mealy had a different approach – as she suggested that lack of empathy could be an adaptation. Thus, dissocial personality disorder (sociopathy or psychopathy) may not merely be a result of normal variation, or a dysfunction, but may indeed be a functioning evolved phenotype: an adaptation.

Thus, personality disorders may not be ‘disorders’ in some cases but can be specific adaptive strategies that have reproductive benefits under certain ecological conditions that the ‘normal’ phenotypes do not fully take advantage of. Frequency dependent selection suggests that minority strategies may be beneficial as a result of interactions with qualities of the typical strategy: Consider a simple two-strategy game consisting of two types, exploiters and cooperators that due to their strategy are able to produce a surplus. There will be a threshold that decides what percentage of the population may be exploiters, and yet be sustained by the cooperators. At a certain point, the exploiter strategy will not be helpful, and the number of exploiters will be regulated.

Schizophrenia

Some evolutionary models of schizophrenia focus on social hierarchy theory. There are also group selectionist explanations. Others focus on changes in our modern nutritional habits, suggesting that a decreased intake of fatty acids has made schizophrenia and related mental states more common. Viral explanations also exist within the evolutionary literature.

One of the most interesting models, suggested by Timothy Crow, considers schizophrenia to be a result of the speciation event – schizophrenia is a result of what made us human. As such this is a by-product explanation. Schizophrenia was not selected for, but our language capabilities and hemispheric lateralization and the necessary genetic evolution underlying these mechanisms made us vulnerable to schizophrenia as a species.

One of the reasons why schizophrenia has been given a lot of attention from an evolutionary perspective is that it poses the schizophrenia paradox: a condition with a known genetic mechanism of transference and also a clear fitness-reducing phenotype. Recent evolutionary genetics research by Crespi and colleagues has discovered that genes that are strongly linked to schizophrenia show signs of selection. This research cannot identify why these genes have been selected but concludes that the by-product theory of schizophrenia is supported by these findings.

Sexual Disorders

One of the most prolific and fruitful fields of evolutionary psychology research has focused on normal human sexual behavior from an evolutionary perspective. As such, it is surprising that the research on sexual disorders from an evolutionary perspective has been rather limited.

Both sexes may experience lack of desire or orgasm – or, in males, erectile dysfunction. Sex differences are more evident

when considering problems such as premature ejaculation in males and pain during intercourse for females. These conditions are obviously partly understandable from sexual strategies theory, life history theory, etc.

The evolutionary functions of sex and sex differences have been addressed by evolutionary psychology. The same theoretical foundations promise to provide clinical sexology with important insights. Some work on excessive and violent jealousy is relevant for a clinical and forensic psychology, as is work on stalking behavior.

Substance Abuse and Dependency

Another of the most debilitating and common groups of mental disorders in the world are disorders of substance abuse and dependency. These are a complex, multicausal disorder – where biochemical, genetic, cultural–historical, social factors need to be considered. Different evolutionary approaches from life history theory to different hypotheses about the EEA (was this a substance-free or substance-rich environment) have been addressed in the literature. The evolutionary perspective has offered both biopsychosocial integration as well as novel hypotheses to the field of addiction research – but despite a promising start in the beginning of the last decade, the last few years have not seen the same interest in this topic.

Evolutionary Informed Psychological Treatments

Both Freud (classical psychoanalysis) and Bowlby (attachment theory, a combination of psychoanalysis and ethology) based their therapeutic theories on contemporary evolutionary insights. Although the biological underpinnings of their theoretical approaches have not been much focused on by the clinical community in general, there has been a rekindled interest in evolutionary explanations within psychodynamic theory and practice as evolutionary and biological approaches have become more popular in general. Freudian, Jungian, and more mainstream psychodynamic theorists have explored possible insights from evolutionary theory, and this has caused a small revival of phylogenetic explanations.

Aaron Beck's cognitive behavioral therapy (CBT) – which is the most evidence-based psychological treatment method – is also explicit about the evolutionary underpinnings of his thinking. Evidence-based and scientific approaches to psychological treatment cannot be at odds with evolutionary theory.

Many of the approaches to anxiety – especially the simple phobias – have always had a functional approach. This understanding has probably been relevant for the subdivision of anxiety disorders, as one has focused on what elicits the fear – that is, what the organism is attempting to protect itself from. This more modular approach has been a benefit for anxiety disorders, and we are today more capable of treating these than, for example, depression – maybe due to a better understanding and general acceptance of the function of fear.

While many researchers and clinicians believe that insights from evolutionary theory may be implemented directly, I would stress the need to perform clinical trials. The scientific foundation of evolutionary theory does not make an

evolutionarily informed intervention scientific. The efficacy of such interventions needs to be compared both with control groups (to check for natural fluctuations of symptoms and spontaneous remission) and with other evidence-based treatments to check for relative efficacy. Nonevolutionary insights might still be more efficacious, and thus be the treatment of choice. Any other approach would turn evolutionary theory into an ideology.

Paul Gilbert has developed a treatment based on an explicit evolutionary approach. Gilbert and coworkers have developed a treatment method – compassion-focused therapy – that combines different ideas but especially draws on ethological work and internalized social hierarchical behavior. Insights from this work have also informed less explicit evolutionary work within mainstream CBT on schizophrenia and other disorders.

Conclusions

The integrative power of the evolutionary psychology meta-theory has been focused on by many authors. The greatest mysteries within mental health care are maybe the following questions:

- What is psychopathology?
- How do we specify specific diagnostic categories?
- Why does psychopathology develop?
- How can we prevent psychopathology?
- How do we most efficiently treat the specific disorders?
- How can we prevent relapse?

The question of treatment is being addressed by more proximate approaches, but for those conditions we have yet to develop efficacious treatment methods, answers to the questions above might be assisted by an understanding of the evolutionary functions of the mental mechanisms involved. Existing approaches have not been able to address these questions satisfactorily.

Evolutionary approaches to the definition of psychopathology have improved our understanding of mental disorder as a phenomenon. Evolutionary analyses of diagnostic categories as phenotypes might further improve our ability to understand disorders – including subtypes of disorders, relevant mental mechanisms and contextual stimuli. For anxiety disorders, the sociopsychological explanations of etiology have been challenged, and evolutionary explanations have got increased attention. Several treatments have been suggested based on evolutionary insights, but a common problem is the lack of studies on the efficacy of these interventions. The prevention question is very important, as it is probably very cost effective at a societal level to reduce the number of people who develop mental disorder – an evolutionary approach may address the

ecological contexts that cause problems. Relapse prevention, especially in disorders such as depression, is a major focus of mainstream treatment research – yet again, ecological contexts might be predicted by evolutionary theory.

An integrative meta-theory will most likely address all relevant questions. Evolutionary clinical psychology is therefore not merely an academic exercise – or a luxury explanation. The evolutionary approach improves our knowledge of the nature of mental disorder and mental health, and thereby promises to have very practical implications for the future of mental health care.

Glossary

Distal (ultimate) causation Explanation of an animal's behavior based on changes in the heritable genes of that organism that were favored by natural selection.

Genotype An organism's genetic makeup.

Ontogeny The developmental life history of an organism from conception to death.

Phenotype All of an organism's observable characteristics – which are influenced both by its genotype and by the environment.

Phylogeny The developmental history of a species, genus, or group.

Probabilistic epigenesis A bidirectional process by which an organism's genes, environment, and development all continually affect each other at all stages during the organism's ontogenetic development.

Proximate causation Explanation of an animal's behavior based on an event which is most immediately responsible for its cause. This is in contrast to higher level distal, or ultimate, causes of behavior.

Evolutionary Developmental Psychology

The field of evolutionary developmental psychology (EDP) has garnered interest in recent years as yesterday's critics have begun to embrace the union of developmental psychology and evolutionary biology. The core principles underlying EDP date back to Darwin's theory of evolution by natural selection and its application to the study of human development and, more recently, developmental systems theory (DST). EDP attempts to explain both species-typical universals and adaptive individual differences, and focuses on how proximal factors influence the expression of evolved psychological mechanisms over time. In this context, EDP has been defined by Bjorklund and Pellegrini as "the application of the basic principles of Darwinian evolution, particularly natural selection, to explain contemporary human development. It involves the study of the genetic and environmental mechanisms that underlie the universal development of social and cognitive competencies and the evolved epigenetic (gene-environment interactions) processes that adapt these competencies to local conditions; it assumes that behaviors and cognitions that characterize not only adults but also children are the product of selection pressures operating over the course of evolution." Following this definition, the current article is divided into two parts: (1) species-typical patterns of social and cognitive development that are common to all humans reared in a species-typical environment and their 'real-world' applications, and (2) individual differences among humans as a result of adaptively structured phenotypic plasticity and genetic variation.

Evolutionary Psychology and Developmental Systems Theory

The growing popularity of EP has brought evolutionary perspectives into mainstream developmental science and has even found its way into the media-driven pop-psychology realm. In the past years, developmental psychologists have criticized EP

for neglecting to take into consideration human development and, instead, focusing solely on distal, rather than proximal, causes of adult human behavior.

Although the fields of EP and developmental systems have disparate histories, we believe that each could benefit from the insights of the other. Indeed, EDP attempts to synthesize these two fields of study. On the one hand, studying developmental processes – gene \times environment \times development interactions – without considering the fundamental role of evolution in structuring these interactions necessarily paints an incomplete picture of the developing organism and its adult phenotype. On the other hand, studying the evolved psychological mechanisms and behavioral adaptations of adults without considering their developmental history – the continuous and bidirectional interactions over time between the developing individual and the environment – is equally limited. In this section, we discuss the differences between mainstream evolutionary psychology (EP) and DST and argue that, by integrating the two and forming a new field (EDP), a resolution is afforded which allows researchers to integrate the tenets of each respective field and apply a broader perspective to the study of human development. We then outline relevant applications of the newly synthesized field of EDP before concluding with a discussion of the individual differences between humans resulting from our species' remarkable plasticity and variation.

Evolutionary Psychology

EP is the application of the principles and knowledge of evolutionary biology to psychological theory and research. Its central assumption is that the human brain is comprised of a large number of specialized mechanisms that were shaped by natural selection over vast periods of time to solve recurrent problems associated with survival and reproduction faced by our ancestors. These problems include such things as finding and choosing which foods to eat, negotiating social hierarchies, dividing investment among offspring, and finding and retaining mates.

Evolved cognitive mechanisms

According to Bjorklund and colleagues, the field of EP posits that our cognitive mechanisms were 'shaped by natural selection to (a) detect and encode information associated with recurrent problems of survival and reproduction in ancestral environments and (b) generate physiological activity and manifest behavior directed at solving the specific problem that brought the mechanism online.' In essence, natural selection is operating at the mechanistic level, mediated through environmental interactions, to generate manifest behavior aimed at solving real-world problems. As a field, EP has focused on identifying recurrent adaptive problems faced by our ancestors and the information-processing mechanisms that evolved to solve them. This process has produced species-typical cognitive mechanisms that are shared by all biologically normal members of the species.

Universal features of the human mind

The main focus of EP has been on species-universal characteristics of the mind. Necessarily, the distinction between evolved cognitive mechanisms and individual differences in manifest behavior is of great importance. Proponents of mainstream EP would argue that regardless of individual differences in behavior, all humans possess fundamentally the same set of evolved psychological mechanisms. From this view, individual differences in manifest behavior are due not to differences in evolved psychological mechanisms, but to interactions between the psychological mechanisms and environmental variability. A common example of the universality of evolved cognitive mechanisms is that of language. Environmental input mediates what language a child will learn to speak; but regardless of environmental variation, all children universally acquire language by engaging species-typical cognitive mechanisms to make sense of their surrounding verbal stimuli. While evolutionary theorists recognize the potential importance of variation between people, their primary focus remains on species-universals rather than individual differences.

Historical nature of biological adaptations

An assumption of EP is that the mind comprises highly specialized cognitive mechanisms. In general, genes which have increased the fitness of our ancestors (in terms of survival and reproduction) have been favored by natural selection and have propagated within the population. By contrast, genes which have not been associated with fitness-enhancing benefits have been unlikely to spread throughout the population. This dynamic process, over time, can cause species-level changes. From this perspective, any trait or characteristic described as 'adaptive' is defined as such because it enhanced reproductive success in ancestral environments.

It is important to note, however, that adaptations would have evolved in a very different environment than the one in which we live today. As a result, some adaptations may have at one time conferred fitness benefits to our ancestors while no longer retaining their same adaptive qualities and, indeed, some may actually have detrimental effects in modern society. For example, humans' penchant for sweet and fatty foods was adaptive for our nomadic ancestors living in resource-scarce environments, but is associated in modern times with a host of

general health problems for many people living in developed countries who are inundated with these types of foods.

Modularity of the mind

Another assumption of EP is that most evolved cognitive mechanisms are domain-specific and modular in nature. The concept of domain-specificity stems from the knowledge that these mechanisms evolved in response to specific recurrent problems faced by early humans, making them necessarily 'specific' by nature. Because humans developed domain-specific mechanisms in response to specific problems, a logical extension is that the mind of humans is modular in nature, implying restrictions in human cognition. Tooby and Cosmides argue that the human mind is analogous to a Swiss army knife, comprised of many tools, each designed to 'solve' a specific problem, rather than functioning as a general-purpose problem solver.

Although domain-specificity is a fundamental aspect of EP, others have proposed that in addition to these abilities, domain-general mechanisms may have evolved over time. Because information varies across generations and within lifetimes, these mechanisms would have evolved to solve the more generalized, unique, or novel problems faced by humans and to afford the flexibility of general problem-solving and a high degree of plasticity, both early in development as well as throughout the human life span. Consistent with this idea, David Geary, among others, has posited that the human mind is comprised of multiple modular mechanisms of varying degrees of specificity. From this perspective, higher level executive mechanisms would have evolved to function specifically for integrating information across lower level mechanisms.

A well-studied example of the mind's modularity is the development of theory of mind. Having a *theory of mind* refers to the ability of an individual to attribute mental states to oneself and others; importantly, it requires an individual to understand that the thoughts, beliefs, and intentions of another person do not necessarily reflect, and may in fact contradict, one's own. Although humans are not born with a fully developed theory of mind, development occurs along a continuum and most children exhibit an adult-like theory of mind by about 4 years of age.

Baron-Cohen has argued that theory of mind comprises multiple modules that each solve a specific adaptive problem. For instance, an *intentionality detector* is observed in infants as young as 9 months and serves to interpret moving objects as having some 'intention' toward the individual (e.g., that object may bite – or feed – me). An *eye-direction detector* detects eye-like stimuli and tracks their 'gaze' to determine whether the individual 'sees' something. A *shared-attention mechanism*, developed between 9 and 14 months of age, involves interpreting triadic interactions and representations between the self, another person, and an object (i.e., Mom and I are looking at the same thing). Finally, developing by about 4 years of age is the *theory-of-mind mechanism*, which is essentially a fully functioning belief-desire reasoning ability as described above.

The pattern of development for the modules comprising theory of mind is consistent with that proposed by Geary and Bjorklund regarding the developmental trajectory of evolved cognitive mechanisms, in general. Specifically, they have

asserted that modules should be hierarchical in nature, have sensitive periods for the development of abilities, and be based on implicit knowledge and cognition. As Geary has argued, these abilities are important and may provide the foundation for intelligence because it is likely that they serve as the basis upon which a child's developing cognitive competencies are built.

Developmental Systems Theory

Developmental systems theorists are strong proponents of epigenesis, the continuous bidirectional feedback between an organism and its environment on multiple levels (e.g., biochemical, physical, social) over time. At the core of DST is the idea that an organism, itself, actively influences its own development over the course of ontogeny. In the following section, we outline basic tenets of DST.

Gene–environment interaction (probabilistic epigenesis)

A criticism of EP that is commonly cited by developmentalists is the focus in evolutionary research and literature on adult human behavior and their failure to recognize the significance of environmental variables. Evolutionary psychologists have, in the past, been accused of being genetic determinists because of the importance they place on an animal's genes in explaining its behavior. Although most evolutionists would recoil at the thought of being considered a genetic determinist, developmental systems theorists contend that postulating 'genes for' any given trait, as sometimes occurs in EP, represents a form of genetic determinism.

Instead, developmental systems theorists argue that all development results from interactions between genes and the environment at the genetic, structural, and environmental level. Continuous bidirectional feedback occurs between these adjacent levels and results in an organism's structure and function throughout its life span. From this perspective, genes are not thought of as being encoded with 'instructions' that are in some way carried out during the course of development. Rather, genes are seen as developmentally relevant only within the broader environmental context and should not be studied without considering the organism's developmental history.

Ontogeny of species-typical behavior

DST holds that no behavior is naturally occurring or 'innate.' Furthermore, proponents argue against any structure or function being genetically predisposed, waiting only for specific environmental stimuli for activation. Instead, experience during embryonic development is necessary for animals to display species-typical behaviors. From this perspective, continuous and dynamic interactions between an organism and its environment are responsible for emergent structure and function. As stated by Bjorklund and colleagues, "genetic information is extensively scaffolded by species-typical features of the environment . . . the phenotypic outcome is a predictable, emergent property of the *total* developmental system" (emphasis added).

In terms of developmental timing of species-typical behavior, the sensory systems of all vertebrates mature in a common order. For example, neural areas associated with audition develop before those associated with vision. Given that an

animal develops in a species-typical environment, this developmental pattern will always be the same, thus yielding species-typical behavior throughout ontogeny. Some theorists have argued that the brain develops in part via competition over neurons. Because different groups compete for the same cells, deviations from species-typical patterns of activation during development may result in changes in brain organization. A number of studies have reported alterations in species-typical behavior in precocial birds as a result of early species-atypical experiences. This is presumably because any species-atypical sensory experience (whether the experience is introduced earlier or with greater frequency than is normative) interferes with the animal's species-typical pattern of development, sometimes yielding deleterious patterns of functioning. We will revisit this concept when we discuss applications of EDP.

An Emerging Synthesis

Traditionally, developmental systems theorists have accused evolutionary psychologists of practicing a form of genetic determinism, whereas evolutionary theorists have contended that DST affords a nearly infinite degree of plasticity, with the subsequent result that it lacks the ability to predict species-typical patterns of development. Although these theories appear to be rooted in seeming contradictories, an emerging synthesis between the two has resulted in the new field of EDP. At the crossroad of these theories is the idea that genes and environments interact during an organism's ontogeny to produce competent adult behavior. In the following section, we examine applications of EDP that emerge as a result of the synthesis between EP and DST.

Applications of EDP

Prepared Learning

Although evolutionary developmental psychologists caution against prematurely labeling human traits or characteristics as 'innate,' there are certain instances in which humans show remarkable ease of learning, suggesting that this potential 'prepared learning' stems from an evolutionary history where predictable and recurring environments have prepared the brain to react in certain predictable ways given a species-typical rearing in a species-typical environment.

Predator avoidance

Learning to fear potentially threatening stimuli very quickly is an important ability for survival. Mammals may be 'prepared' to learn to fear predators that were widespread and posed a recurrent threat throughout evolutionary history. Indeed, a fear of snakes and spiders is easily acquired by children via social learning at a young age. A study of infants aged 7–18 months found that when presented with fear-inducing and nonfear-inducing visual stimuli (i.e., moving images of a snake and a nonsnake displayed split screen) and an auditory stimulus (a scary voice or a happy voice), infants associated the fear-inducing sound with the snake, as measured by longer look time.

This selective attention to evolutionarily relevant dangerous animals likely results from an evolved predator-avoidance adaptation. Our ancestors who were able to attend to and avoid potentially threatening stimuli were more likely to reproduce than their conspecifics lacking this ability. Interestingly, past research with nonhuman primates has found that lab-reared rhesus monkeys rapidly learn to fear evolutionarily relevant stimuli (e.g., toy snake or crocodile) even without having any prior exposure, simply by observing a videotape in which a rhesus monkey model responded fearfully in the presence of a toy snake or crocodile. However, upon viewing an identical video in which the model displayed fear of non-evolutionarily relevant fear stimuli (e.g., flowers, toy rabbit) the animal observers did not exhibit the same fear. The acquired fear of evolutionarily relevant stimuli in this experiment was both powerful and potent, with animals displaying distress even while watching the original video with fear responses continuing on posttests up to 3 months after the initial video viewing. Because the fear of snakes and crocodiles was easily and rapidly acquired while the same fear of irrelevant stimuli was not, researchers have posited that this fear is likely driven from phylogenetic rather than ontogenetic factors, suggesting a long evolutionary history.

Nausea associated with food

A similar association that both human and nonhuman animals make with seemingly 'prepared' ease is that of nausea associated with food. Evolutionarily, our ancestors who experienced nausea or vomiting after eating certain unhealthy foods (i.e., rancid meat, etc.) would have benefited from being able to associate the illness with the food previously eaten. The ability to do so would surely have benefited these animals by ensuring they would not continue eating food damaging to their immune system.

Researchers have found that rats quickly and easily associated the consumption of novel food with nausea when they received the novel food paired with an injection intended to make them ill. They did not, however, make the same connection when novel food items were paired with electric shocks, associating the consumption of food with a following aversive stimulus. Interestingly, the rats did learn to avoid the electric shock when it was preceded by light and noise. This may hint at an evolutionary history of learning to avoid environmental hazards like lightening or falling objects, which would have also had significant evolutionary relevance.

In addition to an evolutionary 'preparedness' for pairing illness with consumption of food, many researchers have posited that nausea and illness associated with pregnancy, often referred to as 'morning sickness,' may serve an adaptive function. Cross-cultural analyses of 27 traditional societies have resulted in many findings consistent with this view. First, nausea and vomiting peak when the embryo is most susceptible to chemical effects (6–8 weeks); second, women who experience morning sickness are less likely to miscarry than those who do not experience any illness; third, women who vomit are less likely to have a miscarriage than those who only experience nausea; and finally, many pregnant women have aversions to substances that would be especially harmful to their developing embryo (i.e., alcohol, caffeinated beverages, meats, poultry, and eggs). From this perspective,

morning sickness is adaptive because it causes women to avoid substances that could be potentially dangerous to themselves or their embryos. Interestingly, women from 7 of the 27 societies never experienced morning sickness. Of interest from an evolutionary developmental perspective is the fact that the diets of women in these societies were largely vegetable-based, with corn as one of the main staples. In contrast, the diets of women from the remaining 20 societies who did experience morning sickness were largely meat-based, again providing evidence for environmental interaction in this evolved adaptation.

Species-Typical Development Depends on Species-Typical Environments

Information-processing mechanisms have evolved to solve recurrent problems faced by ancestral populations; however, they are expressed in a probabilistic fashion in each individual in a generation, based on the continuous and bidirectional interaction over time at all levels of organization, from the genetic through the cultural. These mechanisms are universal, in that they will develop in a species-typical manner when an individual experiences a species-typical environment over the course of ontogeny. That is, consistent with Brunswik's theory of probabilistic functionalism, evolved cognitive mechanisms make use of and depend upon systematic information and relations in the ecological–environmental contexts in which development regularly and predictably occurs. However, these mechanisms are subject to modification in any particular individual as a result of perturbations in these contexts.

Visual abilities

As we have already discussed, domain-specific modules have been theorized to have evolved to deal with recurrent and relatively invariant aspects of ancestral environments. Most visual abilities, for example, will develop in all humans living in all but the most deprived conditions. This is because natural selection would have favored domain-specific, modular-like mechanisms, which require only a species-typical environment for their proper development. Importantly, species-atypical environments can actually alter the development of these abilities.

For example, to study the effect of presenting animals with experiences outside the boundaries of species-typical environments, researchers removed part of the eggshell of bobwhite quails prior to hatching and provided chicks with visual stimuli (patterned light) that they would not otherwise have been exposed to until after hatching. A control group of chicks also had part of their shells removed but were not exposed to visual stimuli. After hatching, chicks were presented with the maternal calls of their own species as well as that of a chicken.

Findings indicated that the experimental group of chicks, compared to the control group, could not discriminate between the maternal calls and, thus, showed no preference for one over the other. They did, however, show enhanced visual discrimination, but at the expense of auditory discrimination. This research indicates that providing young animals with stimuli outside the realm of normative species-typical experiences may have negative consequences for development.

Language acquisition

A heavily studied example of 'prepared learning' is that of language acquisition. Although many species communicate in varying, but limited, ways, language is unique only to humans. Although we can only theorize as to when language emerged within the human population, evidence from biological sciences has suggested that the expansion of pathways carrying nerves to intercostal muscles in vertebrates – which occurred 300 000 years ago – helped control the pulmonic pulsing driving human phonation, thus, indicating a developing reliance on vocal communication as far back as 300 000 years ago. Evidence suggests that language produced at that time was limited in structure and lacked the complexity we see in today's languages, but it surely served as support for the development of a linguistic society dating far back into our evolutionary history.

During the 1980s, a set of cognitive developmental psychologists began expanding on *neonativist* theories originally put forth by Noam Chomsky, arguably the world's most well-known linguist. Central to a neonativist perspective is the claim that children are born with *universal grammar*, some basic knowledge about language's structure and syntax. Furthermore, neonativists would argue that children also possess a *language acquisition device*, a mental ability to compare language input from a child's environment with their own universal grammar, and to make modifications as necessary, permitting children to learn the basics of the language spoken in their environment and aiding them in the acquisition of this language.

Support for the universality of language acquisition comes from studies in which children spontaneously 'invent' new languages when isolated from society or exposed to poorly structured verbal codes. One compelling instance of this was studied among deaf children in Nicaragua. Prior to the 1970s, no deaf education was in place in the country, and deaf children were isolated from the rest of their society. However, a group of deaf children spontaneously began creating their own sign language, first studied in 1978, and subsequent generations of deaf children not only learned this rudimentary language but actually modified it from a *protolanguage* (a rudimentary representation of language lacking syntax), to a more complete language.

Interestingly, evidence for a sensitive period of language acquisition suggests that although the acquisition of language is universal for all humans reared in species-typical environments, humans reared in atypical environments may be subjected to a limited period of time within which they are easily able to acquire language. After this sensitive period, any child who has not yet acquired language will have a difficult time mastering even basic linguistic abilities and will be unlikely to ever acquire language comparable to that of the average adult.

Evidence for a sensitive period comes from studies of feral children who have been discovered in late childhood living in conditions presumably without any significant human contact. These children, when not 'discovered' until adolescence, have difficulty acquiring even rudimentary language and fail to achieve language proficiency comparable to most 3-year-olds, even after intensive education. Although there is no definitive cutoff age at which the ability to learn language ceases, studies have generally found that the younger the child at time of

recovery, the greater the likelihood that they will be able to acquire language. Conversely, once children reach adolescence, even intensive instruction may prove futile in attempts to teach a primary language. Similarly, individuals learning second languages benefit greatly from instruction in childhood, during which time they are best able to learn the subtle nuances of a second language. If not exposed to a second language until adolescence or adulthood, people often have trouble mastering the syntax and phonology of the second language and are rarely able to obtain linguistic ability comparable to that of their primary language.

Characteristics of Childhood

Another unique feature of *Homo sapiens* is our extended juvenile period. Having an extended childhood imposes specific costs both to parents and offspring, themselves. In addition to children's physical and sexual immaturity, an extended childhood is also a time of social and cognitive immaturity. For evolution to have favored an extended juvenile period in spite of so many seemingly adverse effects, it must have served adaptive purposes. One explanation for humans' extended childhoods is that it serves to prepare children for adulthood by allowing time with which to learn the social complexities of their environment.

Certain characteristics of childhood are seen cross-culturally and worldwide. Some of these universal characteristics have been hypothesized to occur as preparations for adulthood (*deferred adaptations*) whereas others serve adaptive purposes specifically during childhood, with no relevant benefits to later adulthood (*ontogenetic adaptations*). Because all individuals must survive childhood in order to reach adulthood and pass on their genes, it is not unreasonable to expect that certain selective pressures may only operate during childhood and that, as a result, adaptations that help children to survive would have been selected for throughout the course of human evolution. For example, observed sex differences in children's play provide evidence that an extended childhood may have evolved both for immediate and delayed benefits. An immediate benefit of play is that it serves as a form of exercise. Delayed benefits, which we argue serve as preparations for adulthood, include learning about dominance hierarchies (seen particularly in boys' play) and the establishment and maintenance of social relationships, which foster skills that are undoubtedly relied upon throughout an individual's life span.

Extended childhood

One hallmark of our species is our unusually long childhood and juvenile period, relative to those of other mammals. Because the costs of an extended childhood are likely to be substantial, evolution would only have favored this strategy if it allowed for specific adaptive advantages (in terms of survival and reproduction). Importantly, one benefit of an extended childhood is that it permits children to adjust to variations in social environments and to anticipate future ones. Because a prolonged period of immaturity was (and continues to be) vital for learning the complexities associated with group living, humans are uniquely susceptible to (or able to cope with) environmental variations. In addition to serving as a learning

ground for developing human social competencies, an extended period of immaturity may serve other adaptive benefits, as well.

Although some of the immediate benefits for delaying sexual development are rather intuitive (e.g., delaying reproduction allows a child the time to build their physical and cognitive abilities to make them a 'fit' parent prior to raising offspring), other benefits of an extended childhood may be less obvious. One characteristic of childhood that has been argued to be pivotal for developing social and cognitive competencies is that of child-initiated play. This is because in contrast to 'organized' play, child-initiated play is often person-centered, allowing children to develop important social competencies and to learn about the structure of the physical world.

Examples of the social competencies gained from children's play stem from naturally occurring observable sex differences. For example, boys' play is more likely to be rough in comparison to girls' play. Boys' play, relative to that of girls, focuses on social dominance and group-level competition, which serve as preparations for physically aggressive male-on-male competition that would have served to increase social status and acquire mates for our male ancestors. In contrast, girls' play is more often focused on developing and maintaining social relationships with other girls. It is more likely to be fantastical in nature and to involve make-believe or dress up, helping girls learn how to form and maintain stable social support systems, which surely bolstered the survival of our female ancestors. As a result, play serves an important role for both boys and girls because it can serve as the foundation upon which later innovations and creativity may take root, which are certainly beneficial in adulthood. In addition to the delayed benefits of play, immediate benefits such as those gained through exercise and the establishment and maintenance of social relationships during childhood also serve an adaptive function.

Adaptive Individual Differences

Individual differences in EP have traditionally been viewed as nonadaptive (noise in the system). However, mounting theoretical and empirical evidence (much of it stemming from EDP) suggests that there is not just a species-typical human nature but also diversity within species at the genetic level as well as phenotypic plasticity. Natural environments are often complex and afford more than one way to survive and reproduce. Such multi-niche environments provide the ecological basis for the evolution of adaptive phenotypic variation within species. This adaptive variation can evolve in response to the physical diversity of environments (i.e., ecological niches that vary over time or space) or as alternative solutions to problems of social competition.

Adaptive Phenotypic Plasticity

Whereas the development of all adaptations depends on various regularities in the environment, the development of many adaptations also depends on systematic (structured) variation in the environment. That is, for many adaptations, the types of environmental information that interacts with underlying genes vary substantially within species-typical environments

(e.g., as does diet, quality of parental investment, social competition, and mortality rates). When, over evolutionary time, the fitness of alternative phenotypes is predictable on the basis of observable environmental cues, natural selection tends to favor *phenotypic plasticity*: neural circuits that reliably guide development of alternative phenotypes (anatomical, physiological, behavioral) in response to given ecological or developmental conditions. Adaptive phenotypic plasticity enables matching of the phenotype to conditions where it is expressed.

One form of adaptive phenotypic plasticity is *conditional adaptation*, defined by Boyce and Ellis as "evolved mechanisms that detect and respond to specific features of childhood environments – features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature – and entrain developmental pathways that reliably matched those features during a species' natural selective history."

Conditional adaptation in the Arizona caterpillar

According to this view, organisms have evolved to detect and encode information from their environments and develop organized and contingent adaptive phenotypic responses. These responses serve to match the organism to their environment. These responses can be reversible (polyethisms) or permanent (polyphenisms). One example of a polyphenism is the caterpillar *Nemoria arizonaria*, commonly referred to as the Arizona caterpillar. The Arizona caterpillar has evolved an adaptive phenotypic response to the type of food they consume within the first three days of life. Food available during the spring cause the caterpillar to develop a flower-type morph while food consumed during the summer cause the caterpillar to develop a twig-type morph. These different morphs have been found to be contingently responsive to spring and summer food even when they are experimentally administered out of season. Thus, development of one morph over another represents an evolved adaptive predator-avoidance mechanism that matches the caterpillar to their expected environment (floral environment in the spring, a more sparse environment in the summer).

Conditional adaptation in human reproductive strategies

A much studied example of conditional adaptation in humans is adjustment of rates of sexual development and behavior in girls to match conditions in and around the family. This work is based in life history theory, which suggests that early experiences bias reproductive decision (e.g., decisions about how to allocate effort toward mating vs. parenting, or quality vs. quantity of offspring) in adolescence and adulthood. The theory assumes that, in response to specific developmental contexts, individuals adjust reproductive strategies in ways that historically increased reproductive success and thus fitness in those contexts. Accordingly, behavioral profiles or 'strategies' are conditional and responsive to environmental (including social) cues. According to prevailing models of human sexual development, of particular importance is a sensitive period (approximately the first 5–7 years of life) when environmental exposures – cues to the availability and predictability of resources, the trustworthiness of others, the stability of pair bonds, and the endurance of close personal relationships – function to entrain alternative reproductive pathways.

The basic premise of the model, as developed by Jay Belsky and colleagues, is that there are two alternative pathways – fast and slow – underlying variation in reproductive strategies. The fast pathway is characterized by early high-stress environments such as high marital discord, father absences, and/or inadequate resources. This acrimonious family context undermines parenting behavior resulting in harsh, rejecting, insensitive/inconsistent parenting. These parenting behaviors are thought to promote insecure attachment accompanied by a mistrustful internal working model and an orientation toward opportunism in interpersonal relationships. This in turn is hypothesized to accelerate somatic development (e.g., cause earlier puberty) and leads to a faster reproductive strategy (e.g., earlier sexual activity, more sexual partners). The second pathway, the slow path, is very nearly the complement of the fast path. Children whose reproductive trajectory follows the slow path inhabit early environments characterized by adequate resources and low spousal discord, sensitive and supportive parenting behaviors, secure attachment, and trusting internal working models. These children are hypothesized to delay the onset of puberty relative to their peers and have later sexual activity and more enduring relationships.

Empirical research testing this model, much of it conducted by Bruce Ellis and colleagues, has generally found that girls who are reared in homes prone to economic or psychological stress, marital discord, father absence, and unreliable social relationships reach puberty sooner, become sexually active earlier, and reproduce at a younger age than do girls raised in more supportive environments. Consistent with life history theory, these differences in girls' reproductive strategies are hypothesized to reflect adaptive responses to their early environment. Although it may be counterintuitive for girls' best adaptive strategy to include early puberty and sexual activity, this pattern may actually reflect a 'good' strategy (from a Darwinian perspective) for a girl living in a harsh or unpredictable environment. When living in dangerous conditions, girls can increase their inclusive fitness by accelerating reproduction, thus increasing the chance of reproducing at all in a high-mortality environment. Individuals may also be selected to hedge their bets in this context by producing multiple offspring and investing relatively little in each one, rather than investing a lot in a given offspring who might die young. This 'strategy' is, of course, not necessarily conscious but is based on children's sensitivity to early environments and their physical and psychological responses in anticipation of future ones.

Adaptive Genetic Diversity

Despite the apparent advantages to plastic organisms that can alter development to match environments, there are potentially high costs of phenotypic plasticity (e.g., producing and maintaining the appropriate regulatory and assessment mechanisms for alternative development); thus, in some cases, genetically based polymorphisms will be selected for, instead. Such polymorphisms are likely to be favored by selection when advantages of niche specialization are high, when organisms can evaluate and select their niches, and when reliable environmental cues for entraining or switching between alternative phenotypes do not exist. Genetic polymorphisms can also be maintained by an evolutionary history of fluctuating

selection pressures whereby the fitness of alternative genotypes (and their expressed phenotypes) varied depending on their frequency in the population. In this context, the fitness of each genotype changes over time as it becomes more or less frequent. The most common and viable form of frequency-dependent selection is negative, selecting against genotypes as they become more common. For genetic polymorphisms to be maintained by natural selection, they must evolve toward a state of equilibrium in which the average fitness of the alternative alleles (or variants of the same gene within a population) is equal.

Allelic variations can support the development of alternative phenotypes that may have adaptive consequences for the organisms. For example, consider the situation where two gene variants exist at a given locus, *a* and *b*. For diploid species, such as humans, three alternative genotypes are possible, homozygous *aa*, *bb*, and heterozygous *ab*. If one of the genotypes (and corresponding phenotype) confers a selective advantage over the others, then natural selection will tend to favor this genotype. This implies that selection will act to eliminate the other alternative genotypes since they are nonequivalent in terms of their fitness benefits. However, as noted above, alternative genotypes can thrive in multi-niche environments when individuals can choose niches that match their genomes. Consider the example of the dopamine 4 receptor gene (*DRD4*).

Maintenance of adaptive genetic variation in humans: The case of the *DRD4* gene

The *DRD4* gene has two allelic variants that are associated with distinctive phenotypes. The first, *DRD4* 4R (also known as the short allele), is associated with more risk averse behaviors while the *DRD4* 7R (also known as the long allele) is associated with more novelty-seeking and risk-prone behaviors, though the main effects of the 7R allele are relatively small and inconsistent. A possible explanation is that individuals with the 7R allele are generally more susceptible to environmental influence: such individuals display enhanced sensitivity to *both* negative and positive environments, that is, to both risk-promoting and development-enhancing environmental conditions. This enhanced sensitivity increases *developmental* receptivity to the environment. That is, more susceptible individuals are more likely to experience sustained developmental change in response to environmental exposures.

The 4R allele was the most common form of the *DRD4* gene throughout human prehistory. Under conditions of environmental harshness and resource limitation, which are common in preagricultural foraging societies, biparental investment in offspring, durable pairbonds, and strong family ties and cooperation (i.e., slower LH strategies) are generally needed to survive and reproduce successfully. These ancestral conditions may have helped to maintain the 4R allele, which is associated with more risk-averse mating and social behavior.

Whereas the *DRD4* 4R allele appears to have emerged around a half-million years ago and is common in most geographical locations, the *DRD4* 7R allele, which is associated with greater developmental plasticity and, under certain conditions, more impulsive and risk-prone behavior, appears to have been selected for over the last 40 000–50 000 years and has a widely variable and nonrandom global distribution. Based on an analysis of this distribution, some researchers

have concluded that the 7R allele promotes migratory behavior, with bearers of 7R more likely to lead populations far away from their ancient lands of origin (e.g., South American Indians, Pacific Islanders). An alternative explanation, however, is that carriers of the 7R allele are more behaviorally plastic and thus better able to adapt to new environments. Still another explanation is that the 7R allele is favored by selection under conditions of surplus resources. In such luxuriant contexts, where offspring can be successful without intensive biparental investment (as is common in many agricultural and modern societies), higher levels of energetic, impulsive, and noncompliant behavior characteristic of male bearers of the 7R allele may facilitate fast sexual behavior and success in intrasexual competition. Recent increases in the frequency of the 7R allele are consistent with this hypothesis. In total, 7R bearers may not only be more likely to become propagules colonizing new environments (generating between-group variation in reproductive strategies) but may also employ faster reproductive strategies than 4R bearers in well-resourced, multi-niche environments (supporting within-group variation).

Concluding Remarks

An evolutionary perspective can contribute significantly to the study of human development, but a developmental perspective, especially the careful consideration of epigenetic effects, should also be recognized by evolutionists. While most evolutionary psychologists acknowledge the role the environment plays in development, they rarely address the issue in depth and fail to fully explore the implications of probabilistic epigenesis on emerging human social behavior and cognition.

Ultimately, adopting a developmental perspective in EP has the potential to broaden the horizons of mainstream EP by providing a more thorough background of the environmental variations and individual differences that account for the development and expression of evolved human behaviors. Failing to do so can potentially limit the influence of evolutionary theory by failing to take into consideration an adult's ontogenetic history when discussing their current behavior. The two cannot be separated in the natural world and, therefore, must be considered only within the context of each other.

EDP represents an emerging synthesis between species-universal traits and characteristics and those which result from adaptive phenotypic plasticity or genetic diversity. Although the field is still in its infancy, EDP has the power to make its way into mainstream psychology by providing the most complete picture of adaptive human behavior, taking

into consideration our species' rich evolutionary history in conjunction with unique individual experiences in such a way as to explain adaptive human behavior and cognition.

Glossary

Apparent context The set of apperceived and ordered psychological manifestation of extant adaptive problems.

Assortative mating Preferential assortment between phenotypically similar (if positive) or dissimilar (if negative) sexual partners.

Assortative sociality Preferential association between phenotypically similar (if positive) or dissimilar (if negative) social partners.

Balanced polymorphism An evolutionary stable strategy of multiple behavioral types coexisting within a population.

Behavioral flexibility The temporary, reversible behavioral changes that can occur throughout the life span.

Developmental plasticity The permanent behavioral, anatomical, or physiological changes in the developmental trajectory adopted by an organism during the life span.

Directional selection Changes in gene frequencies within a population that ensue when natural or sexual selection favors a single phenotype over others and shifts the relative allele frequencies continuously in one direction.

Disruptive selection Changes in gene frequencies within a population that simultaneously favor individuals at both extremes of the distribution over those in the middle of the range, also called diversifying selection.

Ecological validity coefficients Correlations, ranging between zero and one, that characterize the predictive validity of ecological cues that signal the presence of particular adaptive problems.

Epigenetic Changes in phenotype caused by mechanisms other than changes in the underlying nucleotide sequence of DNA, such as changes in gene expression.

Frequency-dependent selection A dynamic form of balancing selection that occurs when the fitness of a given phenotype increases or decreases based on its prevalence relative to alternative phenotypes within a population.

Gene–environment correlation An association between an individual's genotype and the environment that it inhabits.

Gene–environment interactions Environmentally induced changes in gene expression.

General factor of personality A certain profile of personality traits that is purportedly both socially and sexually selected for mutually beneficial cooperation and has been associated with a number of cooperative and prosocial traits.

Genetic diversification Increasing the level of heritable variation within and between populations, providing a mechanism for organisms and populations to adapt to changing environments.

Genetic drift Nonadaptive changes in relative frequencies of gene variants (alleles) that occur in a population due to random chance over time.

Heritability The proportion of the variance in phenotype that is attributable to variance in genotype.

Natural selection Changes in gene frequencies favoring phenotypic traits that increase survival and fecundity.

Ontogenetic Referring to the sequence of developmental stages through which the organism passes during its lifetime.

Sexual selection Changes in gene frequencies favoring phenotypic traits that enhance success in obtaining and retaining sexual partners.

Social selection Changes in gene frequencies favoring phenotypic traits that enhance success in obtaining and retaining social partners.

Sociality hypothesis The theory that disruptive selection favors the diversification of personality in social species.

Theoretical evolutionary ecology The mathematical equations and probability distributions that govern the demography and biogeography of species over evolutionary time.

True context The extant subset adaptive problems currently facing an individual organism, independent of origin.

Introduction

Multiple mechanisms of selection shape individual differences in human personality, both within and between different populations. Together, these selective forces operate to change the relative frequencies of the genes influencing the development of personality traits in various ways. All human personality traits are at least partially heritable, with *heritability coefficients*, an index of genetic influence, mostly ranging from 40% to 50%. The way that most genes influence personality development, however, may not be through simple Mendelian inheritance. For example, genetic influence may operate through biologically

prepared mechanisms of phenotypic plasticity. These epigenetic processes consist of systematic changes in the phenotype (observable traits) through ontogenetic shifts at specific points of the life cycle by altering the expression of the genes themselves throughout development. These genetically influenced developmental programs may be guided by adaptively fine-tuned *developmental switches* that are strategically preprogrammed to be contingently activated upon encountering prespecified environmental cues, signaling the presence of the particular *adaptive problems* to be solved at each successive stage of life.

Nevertheless, genetic influences are intimately involved in personality development, one way or the other, making

personality variation a potential target of various forms of selection. Depending on prevailing ecological conditions, one of these selective pressures may be more or less influential at any given time. Although space constrains the provision of an exhaustive overview, the influences of (1) directional social selection, (2) disruptive social selection, (3) genetic diversification, (4) developmental plasticity, and (5) behavioral flexibility upon the evolution of individual differences in personality have been addressed.

Directional Social Selection

The need for *social cooperation* among humans produces directional selective pressures favoring a certain degree of convergence among individuals in behavioral dispositions. Such selective pressures were identified as early as 1871, in Darwin's seminal work *The Descent of Man*. This kind of social selection may act either through contest competition among rival groups, as Darwin maintained, or through social adaptations to better fit individuals to optimize their survival and reproduction within the complex social context of such interacting groups.

Recently, this type of selection has been theorized to promote the evolution of a certain profile of personality traits purportedly best suited for social cooperation. This personality profile has been referred to as the *general factor of personality*. Although it has been derived from a variety of different personality inventories, some measuring different subsets of lower-order personality factors, this higher-order factor is best described as a trait profile consisting of high openness to experience, high conscientiousness, high extraversion, high agreeableness, and low neuroticism.

The general factor of personality appears to be both socially and sexually selected. For example, when asked to rate their *ideal romantic partner* on a standard personality inventory adapted for the purpose, most respondents reliably rate this imaginary partner somewhat higher than themselves on this characteristic profile of personality traits. This indicates both assortative mating (pairing of individuals on similar levels of phenotypic, and perhaps heritable, traits) on individual differences and a population-wide directional preference, at least in romantic aspirations. When people say that they would like someone with a 'great personality' as a sexual or social partner, this is evidently what they generally have in mind.

In addition, the general factor of personality is associated with a number of cooperative and prosocial traits, including altruism, sociability, subjective well-being, satisfaction with life, self-esteem, and emotional intelligence. The profile is so self-evidently socially desirable that it has led some to question whether the entire common factor is not just an artifact of shared evaluative bias. Recent behavioral genetic twin studies, some using multiple raters and not limited to self-reports, however, demonstrate both substantial heritabilities for this higher-order factor as well as genetic correlations with both better overall physical and mental health and slower life history (for more on this reproductive strategy, see section 'Disassortative Mating as a Strategy for Genetic Diversification').

Classical neo-Darwinian theories of sexual selection predict that a population-wide sexual preference for a trait, or for a certain coordinated profile of traits, inevitably becomes

genetically associated with the trait itself over evolutionary time. Therefore, even if the general factor of personality started its evolutionary history as an evaluative bias, it would have quite quickly become a target of both sexual and social selection and would have been shaped into being, even from an assortment of previously uncoordinated personality factors. Thus, some of the methodological criticisms of the higher-order personality factor are psychometrically, but not evolutionarily, informed.

Disruptive Social Selection

Theoretical Evolutionary Ecology

When considering the evolution of a species over time, it becomes apparent that the heterogeneity (nonuniformity) of the spatial habitat alone cannot account for the diversity both between and within species. One must think of species and individuals as existing within the multiple intersections of many different environmental factors. Each factor comprises some aspect of the environment, living or nonliving, to which the species or individual is subjected. For example, domestic dogs have lived in many different habitats. Many other physical and biological factors, such as the temperatures and humidities of their environments, their interactions with humans and their other domesticates, the available prey, and other predators, have influenced their evolution. All of these environmental factors taken together constitute an *ecological niche*. This conception treats an individual within the species as an element within an ecological system influenced by the many environmental factors affecting its survival and reproduction.

Humans have been described as generalists. As a species, humans have a wide range of potential niches that allow for variability in the means of both survival and reproduction. A major contributor to this large niche space is that humans have become molders of their environment, modifying once uninhabitable habitats to become habitable for them. This *ecological dominance* has been dramatically facilitated first through the advent of agriculture and then later through the industrial revolution, both allowing for greater population densities and release from some between-species pressures. These greater population densities, however, foster greater within-species competition.

Release from this within-species competition has come in part through technological revolutions. These technological revolutions allowed for more division of labor (e.g., farming vs. hunting) and a consequent increase in within-species dependencies (e.g., the exchange of grain for meat). New technologies cut down labor requirements and made new resources within the environment more easily attainable, permitting some individuals to specialize in occupations that were not possible before, but some of which became advantageous in the more complex social environment. In essence, these technologies expanded and diversified the ecological ranges of humans to incorporate and create new niches. This labor specialization requires intensified social interactions and within-species dependencies. As the ease of meeting survival and reproductive needs grew, so did the dependency on others in direct proportion.

Thus, in addition to directional selective pressures produced by *social cooperation*, favoring convergence among

individuals, disruptive selective pressures are produced by *social competition*, favoring divergence among individuals in behavioral dispositions. We propose that individual differences in personality evolved in response to these opposing social selective pressures. Within-species competition grows as a function of the number of social interactions. Paradoxically, more cooperative social interactions lead to more competition within species. For a solitary species, a single response disposition might be optimal, where any deviation from this optimum resulted in shortened survival or lower overall reproductive success. Thus, individual differences were not selectively neutral. For a social species, we might also expect a single response disposition to be optimal if it promotes greater social cooperation, as the general factor of personality described earlier evidently does.

For a social species, increased within-species interactions expanded the number of social niches, eliminating a single and invariant species-typical or *global* optimum and replacing it with a divergent set of *local* optimal response dispositions. These disruptive selection pressures shaped the evolution of what became variable personality traits, each contingently optimal in a different social niche. Ecological dominance relieved some of the between-species pressures selecting the formerly species-typical optimal response disposition, allowing the within-species variance around it to grow. Dispersing from this central tendency, individuals partially released themselves from direct competition with other individuals and became better adapted to a social existence. This process is known in the theoretical evolutionary ecology as *within-species niche-splitting*.

Frequency-Dependent Selection

Several theorists argue that, due to the extreme sociality of humans over recent human evolution, frequency-dependent selection offers the best framework for understanding such personality variation. Frequency-dependent selection is a dynamic form of balancing selection that occurs when the fitness of a given phenotype increases, or decreases, based on its prevalence relative to alternative phenotypes within a population. Essentially, the frequency of an alternative phenotype affects the fitness payoff of an individual's traits in that environment. If the alternative phenotype is abundant, making it more costly, a selective pressure working against the alternative may increase the fitness of an individual's phenotype, thus making it more common. This outcome is called *positive frequency dependence*. If the alternative phenotype is less abundant, and less costly, a selective pressure working against the individual's phenotype will make it less fit. This outcome is called *negative frequency dependence*.

Such a process, occurring across evolutionary time, can lead to an *evolutionary stable strategy* of multiple behavioral types coexisting within a population, called a state of *balanced polymorphism*. This evolutionary stable strategy may work at both the between-species level, as with species that coexist within a given environment, and at the within-species level, as with multiple morphs of the same species competing within a population. This latter process is the most applicable to individual differences in human personality. As an illustration, one might examine the universal personality dimension of extraversion/introversion. This personality trait is heritable, tied to

physiology, and predictive of specific behaviors. It is not difficult to envision social niches where extraversion is beneficial. Extraverted individuals are more assertive, social, dominant, active, and sensation seeking than their introverted counterparts. As the number of extraverts increases in the population, however, competition among them would also increase, opening up a niche for the lower-competition solution of introversion.

Some evolutionary models use frequency-dependent selection to explain such variations in human personality traits. Inherent to these models is the understanding that within any given social environment there are multiple niches individuals may exploit, each of which may lead to an increase or decrease in the fitness of a given behavioral phenotype. Population-level variation in personality is a mixture of genetic variation and phenotypic plasticity. Individuals may be ecological specialists (i.e., genetically constrained to fill a particular social niche) or ecological generalists (i.e., who can match their phenotype to respond to their current social niche). As a logical extension of the previous extraversion/introversion example, it has been argued that those who score at the extreme ends of the dimension (highly extraverted or highly introverted) tend to be more strongly consistent across time and context, suggesting a constraint on their behavior, while individuals who score more toward the population average of the dimension are contextually sensitive and flexible in their behavior. This simplified example therefore suggests that frequency dependence acts not only in relation to the frequency of other 'types' in a population, but also in relation to the environmental niche that an individual inhabits.

Both theories rely on the selective pressures produced by social environments. As the sociality of a species increases, so does the within-species competition for access to resources such as food, shelter, mates, and antipredator defenses. Frequency-dependent selection operates to diversify behavioral traits as a means to decrease the likelihood of such costly competition. Social environments are not consistent, and multiple niche spaces exist within each. Within every niche space, there is a balance among alternative phenotypes under the effect of frequency-dependent selection. Thus, within-species variation in personality is predicted to increase as the species becomes more social with prolonged, repeated interactions among individuals; this prediction of the *sociality hypothesis* has generally held true. Nevertheless, while some evolutionary personality theorists argue that this mechanism operates primarily at the group level by decreasing within-group competition and enhancing success in between-group competition, others argue that it is primarily focused at the individual level of selection, conferring the advantages of competitive release upon individual survival and reproduction.

Frequency-dependent selection for alternative niches requires the presence of *gene-environment correlations*, in which an individual's genotype influences the environments that it inhabits. That is to say, genetically different individuals must identify and exploit alternative social niches in any of the various possible ways. This may be done passively through mechanisms such as random genetic drift, or actively through mechanisms such as *selection* (of a social niche), *evocation*, or *manipulation*. Selection of a social niche means that an individual specifically chooses which environment to occupy.

This may be done through conscious appraisal of one's personal attributes in relation to social activities. Evocation refers to the individual seeking to elicit predictable responses from the environment. Manipulation of an environment allows individuals to create a social space that is more suited to their particular phenotype.

Genetic Diversification

Social organisms are especially well suited to adapt in ways that enhance genetic diversification because of the inherent instability of social niches. Sexual recombination, for example, is a common means of genetic diversification even though this behavior comes at an enormous cost, evolutionarily speaking. Offspring of sexually reproducing species carry only half of the parents' genes. Additionally, an asymmetry exists in parental effort such that one sex bears a disproportional cost of sexual reproduction, which produces a selective pressure against this type of reproduction. Given these costs, evolutionary biology struggled to explain why this phenomenon evolved in the first place, and in doing so has produced several possible explanations. Some argue that sexual reproduction thwarts attacks by pathogens by creating a 'moving target'; while others suggest that recombining genetic material increases resistance to environmental fluctuations in general, including the prevalence of parasites. Sexual recombination has been shown to help remove deleterious mutations that would otherwise 'ratchet up' in an asexually reproducing species.

Disassortative Mating as a Strategy for Genetic Diversification

Life history theory predicts different adaptive strategies depending on the stochastic characteristics of the environment. When the environment is unstable and unpredictable, the sources of morbidity and mortality are consequently uncontrollable. These risks are called *extrinsic* sources of morbidity and mortality, because organisms cannot evolve adaptations to avoid them with genetically influenced developmental processes. Instead, they adopt a *fast life history strategy*, characterized by allocating material and bioenergetic (energy flowing through living systems) resources toward mating effort to maximize the production of offspring. In contrast, when the environment is stable and predictable, and when organisms can minimize *intrinsic* sources of morbidity and mortality with genetically influenced (and thus, evolvable) developmental processes, they adopt a *slow life history strategy*, characterized by the allocation of resources toward somatic growth and parental investment to enhance competitive advantage.

The increased mating effort of fast life history strategists also functions to increase the rate of genetic recombination, through the increased number and diversification of sexual partners and hence of offspring, which could serve to enhance survivability of at least some of the resulting offspring in the unpredictable environment by providing more genetic variation and, presumably, phenotypic variation among them to contend with the fluctuating environment. In contrast, slow life history strategists engage in *positive assortative mating*, as well as *positive assortative sociality*, on genetically influenced traits, thereby preserving locally well-adapted and possibly coadapted genomes,

because stable environments select against high rates of genetic recombination that could otherwise split up these adaptive genetic combinations. As predicted by this theory, recent cross-cultural studies have shown that fast life history strategists do assortatively mate less strongly than do slow life history strategists and that the relationship is consistent across several cultures and across both sexual and social relationships.

Developmental Plasticity

Developmental plasticity describes the permanent behavioral, anatomical, or physiological changes in the developmental trajectory adopted by an organism during the life span, influenced by external environmental factors or other internal physiological factors, and that occurs through gene-environment interactions. Developmental plasticity can be contrasted with behavioral flexibility, which describes the temporary, reversible behavioral changes that can occur throughout the life span.

Gene-environment interactions involve environmentally induced changes in gene expression. This is mechanistically possible because environmental factors (including both the external and internal environment) can lead to biochemical modifications of epigenetic processes that function to activate or suppress the production of proteins. The thresholds for these developmental switches influence responses to environmental cues and are genetic in nature. Thus, natural selection can act to adaptively modulate genetically controlled thresholds for environmental influences.

Human pubertal development is an illustrative example of developmental plasticity. This physiological event results in permanent biological change; however, the age of puberty is plastic and depends on the threshold of a developmental switch. Internal (e.g., body fat composition) and external (e.g., stress) factors alter the neuromodulatory system that controls a specific neurotransmitter network that controls puberty in human females. Onset of puberty depends on ecological conditions, such as resource availability and environmental variability, leading to the suggestion that the threshold sensitivity may have evolved to calibrate physical and reproductive development according to the social and ecological circumstances encountered during development. For example, absence of the father accelerates the onset of puberty in females.

Role specialization may represent an additional example of developmental plasticity in humans, such as in *niche-picking* within families. Empirical tests of the theory of birth order as a determinant of personality have provided some support suggesting that this factor is related to attitudes toward family, friends, and sexual fidelity. Underlying these findings is the theoretical proposition that siblings may adopt specialized roles to obtain adequate parental investment. This model of within-family niches may be expanded to describe society as a whole such that the social niche space may be partitioned to reduce competition and maximize individuals' access to resources. Thus, under conditions of high population density or limited resource availability, a selective premium is placed on the evolution of individual differences in personality.

Populations of organisms are expected to evolve traits that enable them to survive and reproduce in their own unique ecological circumstances. If the environment varies such that organisms are facing unpredictable changes over many generations, an adaptive response to these changes is to evolve a plastic phenotype that enables learning during development so that the organism can detect current, relevant environmental cues and respond accordingly. These cues can be conceptualized as *ecological validity coefficients* that range between 0 and 1 and characterize the predictive validity of ecological cues that signal the presence of particular adaptive problems. When there is moderate variability in conditions, organisms will evolve a combination of genetic diversity and developmental plasticity, allowing them to maximize survival while diversifying to fill available ecological niches.

Behavioral Flexibility

A Taxonomy of Ecological Contexts

True contexts

An *environment* can be defined as the full set of adaptive problems an individual organism of a given species faces throughout development, independent of time. A *context* can be defined as the extant subset of adaptive problems currently facing an individual organism, independent of origin. A *setting* can be defined as the subset of adaptive problems currently facing an individual organism, originating from the extant nonliving environment. A *situation* can be defined as the extant subset of adaptive problems an individual organism currently faces, originating from extant biotic sources. A *between-species situation* can be defined as the subset of adaptive problems the organism currently faces, originating from any physically present species other than that of the individual. A *within-species situation* can be defined as the subset of adaptive problems the organism currently faces, originating from any physically present individual of the same species.

Apparent contexts

An individual, by definition, cannot act on unsensed, or 'unrecognized,' adaptive problems. Hence, following Sir Isaac Newton, we contrast an *apparent context* with a *true context* and attempt to analyze how they might systematically, albeit imperfectly, relate to one another.

Whereas the set of actual extant adaptive problems an individual faces defines a true context, setting, or situation, the set of apperceived and ordered psychological manifestations of extant adaptive problems that an individual faces defines an apparent context. This apperceived set of extant adaptive problems appears to depend on the true context, the experiential history with similar adaptive problems an individual has faced, and the current physiological state of the organism (e.g., food deprived, socially deprived, etc.).

Given that the physical, psychological, and behavioral structure of the organism bears traces of the experiential history of the current organism, we call this apperceived and ordered psychological manifestation of extant adaptive problems the perspective the organism takes on its current context. The perspective is the subjective importance of the extant adaptive problems constituting a full context. The current organism

apparently matches behavior to true adaptive problems by sensing, classifying, and differentially responding to apparent adaptive problems.

Relations between true and apparent contexts

Hence, apparent adaptive problems present themselves to an individual, driven by true setting and situation, filtered through genetically, physiologically, developmentally, and experientially determined schemata. These schemata appear causally prior to adaptive behavioral strategies, which in turn may be thought to guide adaptive behavioral tactics. More completely, a schema is an individual conception of how the world works and one's relation to it. A strategy is how one goes about dealing with the world as conceived through the schema. A rational individual activates appropriate tactics, predicated upon what one perceives to be the objective state of the world and one's place within it, which is constrained by one's schema. Although a schema-driven conception of the world may or may not be objectively correct, it is the schema that should logically predate the strategy, which guides the tactics used to solve extant apparent adaptive problems, which, at least in the ideal, are tightly coupled to extant true adaptive problems.

The causal and statistical relations among the true and apparent context, schemata, strategies, and tactics are, however, not strictly unidirectional. Individuals sometimes find that others place them within a situation, or even within various settings, without that individual's choice and independent of one's schema. In contrast, an individual's behaviors, predicated on one's contextually activated strategies, in turn apparently predicated on one's schema, may bring the individual to a greater-than-average number of situations or settings of a given type. Hence, thinking in terms of unidirectional causality, a given individual's behavior may be causally prior to, at least from one perspective, entering a specific context.

One may characterize contexts, especially within-species situations, along a strong-to-weak dimension: in strong contexts, one must solve apparent adaptive problems immediately and efficiently. In this case, there will be little evidence of stable individual differences in overall behavior (traits); instead, one will observe stable context-specific behavioral patterns. In weak contexts, there are few important extant adaptive problems. In this case, there will be consistent evidence of stable individual differences in overall behavior (traits) and few idiosyncratic context-specific behavioral patterns.

This range appears to be partially due to individual differences in specific and temporally persistent behavioral traits that exist and serve as raw material upon which the law of effect (or any other related law) acts. Behavioral genetics and related fields have discovered many of the laws relating genetic contributions to these traits (and hence to both perspective and discrimination), demonstrating that traits exhibited by the current organism produce a tendency for trait absorption in some contexts, trait rebuffing in others, and, if being rebuffed is not an option, activity to change the true context, apparent context, or both in a way that matches the traits and perspectives of the current organism. These forms of *niche-picking* (including niche-rejection and niche-building) appear, as before, to be a joint product of innate behavioral dispositions, preferences, and abilities, the developmentally and

experientially acquired behaviors of the organism, the current physiological (motivational) state of the organism, and the adaptive problems that it encounters in the environment.

With this in mind, consider within-species situations. Four major categories of within-species situations exist – within-sexual situations composed of the adaptive problems that (1) a male presents to another male and (2) a female presents to another female; and between-sex situations composed of the adaptive problems that (3) a male presents to a female and (4) a female presents to a male. These adaptive problems may be competitive, cooperative, or any combination of the two. The form of the adaptive problems offered by within-species situations will be determined by factors such as the degree of perceived relatedness and the developmental stages of the participants. ‘Recognizing’ and responding appropriately to a situational category is called discrimination. Hence, contextual discrimination sets the stage for the activation of various schema, strategies, and behavioral tactics.

Focusing on behavior, a given tactic within any given context may produce conflicting outcomes. For example, certain behaviors within the confines of a within-sexual situation involving two males may reap consequential immediate costs but simultaneously reap consequential benefits in an encompassing within-species situation (e.g., injurious fighting may produce reproductive gains). Conversely, certain behaviors within the confines of, for example, a between-sex situation may reap consequential immediate benefits but simultaneously reap consequential costs in an encompassing context (e.g., immediate sexual activity produces immediate gains but consequential opportunity costs in the long term). Those contexts that involve short-term gains but substantial long-term costs are labeled *contingency traps* and those contexts that involve short-term costs but long-term gains *contingency augmentations*.

Conclusion: An Integrated Overview

The evolution and development of individual differences in personality among human and nonhuman animals therefore depend upon not one but multiple selective pressures, some acting in concert, and others in partial opposition to each other. The ecological conditions prevailing at any given time determine which one of these selective pressures may be more or less influential. Thus, the evolution of individuality in behavioral dispositions cannot be ascribed to any simple, single causal factor.

Directional social selection favors the profile of personality traits that best enhance the prospects for mutually beneficial cooperative interactions within social groups; disruptive social selection favors divergent, frequency-dependent phenotypic variations that provide the most release from within-species competition from other individuals; genetic diversification of offspring can be adaptively upregulated or downregulated in response to the stochastic characteristics of environmental hazards of morbidity and mortality by manipulating the extent of sexual recombination of genetic material achieved through differential degrees of assortative mating and assortative sociality for genetic similarity, as indicated by shared heritable phenotypic traits; developmental plasticity epigenetically directs development adaptively along different alternative pathways,

depending on critical cues signaling relatively enduring states of the environment, presenting differing adaptive problems, and modifies permanent and stable behavioral dispositions to suit these long-term contingencies of survival and reproduction; behavioral flexibility permits the deployment of rapid and reversible short-term adaptive behavioral responses to different classes of transient situations, each presenting its own suite of unique adaptive problems.

These are *not* alternative hypotheses from which we may endeavor to select the one true causal influence shaping the evolution of individual differences in personality. They are all evolutionary mechanisms that demonstrably operate simultaneously, each exerting its own characteristic influence upon personality variation, and both the central tendencies and the dispersions of the behavioral dispositions that have been observed both between and within individuals are the joint product of their synergistic interactions.

Glossary

Adaptation A feature of an organism's phenotype, sculpted by the process of natural selection, that performs a function that solved a problem of survival or reproduction in a species' evolutionary history.

Environment of evolutionary adaptedness The set of features of the environment (physical, social, etc.) that generated selection pressures that caused the particular design of a given adaptation.

Modularity The degree to which an information-processing system consists of specialized computational mechanisms.

Natural selection The process by which some genes are retained in a population relative to others by virtue of genes' different causal effects on their own rate of replication, leading to gradual changes in the traits of that population. The only process by which functionally complex traits arise.

Phenotype The physical characteristics of an organism. Its physical traits, as opposed to its genotype, which is the set of genes the organism possesses.

Evolutionary psychology (EP) is an approach to understanding and explaining behavior, especially human behavior. It rests on the foundations of evolutionary biology and cognitive science and has been applied to research questions across the behavioral sciences.

Principles of EP

The assumptions and logic that underpin EP begin with the basic principles of physics. Because the laws of thermodynamics dictate that matter becomes less ordered over time, configurations of matter that show order – as all biological systems do – can only be explained with the single known natural causal principle that gives rise to increasing rather than decreasing order: evolution by natural selection. Even 'simple' life forms such as viruses represent wildly improbable arrangements of atoms and molecules which, absent natural selection, would never exist. For this reason, all such arrangements of matter require explanation beyond the causal principles of physics and chemistry.

Darwin's theory of evolution by natural selection, combined with recent refinements, provides this causal explanation. Once there were entities that caused near-copies of their physical arrangements to come into existence, the ingredients of selection were present. Modern biological forms are descended from those organisms whose physical properties caused the propagation of the information that gave rise to them. The properties of the human mind, whose order represents perhaps the single greatest departure from randomness in the entire corpus of human knowledge, will ultimately need to be explained in terms of evolution.

While the social sciences have historically been – and to a substantial extent continue to be – indifferent to the idea that the phenomenon under study requires an explanation in these terms, EP begins with this idea, and in this sense can be understood as making explicit what is left implicit in other areas of psychology. For example, the precise, systematic, and useful changes to neural tissue that occur in response to information taken in from the environment – that is, 'learning' – are

prototypical departures from disorder which demand an explanation in terms of natural selection. While some have suggested that 'learning' is an alternative to evolutionary explanation, learning is the prototypical phenomenon that requires an evolutionary explanation.

Biological Function

Useful information is preserved in genes by virtue of the genes' contributions, however indirectly, to their own replication. The specific ways in which such contributions are made varies from organism to organism and from trait to trait. Genes, in concert with other genes and the environment (broadly construed) give rise to the organisms' features. The way in which the action of genes contributes to their own replication gives rise to the biological concept of 'function.' The function of a spider's web is to catch flies in the sense that its insect-catching properties – tensile strength, elasticity, bonding properties, etc. – led to the differential success of the genes causally relevant to these properties.

This idea allows a principled way to divide up the phenotypic properties of organisms, with respect to the way they are organized to execute functions in this sense. The anti-entropic process of selection occurs by virtue of the feedback between genes' effects on the world and their own replication rate. This is why organisms have features that are exquisitely well engineered to accomplish goals relevant to survival and reproduction. The engineering has been done by the process of natural selection, with modifications to the existing organization of the organism tested, tried, and sieved over generations.

In the case of the human mind, the way that nervous tissue is organized to contribute to function is by virtue of the way that it processes information. In this sense, EP merges the adaptationist program with cognitive science, locating design in the computational properties of the mind. Natural selection acted on the relationship between various computational mechanisms that developed in concert with the environment in the brains of our ancestors and the reproductive consequences of these mechanisms. The properties of these mechanisms – how they acquired information, changed in response to

this information, and structured behavior contingent on information – caused the underlying genes that gave rise to them to change in frequency by virtue of reproductive outcomes.

To evolve by the process of natural selection, then, computational mechanisms had to discharge adaptively relevant functions. These functions range from low-level perception, including the construction of a rich visual representation from sense data, to high level, including emotional systems, which dynamically activate and deactivate suites of computational mechanisms designed to cope with particular adaptive problems. Importantly, many computational devices gain advantage by virtue of adaptive flexibility, causing behavior that is contingent on local circumstances, recent, and distant history, and the individual's current state.

The central motivating question in EP is to describe the computational mechanisms of the mind.

The Environment of Evolutionary Adaptedness

The complex functional traits of organisms – adaptations – have their properties by virtue of the way their features interacted with the environment of the organism. For instance, because of the specific wavelengths of electromagnetic radiation at the surface of the Earth, photoreceptors are sensitive to particular frequencies of light. Adaptations reflect features of the environment because selection favors designs that successfully exploit the world as faced by the organism.

The set of features of the environment that existed over the course of many generations that were relevant to the function of a particular adaptation is frequently referred to as the 'environment of evolutionary adaptedness' (EEA). Rather than being a specific time or place, the EEA is a collection of properties relevant to a specific adaptation. Different adaptations, then, have different EEA's.

The composition of the EEA of an adaptation is potentially very broad, and can include any feature of the environment that was repeatedly present over the course of a species' evolutionary history and had an effect on selection. The EEA of an adaptation can encompass a wide array of properties. Physical properties, such as light, gravity, and temperature have obvious relevance to traits such as photoreceptors, balance systems, fur, and so on. There are also features of the social world that recur sufficiently frequently that adaptations are sculpted around them, such as, in humans, the presence of kin, allies, potential mates, and so on.

The EEA of adaptations depends exquisitely on how the organism survives and reproduces. Hawks' excellent visual acuity, for example, is causally related to their natural history as a high-flying predator. Adaptations reflect the features of their environment, including the physical world, the social world, and, crucially, other properties of the organism.

Currently, human environments differ in significant ways from the environments that human ancestors inhabited. Population densities are greater, food is in greater supply, technology has provided any number of new tools, and so on. Because adaptations were designed to function in ancestral environments, these environmental differences can have important effects on how they operate. For example, in the past, animal fats were not as readily available as they are today; the evolved appetite for fats – which would have led to good nutritional

outcomes in the past – leads to negative health outcomes in modern environments because of the modern abundance of high fat foods.

However, many features of the world are very much like they were in past environments. The physical properties of the world, including gravity, light, and so on, are more or less the same. The social world similarly has many properties in common with past social world, including phenomena such as kinship, friendship, membership in groups, locally relevant accumulated knowledge, and so on.

Specialization

By virtue of the competitive nature of natural selection, organisms come to have properties that more efficiently and effectively solve adaptive problems relative to alternatives. This makes the criterion by which selection acts fundamentally a matter of engineering.

Physical mechanisms' effectiveness depends on their physical properties: their structure, form, and shape. This idea was a big clue in Darwin's discovery of the principle of natural selection. The beaks of the finches on different Galápagos islands have different forms depending on the foraging problem posed by the environment because different beak shapes are best for solving different mechanical problems.

Selection drives morphological form toward greater specialized functionality. This is the case at every level of description, from cells to tissues to organs. Because of the relentless pressure of selection, better-engineered designs will tend to out-compete poorer designs. Organisms' features, therefore, reflect the principles of engineering. In particular, any given form which solves some problem or problems effectively necessarily cannot solve others: a short, stout beak, good for cracking open nuts with thick shells, is necessarily poor for reaching nuts or seeds at the ends of long, narrow tubes. For this reason, the parts of an organism tend to reflect the engineering advantages of specialization. In turn, as the parts of an organism become specialized to execute their function, they necessarily trade off the ability to execute other functions. A neuron can effectively transmit information, but cannot efficiently store calories, as a fat cell can.

The advantages to specialization inherent in engineering explains why selection, which is sensitive to even small advantages in function, tends to yield specialized structures at all levels. Functional specialization is, for this reason, the hallmark of evolution.

Modularity

Information-processing problems obey the same logic as physical problems. The particular procedures that must be applied to information to generate adaptive responses depend on the adaptive domain in question. This is why photoreceptors are designed to respond to light while hair cells in the ear respond to changes in air pressure. The differences in the transformations that must be computed depend on the function. The same logic applies to other information-processing problems. A computational device that is well designed to process information from the visual world needs to have procedures different from a device designed to process information in the auditory domain.

In the same way that natural selection sifts mutations for improvements to the forms of the organisms' parts, it also sifts for improvements to the computations that execute information-processing functions across the large number of computational tasks the mind executes. Specificity of function in information-processing yields benefits in terms of the efficiency and efficacy in solving adaptive information-processing problems, giving rise to specialization in cognitive function. This is the case for low-level cognitive functions, such as vision, and high-level cognitive functions, such as the mechanisms that underlie social behavior, such as friendship or kin-directed altruism.

Such specialization is obvious among nonhumans. Adaptive cognitive specialization has been well established for such tasks as food caching, navigation, and predator evasion.

Because organisms need to solve many different computational problems, the organisms' brains consist of a large number of specialized information-processing mechanisms. Bundled together, and deployed appropriately in the organism's context, specialized devices together solve adaptive problems effectively.

Many evolutionary psychologists refer to the specialization in function among computational devices as 'modularity.' This term is not used to connote the idea that particular functions are spatially localized in the brain's neural tissue – though it does not exclude this as a logical possibility. Instead, it refers to the idea that the mind's computational mechanisms have describable and empirically discernable functions. This view includes the notion that modules can be composed of sub-modules, and the procedures of some modules might be shared by superordinate modules.

The modular cognitive architecture postulated by evolutionary psychologists shares the advantages enjoyed by modular artificial computational systems. Modularity allows specialization – subroutines can be designed around particular, narrow tasks. This allows information processing to be efficient because the specific procedures required to solve a problem can be deployed for that particular problem.

Second, modularity, because it allows procedures to be used and combined in many ways, allows flexibility. Functionally-specialized menu-driven functions in computer applications provide a useful analogy. The large number of procedures included in modern word-processing software allows users tremendous flexibility in the content and layout of documents. As minds – humans or otherwise – come to include more procedures, these can be deployed in conjunction with others in ways that allow increasing flexibility by virtue of the combination of the functions of the various subroutines.

Similarly, modularity facilitates learning, as incoming information can be used to update variables and procedures in a systematic and useful way. How incoming information should be used depends a great deal on the domain in question. By routing information to a particular subroutine, appropriate information can be extracted, stored, or discarded, as appropriate for the task the module executes. For example, while the meaning of new words needs to be stored, the episodic details of the learning episode need to be discarded. Language learners need to retain what the word 'cow' refers to, but not the circumstances surrounding the acquisition of the meaning of the term.

Finally, modularity – both natural and artificial – allows for changes to be made in one subroutine without affecting many

different processes simultaneously. Such an architecture has an advantage because the odds of a change in one system being useful is vastly larger than the odds of a change that affects multiple systems being advantageous across all of the relevant systems.

Possible Functions

A gene that increases its own rate of replication in one environment relative to an alternative allele will not necessarily do so in another environment. So, to the extent that organisms' environments change in ways that are relevant to different alleles' rates of replication, and the relative advantage genes have over one another varies from one generation to the next, selection might not repeatedly lead to the gradual replacement of one particular allele over others because of fluctuations in the feedback loop on genes' replication.

Selection, therefore, will only lead to the accumulation of genes that fit well, in this sense, with features of the environment that are sufficiently stable to lead to the continuous upward pressure on a gene's frequency. Absent such stability, the process of natural selection will not lead to the accumulation of genes that give rise to functional elements of the organism's phenotype.

So, the only functional organization that will be observed are developmental programs that are well designed to solve adaptive problems faced by a given species' ancestors. Because natural selection is a slow and gradual process that stretches over long periods of time, the human mind consists of developmental programs that aided survival and reproduction in the past. The search for the mind's computational architecture, including the way it changes over the lifespan and in response to information in the environment, according to EP, is the search for information-processing devices that would have solved our ancestor's problems of survival and reproduction.

This view constrains hypothesis generation. The only plausible functions that EP allows are those that would have contributed to our ancestors' reproductive success. Problems that are very recent, such as the problem of over-eating by virtue of an abundant, low-cost food supply, have not been present for a sufficiently large number of generations to allow large numbers of genes to have been selected to give rise to complex, functional arrangements of the human nervous system designed to solve these and similarly recent problems.

Although the genes currently part of the human genome were selected in the past, humans can do many things that our ancestors could not. Every organism is facing an environment that is different, in certain respects, from its ancestors' environment. For example, predator-evasion mechanisms were selected by virtue of these mechanisms' value in causing potential prey to avoid and escape particular predators in the past. Those particular predators are gone, but new instances of them appear in the prey organisms' environments. Although each sea lion, in particular, is one that has not itself tested penguin predator-evasion genes, penguin minds nonetheless direct them away from these novel predators.

In the same way, the human mind interacts with many novel features of the environment. Each face is one that has never before existed, but can be parsed, stored, and recalled with mechanisms designed to do so.

Levels of Explanation

EP seeks to explain behavior at multiple levels of analysis and draws to a substantial extent on the way that researchers such as ethologist Niko Tinbergen have divided up the questions that can be asked to have a complete explanation of behavior. (Note that different research traditions cleave these levels slightly differently.)

1. *Function*: What is the mechanism that gives rise to the behavior in question designed to do so? How did the mechanism in question contribute to survival and reproduction? What was the goal of the mechanism?
2. *Computation*: What are the computations performed by the mechanism? What does the mechanism take as input, what does it generate as output, and how does it transform one to the other?
3. *Implementation*: How are the computations in (2) physically implemented? What neural systems are involved, and how do they give rise to these computations?

These three levels of explanation are not mutually exclusive, but rather mutually informative in both directions. For example, hypotheses about the function of a mechanism give rise to hypotheses about the computations necessary to execute that function. Similarly, knowing what computations a mechanism embodies gives clues about that mechanism's function. Similar logic applies with respect to neural implementation.

Consider a simple mechanism such as a typical thermostat. The function of a thermostat is to regulate temperature (Level 1), and this function explains why it has its particular form and why it carries out the computations that its form embodies. In particular, it performs its function by detecting the surrounding temperature, comparing this to the user's setting, and then causing a heater or air conditioner to turn on or off depending on this comparison (Level 2). These computations are implemented through a small number of parts. One is a mechanism that changes shape depending on the temperature, often a metallic strip that winds or unwinds depending on the surrounding temperature. The movement of this strip causes a mercury switch to move in such a way so as to cause current to flow to the correct circuit, either the circuit going to the air conditioner or the one going to the heater (Level 3).

The emphasis on adaptive function as a source for hypotheses distinguishes EP from other branches of psychology. Research in EP generally considers a hypothesis about a mechanism to be incomplete without some plausible explanation that relates its computational properties to an evolved function.

Researchers in EP often, but not always, begin investigations with an idea about the function of a putative mechanism. These ideas inform the generation of hypotheses about the computational systems that would, in principle, be able to accomplish the putative function. Using the usual techniques available to social scientists (see below), evolutionary psychologists study and measure behavior to evaluate candidate hypotheses about the details of the underlying computations. Such hypotheses are constrained by the functional level of analysis.

Development

EP takes a view of development that is like the view of development found in biology, an explicitly and fundamentally interactionist position, that every aspect of every organism's phenotype is the result of the interaction between the genes and the environment. On this view, genes, in concert with other genes, and the large number of relevant aspects of the organism's environment – chemical, physical, social, etc. – mutually and jointly codetermine the developmental trajectory of the organism.

This view of development fits naturally within the framework of EP because genes act dynamically, during the lifespan, over shorter or longer intervals. Selection, therefore, can be viewed as favoring genes not by virtue of a direct link between a gene and an adult, static phenotype, but rather by virtue of the relationship between a gene and the environment in which it has existed and the changes, in concert with the environment, that it brings about.

In addition, practitioners in the field draw heavily on life history theory. Because the effect that particular traits will have depends on key life history variables – sex, point in reproductive career, size, and so on – genes that influence traits in such a way that they are deployed dynamically and adaptively depending on these variables will tend to have an advantage. The onset of sexual maturation, for example, varies substantially across humans, and research in EP is aimed at understanding what features of the individuals' environments or state might calibrate these maturational mechanisms. For example, recent research suggests that a social factor – the presence or absence of a male parent – influences this developmental program.

For evolutionary psychologists, development includes learning, the particular ways in which incoming information is processed, leading to useful changes in the organization of the mind. A key element of the way research on learning is conducted from an evolutionary perspective mirrors the way it is conducted in biology: different mechanisms underlie different domains. In the same way that jays can store and recall the location of thousands of food caches, requiring dedicated mechanisms to accomplish this feat, human minds have been widely viewed, particularly since Chomsky's famous analysis, as requiring specific learning mechanisms to acquire natural language. Other domains of learning, such as faces, similarly seem to have their own developmental system.

The details of the different learning systems for other domains are a source of ongoing research. Some evolutionary psychologists are exploring the way certain facets of cultural information, such as religious ideas, are generated, stored, and transmitted by human minds. By understanding the functions of learning systems, evolutionary psychologists contribute to the understanding of the details and texture of local, population-specific artifacts, ideas and accumulated knowledge, or 'culture.'

Possibly because evolutionary psychologists believe that genes are, in addition to the environment, a critical causal force in development, researchers in this tradition are sometimes mistakenly taken to assume that genes are the only crucial causal force in development. However, EP does not hold that any feature of the mind is 'innate' in the sense that

it develops independent of the environment. Evolutionary approaches do, however, hold that certain traits tend to develop in similar and reliable fashion, given relatively broad regularities in the developing person's environment. In the same way that every normal human begins as a cell and comes to have four limbs, certain features of the cognitive architecture tend, with appropriate nutrition and input from the (social) world, similarly tend to develop reliably. This occurs by virtue of selection acting on genes that cause these developmental trajectories, preserving those genes that, in normal environments, lead to these (adaptive) outcomes.

Research in EP

EP crosscuts traditional subdisciplinary boundaries, and the approach is applied to areas such as decision-making, development, economics, language, perception, social life, and so on. Researchers in EP, therefore, use methods that vary, making use of the techniques that are most useful given their particular domain of study.

Independent of the domain of study, however, research in EP is not qualitatively different from research in other areas. The same commitment to hypothesis testing, falsification, quantification, and the other details of how science is currently practiced is found in EP.

There are, however, a small number of differences between EP and practices in other areas. Because most branches of the social sciences do not engage with the notion of evolved function, evolutionary psychologists are more constrained in their hypothesis space than are their colleagues in the social sciences, who omit this analysis. This difference explains why the style of explanation for the same phenomenon is often very different in standard social science and evolutionary social science. While standard social science explanations tend to begin with constructs such as 'expected utility' or 'self-esteem,' evolutionary explanations tend to begin with the notion of a goal or a target with implications for survival and successful reproduction.

Standards of Evidence

A difference between EP and subbranches of the social sciences is that evolutionary psychologists develop hypotheses about *function*. In terms of the epistemic commitments of the field in evaluating the evidence for a given function, the field follows the practices used in evolutionary biology as famously laid out in George Williams' seminal work, *Adaptation, and Natural Selection*.

Williams' focal argument is that arrangements of matter that are improbably well organized to bring about beneficial outcomes (with respect to fitness) can have only natural selection as their causal antecedent. This gives guidance in evaluating hypotheses about evolved function. In particular, any given hypothesis about the function of some aspect of an organism's phenotype is supported by evidence that the phenotype has properties that make it particularly – and improbably – useful for executing the function.

In this sense, Williams' analysis is no different from the intuitive analysis that people bring to bear in evaluating

artifacts. A thermostat is recognizable as an artifact designed to maintain the temperature in a room because its properties can be seen to be designed around this function.

Biological forms can be similarly analyzed in the service of distinguishing among putative functional explanations. The eye is frequently used as an example. Of the tremendously large number of forms that cells and tissues can take, the transparency of the lens and the receptivity of the retina to light make it surpassingly unlikely that these structures came about by any process other than selection for the conversion of light from the environment into a representation of the physical world which can be used to guide behavior.

Because we know what nervous tissue is for – processing information and producing useful behavior – it is possible to evaluate the function of the mind's components in the same way. By observing behavior, inferences are possible about the computational mechanisms that give rise to it. By documenting the nature of these mechanisms, putative evolved functions of these component mechanisms can be systematically evaluated.

Just like the transparent lens of the eye – whose soft tissues left no fossil remains – behavior can be evaluated within the framework of adaptationism because of the relationship between complex functional features of the organism and natural selection. Improbably useful computational mechanisms for a particular function lend weight to an explanation in terms of that function in a way that mirrors the improbably useful arrangement of matter that constitutes the eye.

Hypotheses in EP are not about the history of the mechanism in question. To say that the eye is for seeing – that this is its function – is not to commit oneself to any specific hypothesis about the evolutionary history of the eye outside the claim that the current structure of the eye can be understood – and is explained – by virtue of its function of seeing. Hypotheses in EP are about the computational mechanisms of the mind – about cognitive architecture – just like hypotheses in physiology are about the mechanisms of the body, and the same evidentiary criteria apply.

Hypotheses about evolved function are similarly not about how traits contribute to reproductive success in modern environments.

Connections to Other Fields

The principles of EP can be applied to any discipline that studies behavior. For example, economists study human behavior in the context of the exchange of goods and services, as well as other behaviors that fall under the aegis of the discipline as currently constituted. The cognitive mechanisms that give rise to economic transactions are no more or less the product of evolution by natural selection than other mechanisms of the mind, and are therefore just as amenable to the adaptationist analysis developed by evolutionary psychologists.

The same argument holds for the subdisciplines of psychology – cultural, developmental, clinical, etc. – and the other disciplines neighboring psychology that take human behavior and its consequences as the objects of its study, such as anthropology, political science, and sociology.

EP is related to, but distinct from, the field of behavior genetics. Researchers in behavior genetics are interested in the

role that genes play in the development of behavioral traits, and frequently are interested in the heritability of such traits, the extent to which differences among individuals in a particular population are due to differences in the genetic endowment among those individuals compared to differences in those individuals' developmental environments. While evolutionary psychologists are also interested in variation among individuals and the origin of this variation, individual differences are frequently used as a window to help understand how mechanisms are designed to change in functional ways depending on the environment. For example, calluses form as a result of continual friction or pressure on the skin. They reflect the operation of a mechanism designed to protect the skin in the particular areas which are subject to repeated insult. Variation among individuals reflects the operation of a mechanism shared in common across the human species, leading to differences in the phenotype by virtue of the different activities in which individuals engage.

The same is true of computational mechanisms. While every normally developing human has a mechanism that is capable of acquiring language, the details of the developmental environment in which someone grows up will determine which particular language is learned. The language-learning system, like the callus-production system, is designed to lead to a different phenotype depending on the environment in which the organism finds itself.

Controversies in EP

In *The Blind Watchmaker*, Richard Dawkins wrote, "I suppose one trouble with Darwinism is that, as Jacques Monod perceptively remarked, everybody thinks he understands it" (p. xv). A similar remark could be made about EP. The field has been criticized harshly by members of the scholarly community and the lay public. However, while there are of course many issues that are controversial and many active debates in and around the discipline, substantial amounts of controversy surrounding the field are illusory rather than substantive.

Genetic Determinism

Many critics of EP argue that the environment is crucial for understanding human behavior, and that EP ignores this fact. Along similar lines, critics have argued that the brain is flexible, rather than 'hard wired.' However, the evolutionary view holds that every aspect of the phenotype is jointly caused by genes and the environment and that selection will act to give rise to developmental mechanisms that respond contingently and adaptively to the environment. This criticism, therefore, is directed at a position not held by mainstream practitioners in the discipline.

Unfalsifiable Hypotheses

Critics of EP have charged that EP consists of unfalsifiable hypotheses, and so is unscientific. As indicated above, EP follows the usual standards of scientific practice. One source of confusion might have to do with the nature of hypotheses in EP. Critics frequently make the argument that hypotheses

about a particular evolutionary history cannot be falsified or verified because there is no fossil evidence of behavior. Independent of the question of whether one can generate evidence regarding the evolutionary history of computational devices, this argument proceeds from the false premise that hypotheses in EP are about history, rather than design.

Adaptation and Optimality

In some critiques of the field, it has been argued that it is important to realize that evolution gives rise not only to adaptations, but also byproducts – that is, aspects of the phenotype that do not themselves have a function but are simply side-effects of the functional parts of the phenotype. An example of a byproduct is the color of the liver: its hue does not contribute at all to its function, and is merely a side-effect. The argument is that not all aspects of the phenotype, including the computations carried out by the brain, are functional.

This critique represents a correct description of the way that evolution by natural selection operates – it is inevitable that any device that has a function will have properties that do not themselves contribute to that device's function. However, this idea is a crucial component of the discipline. Following George Williams (see above), evolutionary psychologists assume that there are large numbers of byproducts, and take the claim that some mechanism is an adaptation to be a strong claim, requiring design evidence.

A related critique focuses on the fact that evolution does not yield designs that are optimal, perfectly sculpted to execute particular functions. This is indeed the case for well known reasons, such as the possibilities of local fitness maxima, historical and developmental constraints, engineering tradeoffs, rapidly changing environments, continuous mutation pressure, and so on. Evolutionary psychologists do not claim that designs are optimal for such reasons.

Finally, some have critiqued EP by observing that adaptation by natural selection is not the only source of genetic change over time. For example, there is also a genetic drift, a process by which some genes increase or decrease in frequency by virtue of random processes as opposed to the differential retention of alleles by virtue of the effect on reproductive success. While genetic drift can lead to changes in gene frequencies, this process does not cause increasingly functional aspects of the phenotype to arise. Because evolutionary psychologists are interested in the functional architecture of the mind, processes that do not have a causal influence on the object of their study are ignored. Researchers in EP do not often consider genetic drift for this reason.

Modularity

Some critics have taken issue with the idea of modularity, a key element of the discipline as practiced by a number of researchers. The criticism is frequently made that the observation of the many ways in which the human mind shows flexibility undermines the notion of modularity. These criticisms derive from a misunderstanding of the word 'modular.' Critics take the word to mean something like solid blocks or slabs, as if the metaphor were taken from architecture, whereas the term is used in the literature in the field to mean that the mind consists of a

large number of functionally specialized computational mechanisms, in a way that mirrors the use of the term in computer science.

More generally, having a large number of specialized information-processing mechanisms increases, rather than decreases flexibility. This is seen most easily by analogy with modern software. When word-processing programs have more features included, this makes them able to do a larger number of tasks, not a smaller number of tasks.

The debate surrounding modularity, though often derailed because of confusion over the meaning of the term, masks a genuine point of debate. The precise function of any given psychological mechanisms is of course an empirical matter. A good example is the debate in face-recognition: is the mechanism that executes this function designed for faces, in particular, or a larger class of stimuli? Careful experiments have converged on a close specification of the function of this system.

Ongoing research will be needed to identify the functions and computations of the modules of the human mind, a central component of the agenda of EP.

Glossary

Domain specificity A theoretical position that presumes that people have evolved separate specialized mechanisms to help them solve different recurring problems, such as how to get a mate or protect oneself from physical harm.

Environment of evolutionary adaptedness (EEA) In evolutionary theory, it is the environment in which the brain evolved. There may be different EEAs for different adaptations.

Inclusive fitness The survival of one's genes in one's own offspring and in any relatives one helps.

Life history theory A theory that suggests that organisms adaptively engage in different behaviors and hold different goals depending on key maturational and

productive characteristics, such as age and reproductive potential.

Natural selection The process by which characteristics that help animals survive and reproduce are passed on to their offspring.

Parental investment Any energy, time, or resource expenditure by the parent for its offspring. Parental investment theory says that the more investing sex (in mammals, this is usually the female) will be the choosier sex in terms of who to mate with. The other sex must then compete for mating opportunities with the choosy sex.

Sexual selection A form of natural selection favoring characteristics that assist animals in attracting mates or in competing with members of their own sex.

Evolutionary Social Psychology

Evolutionary social psychology is based on a straightforward premise: people's interactions with one another are influenced by mental and emotional mechanisms shaped by natural selection. From this perspective, people's thoughts, feelings, and behaviors toward their families, friends, and enemies can be better understood by considering what biologists have learned about other animals and what anthropologists have learned about people in other societies. In a classic example of this approach, Charles Darwin suggested in 1872 that emotional expressions served an adaptive function – to communicate one person's motivations and intentions to others. For example, expressing anger can decrease the odds of a physical conflict, while smiling can increase the odds of cooperation. Along with physical features such as upright stance and opposable thumbs, evolutionary theorists assume humans inherit brains equipped with mechanisms for managing movement through both the physical world (e.g., seeing in color, discriminating sugars from poisonous alkaloids) and the social world (e.g., speaking languages, bonding between mother and infant).

From an evolutionary perspective, all recurrent human social behaviors reflect the influence of physical and psychological predispositions that helped our ancestors survive and reproduce. This is not to say that every individual social behavior is successful in promoting survival and reproduction, and it does not necessarily imply that people (or other social animals) consciously think about survival and reproduction. It does imply, however, that any social animal's brain is composed, in part, of mechanisms that helped its ancestors succeed in interactions with other members of its species. Thus, humans' reactions to other humans are presumed to reflect the influence of mechanisms shaped to solve the kinds of problems and opportunities our ancestors regularly encountered. Human behaviors are not presumed

to be robotically determined by instinctive mechanisms over which we have no conscious control or which are impervious to environmental inputs. People can and often do exercise control over powerful and fundamental emotional and motivational inclinations, including anger, fear, and sexual arousal. Furthermore, most mental mechanisms reflect the operation of flexible trade-offs, determined in interaction with current environmental conditions and past learning experiences. Although flexible, the influences of evolved predispositions (such as hunger, thirst, sexual arousal, and anger) are nevertheless powerful vectors in our decision making.

To understand the importance of evolved mental mechanisms, it helps to step back from our own species and consider the interaction between other animals' bodily features and their environments. Orca whales, for example, though related to cows, would not do well with a cow's brain, since an Orca's brain must control a body that tracks prey in the ocean rather than eating grass in a meadow. Likewise, bats, though also mammals, need brains designed to run tiny bodies that fly around catching insects at high speeds in the dark. Because all organisms' brains are composed of mechanisms evolved to deal with recurrent environmental threats and opportunities, evolutionary theorists ask: What are the implications of human evolutionary history (e.g., living in omnivorous and hierarchical primate groups populated by kin) for the design of the human mind? Evolutionary social psychologists focus on the subset of questions dealing with recurrent social conditions of human life, and their hypotheses reflect anthropological data about social interactions common in societies around the world (e.g., close relationships with family, dominance hierarchies, long-term bonds between parents, common dangers from other groups competing for resources and territory, etc.), as well as general principles derived from placing humans in the context of other species confronting diverse adaptive problems.

Multiple Levels of Causal Analysis

Biological theorists have stressed the importance of differentiating between causal explanations of behavior involving evolutionary history, adaptive function, ontogenetic development, and proximate determinants. For example, consider the question of why human mothers nurse their offspring. This can be addressed at four different levels of analysis. (1) *Historical* explanations consider *ancestral roots* of behaviors. Researchers adopting a historical perspective might consider human nursing in the comparative context of other animal species. Unlike human language, nursing capacity does not pose much of a historical puzzle, since all primate females nurse their offspring, as indeed do all mammals. (2) *Functional* explanations, on the other hand, are concerned with ultimate *adaptive purposes* of behaviors. A functional explanation might suggest that mothers nurse offspring because it increases offspring survival rates. (3) *Developmental* explanations are concerned with *lifespan-specific inputs* that sensitize the organism to particular cues. A developmental explanation might suggest that mothers nurse offspring because pregnancy and childbirth trigger puberty-dependent shifts in hormones and milk production in mammalian females. (4) *Proximate* explanations focus on *immediate triggers* for particular behaviors. A proximate explanation might suggest that nursing occurs because an infant has begun suckling on the female's nipple, which leads to immediate hormonal changes inside the mother which stimulate milk release.

Sometimes, there are obvious connections between the different levels of analysis. In the case of nursing, developmental changes in lactation capacity accompany other changes during pregnancy; the infant, who receives obvious functional benefits from nursing, triggers the proximate release of milk. But connections between different levels of analysis are not always obvious. Consider why birds migrate each year. A proximate explanation is that birds migrate because days are getting shorter – the immediate cue triggering migration. The functional reason for such migration, however, is survival and reproduction: the distribution of desirable food and mating sites varies seasonally. There are two key implications here: (1) animals, including humans, need not be consciously aware of the ultimate functions of their behaviors and (2) the connection between long-term goals and immediate goals is often indirect and unobvious.

An explanation at one level of analysis must be compatible with explanations at other levels. Positing a proximate or developmental mechanism that reliably leads people to make functionally maladaptive decisions (such as Freud's death instinct) is problematic. Evolutionary psychologists typically advance hypotheses about links between proximate mechanisms and adaptive function, not about the historical roots of the mechanism. In deriving those hypotheses, however, psychologists adopting an evolutionary perspective attempt to take into account pertinent findings from evolutionary biology and/or anthropology. Psychologists can derive hypotheses about proximate causes and development without thinking in evolutionary terms, but disregarding evidence and theory derived from research on other cultures and other species can lead to hypotheses incompatible with other levels of analysis.

For example, psychologists during the last century often assumed most sex differences in social behavior (such as differences in violent aggression) were products of 'American culture,' being unaware that similar differences were found in other cultures, and even other species.

Historical Background of Evolutionary Social Psychology

The evolutionary perspective on human social behavior represents the convergence of several streams of influence. One contribution came from the field of ethology – the study of the behavior of animals in their natural habitats. In 1973, three European ethologists (Niko Tinbergen, Karl Von Frisch, and Konrad Lorenz) were awarded a Nobel Prize for their work on the adaptive significance of animal behaviors. Tinbergen studied how stickleback fish respond with complex behavioral displays to other sticklebacks (e.g., males demonstrate an aggressive display on seeing a red underbelly on another male, and the mechanism can be tricked by using 'supernormal stimuli' – fishlike shapes with bright red paint on the underside). Von Frisch demonstrated that bees engage in complex communications – informing other colony members about the location of nectar-bearing flowers. Lorenz conducted research on imprinting, the process by which young geese became attached to their mothers. Each of these lines of research demonstrated an interaction between an innate mechanism and inputs from the social environment.

In humans, language seemed a beautiful example of instinctive preparedness interacting flexibly with environmental inputs. Comparative linguists had uncovered evidence that languages the world over have a similar underlying grammatical structure, developmental psychologists found that children make similar linguistic mistakes, regardless of the language they are learning, and the languages spoken by adults everywhere were found to be equally complex, regardless of the speaker's education level. Paralleling Lorenz's work on animal imprinting, developmental psychologists had found that young children go through predictable phases in their relationships with parents and strangers (such as a fear of strangers that peaks around 9 months) and that infants engage in complex nonverbal mimicry of their mothers. Paralleling Tinbergen's research on fixed action patterns in sticklebacks, research uncovered a sequence of nonverbal flirtation gestures in societies around the world and revealed that children born blind and deaf, nevertheless, demonstrated appropriate facial expressions in appropriate contexts (smiling when tickled, for example).

The ethologists' research made it clear that much so-called instinctive behavior (such as imprinting) involved what biologist Ernst Mayr called 'open instincts' – innate proclivities requiring environmental inputs to be fully operative. Although a fixed sequence of movements is fine for mating rituals, some innate predispositions require flexibility to be useful. For example, animals need a rapid response system for avoiding other dangerous animals and poisonous foods, but exactly which other species in the local environs pose threats is often quite variable over the range in which they might be born

(consider young English sparrows which, like humans, may be born in deserts, forests, farmlands, or cities on several continents). Hence, those avoidance systems need to be calibrated to reflect local threats.

Psychologists studying learning in the laboratory had presumed that mammals possessed only a very few innate drives (such as hunger and thirst, often referred to as 'primary drives') and that experiences after birth led to the development of 'secondary drives' (desires for other stimuli associated with satisfaction of hunger and thirst). The development of secondary drives was believed to depend on two simple forms of learning – classical and operant conditioning, the rules of which presumably applied similarly to many kinds of learning across many species. This view had the advantage of being parsimonious, meaning it could explain much with few assumptions. However, several behavioral psychologists began to uncover findings challenging this view. The rules of conditioning changed depending on what was being learned and which species did the learning. Consider the rules involved in learning to avoid unpleasant experiences. Some learning requires instantaneous feedback (e.g., a jolt of pain immediately after touching a hot stove facilitates learning not to touch it again); however, people and other animals also learn to avoid foods that made them sick many hours after the food was eaten. Food aversion is also unlike many other types of learning in that it requires only one trial and is difficult to extinguish once learned. Furthermore, the types of stimuli that get conditioned to nausea vary in ways consistent with the organism's evolutionary history and typical ecology. For example, rats have poor vision and rely on taste and smell to find food at night, and they easily condition aversions to novel tastes, but not to novel visual stimuli. Quail, on the other hand, have excellent vision and rely on visual cues in food choice, show the opposite bias – conditioning easily to visual cues but not to taste.

Although not many social psychologists were radical behaviorists, most shared the assumption that social behaviors were products of individual learning experiences and not innate mechanisms. However, two other influences at the time began to challenge that simple empiricist worldview. Behavioral geneticists were uncovering evidence that complex human behaviors could be passed on genetically. For example, twins reared separately shared many adult personality traits, including rare forms of psychopathology, whereas adopted children shared surprisingly few such traits with the families in which they were raised. At the same time, advances in cognitive science, including the study of artificial intelligence, were beginning to suggest that complex cognitive processing could be programmed from very simple 'on-off' components. The culmination of these new research directions coincided with the emergence of several key concepts – life history theory, sexual selection theory, and parental investment – that are now cornerstones of evolutionary research. In the next section, we discuss each of these theories in detail.

Life History, Parental Investment, and Sexual Selection

Studying the array of unique adaptations found across the animal kingdom has uncovered several general principles

governing the evolution of diverse traits. One powerful set of principles is embodied in *life history theory* – which assumes that all organisms must resolve a key set of trade-offs throughout their lives. Central trade-offs involve allocating energy to development versus mating versus parenting (effort spent on attracting mates is effort that cannot be spent on caring for young, for example). Depending on ecological factors, different animals allocate effort very differently across their life-spans. Some fish, for instance, change from small drab females into large colorful males if a territory becomes available. Some small mammals start reproducing weeks after they are born, others wait decades. Some animals (such as salmon) reproduce in a single grand effort; others (such as elephants) reproduce repeatedly over their life-spans. Human life history involves a long period of somatic development, earlier sexual maturity in females than in males, and more lifespan mating effort by males than by females.

Why do females and males within species often have different life histories? Part of the answer has to do with *differential parental investment*, which usually involves greater amounts of offspring care by females. In mammals, for example, females carry developing young inside their bodies and nurse them after they are born. Within a species, the sex investing less in offspring tends to compete for mating opportunities with the higher-investing sex. Because mammalian females always pay a high price for reproduction while males may contribute little or nothing to offspring care, females are relatively more selective in their choice of mates. This is linked to *sexual selection*, which refers to the relative success of traits that assist in mating (by helping either to attract the opposite sex or to compete with one's own sex). Darwin developed the idea of sexual selection to address the fact that one sex is often larger, more colorful, and more competitive than the other (sexually dimorphic). A peacock's bright feathers increase his chances of attracting peahens as mates while at the same time making him more susceptible to detection by predators. Females do not need ostentatious ornamentation displays because they make a higher investment in the offspring and are therefore choosier about their mating partners (who must consequently compete with other males to be chosen). These evolutionary concepts can be applied to numerous and diverse aspects of human thought and behavior. In the next section, we consider how an evolutionary framework can shed light on many different types of human relationships.

Evolutionary History and Human Relationships

For most of human evolution, our ancestors lived in groups of about a hundred people who were often related to one another. Thus, human cognitive mechanisms were designed not for life in modern cities but for coexistence in small hunter-gatherer groups. Because hunter-gatherers everywhere faced some similar problems and opportunities, evolutionary theorists expect to find a number of human universals beneath the surface diversity of modern cultures. We consider some of the functions that relationships might have served in ancestral human groups, focusing on six domains of social interaction: affiliation, status, self-protection, mate search,

mate retention, and kin care. Each domain is characterized by different problems and opportunities and each is likely to operate according to slightly different sets of decision-making rules.

Affiliation

Research on hunter–gatherers suggests that social alliances may have been critical to our ancestors' survival and reproduction. Anthropologists studying modern hunter–gatherers, such as the Ache of South America, find that the likelihood of capturing game is often quite low on any given occasion for any given individual. If one individual catches a large fish or a deer, however, it is often too much to consume alone and will rot if not shared. By sharing, individuals help other members of the group survive and accrue credit for the future when their own luck is down. Furthermore, people in cooperative networks can accomplish tasks that none of them could easily do alone (such as hunting large game).

There are costs as well as benefits to alliances: it takes time and resources to help other people, and those people might want to take more than they give in return. Group members also compete with one another for food, status, or mates. How much to cooperate, and with whom, is influenced by two powerful evolutionary principles – *inclusive fitness* and *reciprocity*.

Inclusive fitness refers roughly to an organism's success in getting its genes into future generations. The term 'inclusive' refers to the fact that fitness is measured not simply by the number of offspring an organism produces but also by contributing to the success of relatives. Hence, all living organisms, including humans, are expected to cooperate more readily with close relatives. There are many examples of inclusive fitness in nonhuman animals. For instance, Florida Scrub-Jays often stay at the nest to help their parents raise new offspring for at least 1 year. In human hunter–gatherer societies, individuals tended to be closely related, and even in modern societies, people spend most of their lives in close contact with kin.

Human beings are also cooperative and generous with people who are not related to them. *Reciprocal altruism* involves kindness toward nonrelatives whom one expects to be beneficial to oneself in the future. Unlike relationships with kin, people are more sensitive to violations of reciprocity when unrelated individuals are involved. Indeed, people are exquisitely sensitive to other people's violations of social contracts, to the extent of being able to solve difficult logical problems if those problems are framed as involving potential cheating.

Status

Human beings everywhere arrange themselves into status hierarchies. There are costs associated with achieving status, but high status individuals are compensated with greater access to resources. For males, there are additional benefits in gaining status, since females are more likely to mate with higher status males. Consistently, men around the world are more likely to compete for status, sometimes violently. Such competition is most pronounced among young unmated males and tends to decrease once a male gains social position and a mate.

Self-Protection

Ancestral humans frequently confronted dangers from members of other groups, and occasionally from members of their own groups. A number of cognitive biases suggest that people are especially alert to possible threats from others. Males posed, and continue to pose, greater threats of physical violence. Consistently, people are especially rapid at detecting angry facial expressions on men's, as opposed to women's faces. People are also biased to perceive intentions of threat more readily in members of outgroups and surprisingly good at remembering angry males from threatening outgroups. Consistent with the fact that our ancestors were more defenseless in the dark, ambient darkness increases threat-related prejudices against stereotypically dangerous groups. When feeling threatened, people are more likely to band together with ingroup members.

Mate Search

Differential reproduction is the central driving force of evolution. We are here today because our ancestors were successful at mating. For most mammals, courtship involves mostly males competing for the attention of females. This is because mammalian males usually contribute little beyond sperm to their offspring, making female parental investment (and consequent choosiness) much higher. Humans are mammals, which means (a) women are physiologically equipped to raise offspring without help from men and (b) men could, conversely, father offspring with no investment beyond sperm. Unlike most mammals, however, human offspring are born helpless and require more than the usual amount of parental care. In species with helpless young (such as most birds), a common pattern is for males to contribute to offspring care. Although there are many instances of human females raising offspring without male help (the typical mammalian pattern), more common across human cultures is some degree of paternal investment in the offspring.

When males contribute to offspring, they tend to become more selective in choosing mates. Human beings adopt different mating strategies, which seem to be sensitive to levels of parental investment. For casual sexual relationships, males are relatively unselective about mating, whereas females favor especially symmetrical and healthy males (the more typical mating pattern). For longer-term monogamous relationships, in which men make a high investment, men become similar to women in being relatively more selective about their mates. Nevertheless, because mothers and fathers contribute different resources to the offspring, each sex seeks slightly different characteristics in a mate. Men seek traits that would have been associated with fertility (such as relative youthfulness and low waist-to-hip ratios). Women, on the other hand, are generally attracted to men demonstrating dominance and social status.

Mate Retention

Keeping mates involves a different set of challenges and opportunities than choosing them. Both sexes are expected to be alert to other members of their own sex who might disrupt their

relationships. Women are attentive to other women who are highly attractive, men to other men who are socially dominant. Because fertilization occurs inside the female's body, mothers are always certain that their children are their own, whereas men risk investing resources in other men's offspring. Women are at risk for losing their partner's investment of resources and ought to be relatively more concerned that interloping females might establish a long-term relationship with their partners. Consistently, women are, compared with men, more jealous of their partners' deep affectionate relationships and relatively less jealous about casual sexual contacts. These sex differences are relative rather than absolute – neither sex welcomes either sex or love between their partner and another.

Kin Care

Following principles of inclusive fitness, one expects to find relatively less tit-for-tat exchange and more communal sharing of benefits among close relatives. People are indeed more willing to help others with whom they share genes, and such aid takes into account their relatives' reproductive potential. While a 40-year-old woman is equally related to her 17-year-old daughter and her 70-year-old mother, she would be expected to invest more resources in her daughter (whose reproductive potential is high) than in her elderly mother (who, though capable of providing indirect benefits of grandmothering, has no direct reproductive potential remaining). One study examined the impact of such considerations on grandparental effort, finding relatively more investment by mother's mothers, for whom there are no uncertain paternal links involved. On the other hand, investments in sons' children were relatively high if a grandmother did not have (more certain) grandchildren via a daughter.

Evolution and Social Information Processing

The evolutionary perspective was emerging during the period when the social cognitive perspective came to predominance in social psychology. Cognitive and evolutionary perspectives are not just compatible; a full understanding of human nature requires an *integration* of the two perspectives.

In line with this perspective, recent research suggests that human memory is functionally designed to enhance fitness. For instance, people were better at remembering words when they were related to prototypical survival scenarios than nonfitness-relevant control scenarios. In addition, some gender differences in memory and cognition have been speculated to be the result of the sexual division of labor between hunting and gathering in the environment of evolutionary adaptedness. Specifically, men are speculated to have evolved cognitions suitable for hunting while women evolved parallel processes for foraging.

Harking back to Darwin's evolutionary view of emotional expressions, another person's anger is a very functionally relevant stimulus, foreboding potential harm. If that other person is a male, the dangers are substantially higher: males commit ~90% of homicides; even when females do commit murder, it is often a self-protective response to male harassment. Males are also more likely to do physical damage if they strike someone. Women, on the other hand, are more likely to afford

cooperative opportunities to others. Consistent with functionally derived hypotheses about emotion recognition, people not only identify whether a face is angry or happy in a fraction of a second but are also significantly quicker and more accurate at recognizing anger on a male than a female face and happiness on a female face. Interestingly, the reverse is also true – people can identify a face as male or female in a fraction of a second, but are significantly faster at identifying a face as male if it is angry, and as female if it is happy.

In another series of studies linking attention, encoding, and memory, participants were shown crowds of faces containing attractive and average-looking people of both sexes, and later asked to remember which faces they saw. Findings from an eye tracker study indicated that both sexes looked relatively more at attractive women. When asked to judge the frequency of attractive women in a crowd, both sexes overestimated the number if the crowds were presented rapidly, suggesting that attractive women are more immediately cognitively accessible. Consistently, people of both sexes are good at remembering whether or not they have seen a particular attractive woman before. For attractive male targets, on the other hand, there is an interesting disjunction between different levels of processing. Women (but not men) attend more to good-looking guys, but then neither remember them well nor overestimate their frequency in previously presented crowds. These findings make sense in terms of male and female mating strategies discussed earlier. For men, strange attractive women are mating opportunities. For women, who are typically more inclined toward long-term relationships with familiar men, and who typically do not make advances toward strangers, there is less inclination to devote processing time to strange attractive men.

Another study in this program used functional logic to reconsider a bias in memory linked to 'outgroup homogeneity' and the failure to remember individual members of other racial groups. In functional terms, it makes sense to make finer discriminations between members of one's own group (with whom one has more frequent and more cooperative interactions). However, there are also times when it makes functional sense to pay close attention to, and remember the identity of, members of other groups, for instance, when those individuals might pose threats to one's welfare (members of outgroups often have less motivation to inhibit aggressive inclinations than members of one's own group). Consistent with that logic, the standard outgroup homogeneity effect reverses when White participants are asked to remember faces of angry, but not neutral, Black men. In this section, we have considered cognitions and behavior on the individual level; however, an evolutionary perspective can also help us understand group level behaviors. We touch upon this idea in the following section.

Social Dynamics and the Emergence of Culture: The Mind as a Coloring Book

Evolutionary social psychology is one component of a broader interdisciplinary movement toward integrative science. Dynamical systems theory is another attempt to combine ideas from biology, mathematics, computer science, and cognitive psychology. Two fascinating conclusions have emerged from

research on complex systems ranging from ant colonies to world economies. Dazzling fractal images represent one lesson of dynamical systems theory: awe-inspiring complexity can emerge from a few variables interacting according to a few simple rules. Such emergent processes can be intellectually overwhelming, but there is another side to the story. Complex systems at every level from molecules to genes to neurons to ecosystems often reveal *self-organization* – order emerging out of initial disorder.

Exactly which patterns of self-organization arise in complex systems depends on simple decision rules at the individual level. Combined with ideas from evolutionary domain-specificity, this helps explain why different patterns of social organization arise in different aspects of social life, such as the hierarchies associated with status, dyadic pairings associated with mating, and large aggregations associated with inter-group conflict.

This work has important implications for another area of modern social psychology: the emergence of cultural norms. A dynamical evolutionary approach helps us understand how cultural norms encompass underlying universal biases as well as diverse cultural norms. For example, most human societies involve a greater number of marriages between older men and younger women than the converse, as discussed. There are however, a few societies, such as Tiwi aborigines of Australia, in which older women marry younger men. On closer examination, those societies do not involve exceptions to underlying human nature but a new dynamic emerging from multiple evolved biases. Men in Tiwi society are in fact attracted to younger women and Tiwi women are attracted to older, high status men. The Tiwi arrangement is an accommodation to another general feature of human social life – male competition for status – and emergent patterns of patriarchy. In Tiwi society, older men have all the power, and since they are polygynous, they betroth their daughters to other patriarchs, who reciprocate. This leaves the younger men out of luck. Another norm in Tiwi society, however, is that all women – of all ages – must be married. When an older woman becomes widowed, she must remarry, but the older patriarchs with younger wives do not wish to marry her. Instead, she marries a younger man, who thereby does a favor for her older male relatives and puts himself into the game of acquiring younger wives in the future.

These Tiwi mating arrangements suggest that the mind-culture interaction is neither captured by the Blank Slate metaphor nor by the metaphor of a predetermined blueprint. Instead, we can fruitfully conceptualize the interaction using the metaphor of a coloring book – with some predrawn lines, but a great deal of flexibility within which local colors can be recombined in diverse ways. While a coloring book can, in one sense, be colored in an infinite number of ways, it is not so passively receptive as a Blank Slate, since the outlines in a coloring book strongly suggest (though do not determine) particular palettes of inputs to be used on the different pages. A coloring book is not a blueprint, in which a predetermined design fixes the outcome. It has blank space between the lines, leaving room for unexpected outcomes: a given child could choose to color his giraffe purple and green instead of tan and brown. But most children coloring a giraffe will be inspired to search for tan, brown, and yellow rather than purple, blue, and

green. And there's another benefit of this image – a coloring book gives us an easy-to-understand metaphor for teaching students about the flexible interactions between evolutionary constraints and local cultural norms. Indeed, it is as easy to visualize as a Blank Slate, except it is more colorful, and draws a more complete picture of the mind.

Glossary

Biofeedback Biofeedback is a patient-guided treatment that teaches an individual to control muscle tension, pain, body temperature, brain waves, and other bodily functions through relaxation, visualization, and other cognitive control techniques. The name biofeedback refers to the biological signals that are fed back, or returned, to the patient in order for the patient to develop techniques of manipulating them.

Biomechanics The study of the mechanics of a living body, especially of the forces exerted by gravity on the skeletal structure.

BIRGing Basking in Reflected Glory, a phenomenon that occurs when things are going well and identification with a team is high.

Clinical psychology The branch of psychology concerned with the diagnosis and treatment of mental disorders.

Counseling psychology A psychological specialty that encompasses research and applied work in several broad domains: counseling process and outcome, supervision and training, career development and counseling, and prevention and health. Some unifying themes among counseling psychologists include a focus on assets and

strengths, person–environment interactions, educational and career development, brief interactions, and a focus on intact personalities.

Kinesiology The study of the anatomy, physiology, and mechanics of body movement, especially in humans; the application of the principles of kinesiology to the evaluation and treatment of muscular imbalance or derangement; also refers to the professional field in which these applications are practiced.

Licensed professional counselor (LPC) LPC is a subdoctoral licensure for mental health professionals. The exact title varies from state to state and LPCs are not psychologists. The LPC licensure provides for master's level professionals to set up an independent practice, not as psychologists but as LPCs.

Motor learning The acquisition of skills or skilled movements as a result of practice. Motor learning involves a set of internal processes associated with practice or experience leading to relatively permanent changes in motor skill. The study of acquisition of skills.

Social facilitation The effect of the presence of others on individual performance.

Introduction

The world is absolutely sports crazy and it begins only a few short years after birth in many cases. Young people are being brought into the action at much earlier ages than ever before as evidenced by the presence of knee-high tykes in pizza parlors after baseball games or soccer matches, all decked out in form-fitting uniforms appropriate to their particular sport. As these children age and gain experience, they are often channeled into playing for one or more highly competitive travel teams that have as their main focus producing the next Albert Pujols, LeBron James, or Peyton Manning. If these kids stay with sports, and many do not for a variety of reasons, they will take part in interscholastic sports where literally millions of teenagers select from a large sports menu provided for them by their school districts. A few of these athletes will have the privilege of going on to play on an intercollegiate team in their chosen sport. Even fewer become professionals, and a select few may get to experience the immense joys and challenges of being an Olympic-caliber athlete. Such is the nature of sports. As a result of all this sports participation, intense competition, and attendant fandom, an ever-increasing array of sport scientists have been employed to help boost sport performance and fitness adherence through improvements in diet, equipment, and psychological and physical training methods. It is in the

context of enhancing sport performance and fitness adherence that the sport psychologist can make a significant contribution. The remainder of this article will be devoted to enhancing our understanding of the history, present status, and future of exercise and sport psychology.

A Definition of Exercise and Sport Psychology

Exercise and sport psychology is a relatively new area of application within the field of psychology, having only come into its own in the past four to five decades. The field is essentially a blend or amalgam of two domains, the broad area of psychology and the narrower domains of exercise and sport, and it is not unusual to see the professionals in the area referred to as sport psychologists, sport and exercise psychologists, and exercise and sport psychologists. The shorter version, sport psychologist, will be used throughout this article in the interest of parsimony, but the reader should always keep in mind that there is no intent whatsoever to diminish the importance of exercise in the total equation. One of the major exercise and sport psychology professional organizations to be discussed later, Division 47 of the American Psychological Association (APA), indicates on its website (<http://www.apa47.org>) that "Exercise and sport psychology is the scientific study of the

psychological factors that are associated with participation and performance in sport, exercise, and other types of physical activity. Sport psychologists are interested in two main areas: (a) helping athletes use psychological principles to achieve optimal mental health and to improve performance (performance enhancement) and (b) understanding how participation in sport, exercise, and physical activity affects an individual's psychological development, health, and well-being throughout the life span."

The Origins of Sport Psychology

In any discussion of sport psychology, there are at least four historical domains to keep in mind: sport, psychology, physical education (now known most popularly as kinesiology), and the subfield of sport psychology. A brief summary of some of the key moments in the history of sport, psychology, physical education, and sport psychology can be seen in [Table 1](#).

Sport History

Sport historians generally agree that the starting point for their area of inquiry is 776 BC with the advent of the first Olympic Games in Athens, Greece. This designation is not to deny the existence of some kinds of sporting activities thousands of years earlier in ancient civilizations such as China, Egypt, and India. There is clear evidence that sport played an important

societal role in times even more ancient than Greece and Rome, but the 776 BC designation is believed by most sport historians to provide the most convenient starting point for a discussion of sport history.

Sport flourished in the Greek Athenian period with its emphasis on grace, beauty, and the human form. Also, sports and fitness played a huge role in the daily life of the more militaristic Spartans who saw these activities as part and parcel of the creation of the perfect warrior. In 146 BC, the Romans came to power in the ancient world and the sporting activities during their rule moved away from the Greek tradition into a more primitive and sometimes ugly realm that appealed to man's baser instincts with chariot races, festivals dedicated to the slaughter of thousands of animals at a time, and the gladiatorial events in which many people died. For example, when the Coliseum in Rome opened in 72 BC, the inauguration was celebrated with the slaughter of 5000 animals and games that lasted for 100 days. The bloodlust of the Romans is well-documented in sport history.

The savagery of the Roman approach to sport, the overall social, political, financial, and moral decline within the Roman Empire, and the increasing influence of Christianity led to the demise of the Olympic Games in AD 394. The Summer Games were resurrected in 1896 and have been held every 4 years since, with the exception of the World War II years of 1940 and 1944. The Winter Games were first formally introduced in 1924 in Antwerp, Belgium and have been held every 4 years since except for the war years, alternating in 2-year cycles with the Summer Games.

Table 1 Key historical events in sport, psychology, physical education and sport

<i>Sport</i>	
776 BC	First Olympics Held in Athens, Greece
AD 392	Ancient Olympics Ended. Reinstated 1602 Years Later
1896	Baron de Coubertin Leads Revival of Modern Olympics in Athens
1905	President T. Roosevelt Holds Meetings on Future of College Football
1939	Little League Baseball Initiated in Williamsport, Pennsylvania
1947	Brooklyn Dodgers Racially Integrate Major League Baseball
1952	President Eisenhower Commissions Study of Youth Fitness in US
<i>Psychology</i>	
1879	Wilhelm Wundt Opens Psychology Laboratory in Leipzig, Germany
1893	French Physiologist Phillippe Tissie Conducts Study of Cyclists
1894	Edward Scripture Studies Reaction Time in Expert Fencers
1898	Norman Triplett Studies Effects of Social Facilitation on Cyclists
1903	T. W. Patrick Publishes Study of Catharsis Among Football Fans
1915	Karl Lashley and John B. Watson Study Skill Acquisition in Archery
<i>Physical Education</i>	
1861	First Men's Physical Education Program at Amherst College
1865	First Women's Physical Education Program at Vassar College
1866	California is First State to Pass Law Requiring PE in Public Schools
1885	American Association for the Advancement of Physical Education Created
1904	R. Tait McKenzie Becomes Leader in PE and Sports Sculpture
1922	Jesse Feiring Williams and Clarke Hetherington Issue Call for American PE to Move Away from Militaristic German Influence
<i>Sport Psychology</i>	
1925	Coleman Griffith Starts Sport Psychology Laboratory at Illinois
1926–1928	Griffith Publishes <i>Psychology of Coaching</i> and <i>Psychology of Athletics</i> , First Two Sport Psychology Books
1965	International Society for Sport Psychology Formed in Rome, Italy
1967	North American Society for the Psychology of Sport and Physical Activity Formed
1986	Association for the Advancement of Applied Sport Psychology (AAASP) Formed. Known Since 2006 as Association for Applied Sport Psychology (AASP)
1986	Division 47, Sport and Exercise Psychology, created within American Psychological Association (APA)

There is plenty of evidence for sport participation in the American colonial period. [Rice et al. \(1969\)](#) and [Struna \(1981\)](#) reported that popular sports at that time included cricket, fives (handball), goff (golf), rounders (a ball game similar to baseball), shinny (hockey), and others too numerous to mention. Participation in sports also took place during the Civil War where something approximating baseball was apparently immensely popular ([Kirsch, 2003](#)).

The middle part of the 1850s ushered in an era in which there was a huge influx of European immigrants into the United States, and they brought their own sporting traditions with them. Of particular importance in this regard were the highly organized, almost mechanistic Germans who exerted a significant influence on American physical education philosophy and practice for much of the eighteenth and early nineteenth centuries. At the same time these European immigrants were making their way to our shores, there was a technological revolution that had a profound impact on the country in general and sport in particular. The development of the railroads and inventions such as the telegraph, incandescent lighting, ball bearings, stopwatch, and sewing machine, to name just a few, allowed for the creation of improvements in the overall conduct of sports.

The reinstitution of the Olympic Games in 1896; the evolution of sports and fitness in social agencies such as the Young Men's Christian Association (YMCA), Young Women's Christian Association (YWCA), Boy Scouts, and Girl Scouts; the creation of Little League baseball in Williamsport, Pennsylvania in 1939; and the landmark pieces of legislation, the Civil Rights Act of 1964 and the Title IX Act in 1972, were instrumental in furthering the integration of minorities and women into sport and were pivotal in shaping sports and fitness as we know them today.

History of Psychology

It is widely accepted among psychologists that the discipline of psychology essentially began in 1879 with the creation of the first research laboratory in Leipzig, Germany. The emergence of psychoanalysis as formulated and practiced by Sigmund Freud in Vienna, Austria, and Carl Gustav Jung in Zurich, Switzerland, in the late 1800s and early 1900s had a huge impact on the development of psychology. The same can be said for the behavioral approach, which traces its roots to the work on classical conditioning by the Russian physiologist, Ivan Pavlov, in the late 1800s. The American psychologist, John B. Watson, conducted related work in his laboratory at Johns Hopkins University in the early part of the twentieth century, and this led to his designation as the 'Father of American Psychology.' A couple of decades later, the Harvard psychologist B. F. Skinner promoted a new view of behavioral psychology known as Skinnerian Psychology or instrumental conditioning, and his work greatly advanced our understanding of the principles of human and animal learning. Finally, the humanistic tradition within psychology was promoted by Abraham Maslow at Brandeis University in Boston, Massachusetts and Carl Rogers, the famous psychotherapist. The resilience and optimism of the humanistic model was a welcome response to the pessimism of the psychoanalysts and the hard-core emphasis on laboratory-generated, sometimes mechanistic truths of the behavioral psychologists.

History of Physical Education

As can be seen in [Table 1](#), physical education was given huge impetus in the nineteenth century with the creation of the first collegiate physical education program for men at Amherst College in 1861 and the one for women at Vassar in 1865. Also, the 1866 legislation in California mandating compulsory physical education activity classes in the public schools was a giant step forward for the discipline. The field evolved almost totally in its earliest years from the field of medicine to a discipline of its own in the early 1900s. Unfortunately, the place of physical education in the quest for youth and, later, adult fitness has been a political football for many years in both our public schools and universities, with critics constantly calling for it to be minimized or discontinued in favor of other academic pursuits.

History of Sport Psychology

There seems to be general agreement that the first research studies conducted with a sport psychology theme were those of the Frenchman Phillipe Tissie (1852–1935) and Americans Norman Triplett (1861–1934) and Edward Scripture (1864–1945), all in the 1890s ([Benjamin and Green, 2009](#); [LeUnes, 2008](#)). In the case of Phillipe Tissie, he wrote two articles that appeared in 1894 describing his work on the physiological and psychological aspects of bicycle racing ([Baumler, 1997](#)). Though more naturalistic than laboratory-based, the Tissie articles are extremely important since they were the first of their kind with a sport psychology focus. However, Norman Triplett is generally accorded the status of having produced the first sport psychology experiment in 1898 for his study of what is now known as social facilitation (i.e., audience effects on individual performance) among sport cyclists. Benjamin and Green surveyed 33 English language sport psychology textbooks published between 1980 and 2002, and found that 19 identified Triplett as the individual who published the first sport psychology research. It is likely that the appearance of Triplett's paper in the highly accessible *American Journal of Psychology* coupled with the more obscure nature of the French journals in which Tissie published his work in great part accounts for the discrepancy. In any event, both Tissie and Triplett made significant contributions to the history of sport psychology, and their status in that regard is guaranteed.

As for Scripture, his work also predated that of Triplett but was published in an in-house journal at Yale that ceased publication in 1902, thus lowering the visibility of his work ([Benjamin and Green, 2009](#)). Scripture's study compared two classes of fencers on reaction time and speed of movement and found no differences between expert fencers and fencing novices on reaction time, but the expert fencers were superior to the less accomplished ones on speed of movement.

Interestingly, Tissie, Triplett, and Scripture never published another paper with a sport psychology theme. As Benjamin and Green indicate, these one-shot studies were typical in the early years of the discipline.

Though there were other studies conducted in several universities with a diverse pool of subjects embracing a number of countries throughout the world, the field made a quantum leap forward with the work of Coleman Roberts Griffith at

the University of Illinois. According to [Green \(2009\)](#), Griffith had established a reputation as a first-rate scholar by 1920 with a research focus on selected aspects of audition in laboratory rats. Griffith published several important scholarly articles and two books prior to 1923 and, in the process, developed a side interest in sport psychology that was to become a passion for two decades of his professional life. It seems that while teaching introductory psychology, he became enamored with trying to understand the psychological makeup of athletes in his classes. As part of this effort, Griffith engaged in an ongoing exchange of letters with the legendary football coach at Notre Dame, Knute Rockne ([LeUnes, 2008](#)).

To further his understanding of the athlete's psyche, Griffith created the first sport psychology laboratory in the United States in 1920. Three years later, he introduced the first university-level sport psychology course and it gave rise to his third book in 1926, entitled *Psychology of Coaching*. He followed that volume with another in 1928, entitled *Psychology of Athletics*. For reasons not clear, the university closed Griffith's laboratory in 1932 and Griffith was reassigned to an administrative position which he held until his retirement. Though he dabbled for a while in the sports area after the closing of the sport psychology laboratory, his interest in the area slowly waned. Griffith published four more books during his tenure as an administrator, none of which focused on sport psychology. For his efforts, however, Griffith is generally considered to be the 'Father of American Sport Psychology.'

Sport Psychology Professional Organizations

Once Griffith moved on to other pursuits, not much happened in sport psychology for essentially three decades. There were smatterings of research with a psychological theme published related to the purported dangers of Little League baseball and a few other topics, but not much really happened in sport psychology until 1967. It was at a meeting of a national organization for physical educators that a splinter group met to form what became the first sport psychology professional organization in this country, the North American Society for the Psychology of Sport and Physical Activity (NASPSPA). Though NASPSPA represented a step forward for sport psychology, the overriding focus of that organization on research and theory, particularly in the area of motor learning, led to the formation in 1986 of the two dominant professional organizations in sport psychology, the Association for the Advancement of Applied Sport Psychology (AAASP) and Division 47, Sport and Exercise Psychology, of the APA.

Association for Applied Sport Psychology

Since its inception in 1986, AAASP has been at the forefront in promoting the discipline of exercise and sport psychology. In 2006, it was decided that the word 'Advancement' was no longer needed in the title, and the organization became known as the Association for Applied Sport Psychology (AASP) instead of AAASP. AASP has now grown to ~1000 members, pretty much equally divided in academic preparation between psychology and kinesiology. To further meet the interests of the membership, 24 Special Interest Groups (SIG) have been

formed and included are such diverse interests as Business Ownership in Sport Psychology, Disability Sport and Exercise, Gay, Lesbian, Bisexual, Transgender, and Intersex, Humanistic Sport Counseling, Soccer, Sport Fandom, and Youth Sport.

Division 47 APA

Also in 1986, the APA Council of Representatives unanimously approved the creation of Division 47, Sport and Exercise Psychology. This interest group began with perhaps two dozen members, and the rolls have grown to around 1000 including student affiliates.

One of the more important initiatives arising from Division 47 occurred in 2003 when the APA Council of Representatives approved what is known as the Sport Psychology Proficiency. In essence, the proficiency is a form of recognition from the APA that serves to lend validity to sport psychology as a post-doctoral specialization area under the larger umbrella of the field of psychology. The academic and applied requirements necessary for achieving the Proficiency read much like those for certification as a consultant with AASP, and thus are thorough and rigorous. The APA Proficiency in Sport Psychology is designed to serve at least two important functions, one of which is to offer protection for the general public and the other to offer guidelines for better training of professionals in the field.

In terms of training within sport psychology, Division 47 has listed on its website some issues to consider when thinking about a career in exercise and sport psychology ([Graduate training, 2010](#)). As part of that discussion, it is suggested that four tracks be available to people with interest in a career in exercise and sport psychology, and they are:

1. *Track I: Teaching/Research in Sport Sciences and Work with Athletes on Performance Enhancement.* This track requires a doctoral degree in Sport Sciences with a Sport Psychology Specialization. Significant course work in Psychology and Counseling is also expected. The primary sources of employment in this track are teaching and/or research positions within colleges and universities, research institutes, or medical research laboratories, or as a Coaching Educator for a collegiate or sport organization.
2. *Track II: Teaching/Research in Psychology and also Interested in Working with Athletes.* This track carries with it an expectancy of a doctoral degree in a psychological field with significant course work in Exercise and Sport Science. It is anticipated that specialization in this track would allow one to work in an academic position in Psychology within a college or university, a research institute, or a medical research laboratory.
3. *Track III: Provide Clinical/Counseling Services to Various Populations, Including Athletes.* The educational requirement to work in this domain is quite strict, requiring that the person be a graduate of an APA-approved doctoral program in either clinical or counseling psychology. It is further expected that this professional would bolster his or her credentials in psychology with additional work in the sport psychology and related sport sciences. Track III might lead to a private practice in psychology or a counseling or clinical psychology position in a university counseling center.

Track IV: Health Promotion and Working with Athletes but not Necessarily Directly in Sport Psychology. Master's level training with specializations in clinical or counseling psychology augmented by significant training in the sport and exercise sciences or, alternately, a master's in the sport sciences with significant course work in psychology. Academic athletic counseling centers, health maintenance organizations (HMOs), and sports medicine clinics represent job possibilities for people trained in Track IV.

Division 47 offers several caveats or issues to consider concerning employment opportunities in all of the tracks, but especially for those in Track III. Jobs are not plentiful and those that exist are almost always filled with professionals possessing years of extensive experience. An additional caveat suggests that staking one's time and reputation on working with elite athletes is a risky proposition, offering little job security and a less than encouraging job market in the foreseeable future.

From time to time, Division 47 confers Fellow status on exercise and sport psychologists who have made significant contributions to the field over the course of their careers. Thus far, 28 distinguished professionals have been designated as Fellows, 10 of whom are also certified as consultants with AASP which will be discussed shortly.

International Society for Sport Psychology

At the international level, the International Society for Sport Psychology (ISSP) is a major player. ISSP was created in Rome, Italy, in 1965 and was the brainchild of Feruccio Antonelli. ISSP sponsors a journal, *International Journal of Sport Psychology* and conducts a world congress every 4 years in which the exercise and sport psychologists from all over the globe congregate to assess the current status and the future of the discipline. Starting in 1965, the world congresses have been held in such exotic locations as Rome, Washington, DC, Madrid, Prague, Ottawa, Copenhagen, Singapore, Lisbon, Israel, Skiathos Island in Greece, Sydney, and Marrakesh, Morocco.

Other active, prominent, and well-organized societies for exercise and sport psychologists are found in Australia, Canada, and England, and are regulated and promoted by sport psychology or psychology organizations within their respective countries.

What Do Sport Psychologists Do?

As was noted in earlier descriptions of the various training tracks, sport psychologists are engaged in three main activities, teaching, research, and practice. Typically, the teaching and research functions take place within a Department of Kinesiology though, in a minority of cases, the functions may fall within the purview of a Department of Psychology. It is fascinating to note that historically, sport psychology has been almost totally a specialty area within Physical Education or Kinesiology, and remains much that way today. At the same time, however, it is becoming more and more necessary to be licensed as a psychologist in order to reap the full benefits associated with being a sport psychologist. The licensure, in turn, necessitates narrowly specified training within a psychology program. This inconsistency has caused much gnashing of

teeth over the years about who can come to be identified professionally as a sport psychologist. But as we shall see shortly, it is not proper to refer to oneself as a psychologist without passing the licensure examinations provided by the states in the United States and the provinces in Canada. Similar issues are being dealt with by professional organizations or statutory bodies in countries such as Australia, England, and Japan.

The first function, teaching, was mentioned briefly earlier and may take place in a variety of settings, but the most traditional of the possibilities is the university classroom. Also, formal or informal sessions focusing on imparting information to athletes, coaches, athletic administrators, and fitness professionals are common and conducted with both individuals and groups. The second function, research, most frequently is conducted within the confines of academia, though field research sometimes yields very important information, too. In the applied function, the sport psychologist works with athletes and coaches on a variety of things most often aimed at enhancing athletic performance. Included in these applied psychological skills are such things as anxiety management, concentration control, communication, goal setting, imagery, visualization, mental practice, positive self-talk, team building, and time management.

Perhaps an expanded treatment of the topic of research is in order to give the reader a better feel for what domains are most popular. Though hardly inclusive, five broad areas stand out as prominent avenues of inquiry, and they are: performance enhancement, social psychology of sport, psychological assessment, youth sport, and exercise.

Research has demonstrated the performance-enhancing properties of a host of techniques including biofeedback, deep muscle relaxation, goal setting, energizing techniques, imagery, and attentional focus. Also, the stress-reducing or performance-enhancing properties associated with systematic desensitization, stress inoculation training, positive psychology, and learned optimism have been strongly supported.

With regard to the social psychology of sport, the focus has largely been on three domains: leadership, group cohesion, and audience effects. The leadership research has focused more on the coach rather than on player leaders, an omission that represents a gap in the sport leadership literature. The cohesion research has focused on levels of attraction and integration among sports teams or fitness groups with regard to task and social cohesion components. The scale of choice for assessing these group characteristics has been the Group Environment Questionnaire (Carron et al., 2002), and the results have been generally robust. Insofar as audience effects are concerned, two interesting phenomena have emerged from the literature, BIRGing (Cialdini et al., 1976) and the home advantage/disadvantage (Baumeister and Steinhilber, 1984). In BIRGing, the tendency to bask in reflected glory (i.e., BIRGing) when things go well with our favorite teams is assessed. When things go less well, the tendency is to (CORF) or cut off reflected failure, through dissociation with the team. As for the home advantage/disadvantage research, the weight of the evidence strongly suggests a clear edge associated with playing on one's home venue in most sport situations. However, there is evidence that the effect weakens or dissipates in critical junctures in the baseball World Series or finals of the National

Basketball Association (NBA) playoffs, where a home disadvantage appears to be in effect (Baumeister and Steinhilber, 1984). It is believed that this disadvantage may be tied to performance anxiety issues associated with performing before the home but sometimes critical home audience. As is often the case in scientific research, there are points of disagreement. For example, critics have taken Baumeister and Steinhilber to task over some methodological and statistical issues, thus casting doubt about the existence of a true team home disadvantage (Schlenker et al., 1995).

The research in psychological assessment in sport has been robust, not unlike that in the broader field of psychology with its rich history of assessing traits such as intelligence, achievement, aptitude, and personality. One example among many in sports and exercise involves the Profile of Mood States (POMS) of McNair et al. (1971). The POMS is a state measure of mood designed 40 years ago to assess progress in counseling and therapy. During its lifetime, the scale has been used in several thousand studies of which around 600 have been in sports and exercise. LeUnes (2002) reported its use in 396 studies through 2002 and an updated compilation (LeUnes et al., 2010) includes another 200. In general, the efficacy of the POMS in assessing the mood states of tension, depression, anger, vigor, fatigue, and confusion as they relate to sports and exercise has been strongly supported.

One important research topic in youth sport research has looked at why young people continue participating or drop out of organized athletics at a young age. It is clear that the number one participation motive is to have fun whereas winning is consistently a low priority for the vast majority of participants. Conversely, not having fun and experiencing bad coaching account for a large proportion of the sports dropouts. A second area of inquiry about youth participation focuses on anxiety and its effects. For example, high trait anxious youth experience more anxiety about poor performance, and they often expect negative emotion and negative evaluation regardless of how well they may perform. In an interesting side note related to this topic, it was demonstrated three decades ago by Simon and Martens (1979) that band solos and other music activities possess far more anxiety-producing properties than do most sports activities. This finding, of course, flies in the face of the assertion that sports are harmful to children due to anxiety and stress. Finally, Ronald Smith and associates at the University of Washington have published a number of articles beginning in the late 1970s (Smith et al., 1977) extolling the virtues of their training program for youth coaches in the Seattle, Washington, area. The recurring theme of their research is that coaches trained using their sport psychology package produce young people who enjoy sports more, are more positive about their coaches, and feel better about themselves than do children playing for coaches who did not receive the training. Interestingly, no differences in win-loss percentages have been noted in comparisons of the two groups of coaches.

A fifth and final area of inquiry has focused on the many nuances of exercise and fitness. For example, a scan of the table of contents of three top journals in the field, the *Journal of Sport & Exercise Psychology* (JSEP), the *Journal of Applied Sport Psychology* (JASP), and the *Journal of Sport Sciences* (JSS), indicates that slightly over 40% of the articles published in the last 3 years were on various aspects of fitness. In the case of JSEP, the figure

was 60%. These data lend credence to the notion that the field of sport and exercise psychology truly takes the exercise challenge seriously.

Why Sport Psychology?

There are a number of factors that have contributed over the past several decades to the continued growth and acceptance of sport psychology among both sports professionals and the general public. An obvious one is the pursuit of excellence on the part of athletes. Seeking the competitive advantage is not new in sports and has taken many forms. For example, elite swimmers now use streamlined swimming apparel. Many athletes have turned to the use of illegal compounds such as the anabolic-androgenic steroids to build muscular strength. Runners and cyclists have resorted to blood doping, a technique in which blood is extracted from an athlete and centrifuged to isolate the red blood cells. In turn, these red blood cells are infused back into the blood stream just prior to competition, thus giving the athlete a super-oxygenated systemic boost.

Only in the past 30–40 years have athletes figured out that they might also gain a competitive edge if they possess more mental toughness than do their opponents. Prominent athletes who have made liberal and effective use of applied sport psychological skills to improve their performance include professional golfers Camilo Villegas, Justin Leonard, Corey Pavin, and Davis Love, boxer Evander Holyfield, and NBA Hall of Famer David ‘The Admiral’ Robinson of Naval Academy and San Antonio Spurs fame. Teams or organizations that have successfully employed sport psychologists include the California Angels of major league baseball, the collegiate champion baseball team from California State-Fullerton, the many times champion women’s collegiate softball team from the University of Arizona, the Department of Athletics at the Ohio State University and the University of Oklahoma, and the championship World Cup soccer team from Spain.

A second force propelling sport psychology to the forefront is closely tied to the desire to improve performance issue, and that is money. The golfer Eldrick ‘Tiger’ Woods parlayed excellence in his sport to become the first sports billionaire. Michael Schumacher, the fabulously successful Formula One race driver from Germany, has won prizes in his career totaling \$80 million. The world-class soccer player Messi is now the highest paid member of his sport, with an annual salary of \$44 million. The total payroll of the New York Yankees in major league baseball and that of the English soccer power Chelsea are roughly equal, with an annual payout of \$200 million each. There are now major league sports franchises that are worth more than a billion dollars. The recitation of the money in sport could go on endlessly, but suffice it to say that there is indeed plenty of it there. And if an athlete, coach, or team can make more money by using the skills of a sport psychologist, they will find one to assist that process.

A third force, and one with substantial historical significance, is using sport of advance a nation’s political agenda. This search for identity through sports most certainly was powerful in the ancient Olympics, with the Athenians and the Spartans jousting, so to speak, for superiority and validation of their individual city-states. The French philosopher,

Jean Jacques Rousseau, wrote at length in the 1800s about using sport as a political tool. More recently, the Russians and their allies in the Communist bloc most certainly sought validation of their political and economic philosophies through the Olympic Games and other sporting events, and the abuses of sportsmanship they perpetrated through use of banned substances and methods in the latter part of the twentieth century are legendary in sports lore. The Communist bloc countries set in motion the substance abuse monster that is plaguing almost all of organized sport today in every corner of the world. Hardly a day passes without the media calling attention to some athlete who has abused a banned substance or method. No doubt, some of this chicanery is aimed at gaining the competitive advantage and validation of some country's political agenda.

Two other forces that have helped sport psychology gain a foothold in sport are spectator interest and the fitness movement. We have increasingly become spectators rather than participants, and anything that sport psychology can do to make the athletes perform better is much appreciated by the sports fans. Bigger, faster, taller, stronger, and mentally tougher athletes who can run faster, jump higher, lift more weight, or hit a baseball farther are what the fans demand.

As for the fitness movement, it seems at times that the movement is more illusory than real, but there are people out there who truly value fitness and work hard at it. As a result of the evolution of fitness centers and a fitness movement, sport psychology has had to broaden its focus and the end result is what is now known as *exercise* and sport psychology. It stands to reason that exercise and sport psychologists would have much to offer the fitness movement in areas such as motivation, goal setting, and exercise adherence.

Major Challenges Within Sport Psychology

There are five major issues within exercise and sport psychology that are of ongoing concern, and they are training, licensure and credentialing, ethics, image, and employment opportunities. The two major exercise and sport psychology professional organizations, AASP and Division 47 of APA, are working hand in hand to address and resolve each of these five concerns. The fact that the membership of the two organizations and the power structure in each are overlapping almost guarantees a certain agreement on how to proceed in addressing the problems within the field.

Training

As noted elsewhere, sport psychology has intertwined roots in both psychology and kinesiology. One important source of information about where training is conducted is the *Directory of Graduate Programs in Applied Sport Psychology* (Sachs et al., 2001). That directory contains a list describing the location of the various graduate programs at both the master's and doctoral level in Australia, Canada, New Zealand, Singapore, South Africa, the United Kingdom, and the United States. As of 2001, there were 88 master's and 44 doctoral programs in Kinesiology departments. In departments of Psychology, the numbers are 13 and 17, respectively. Clearly, the majority of

exercise and sport psychology training is being conducted in Kinesiology departments.

Such a picture is well and good, for the most part. There is one glaring problem, however, and it serves as a segue into a second area of concern: licensure and credentialing.

Licensure and Credentialing

In the mid-1960s, the APA, in response to a growing perception that the field of Psychology was filled with quacks, charlatans, and perhaps some well-meaning incompetents, conducted a study to assess the status of professional training in people who called themselves psychologists. The APA essentially looked into the academic credentials of a random sample of so-called psychologists advertising their services in the phone book yellow pages of a number of large US cities and found a disproportionate number of grossly undertrained psychologists. In an effort to provide consumers of psychological services with protection from quacks, charlatans, and incompetents, each of the states in the United States and the provinces in Canada began to enact licensure laws. Though there were a few rocky moments in getting the licensure ball rolling, the enacting of this legislation has accomplished its purpose for the most part. If one seeks psychological services today, the consumer is pretty much guaranteed a reputable practitioner who has met a solid set of qualifications in order to obtain the license.

It was never anticipated that these new licensure standards would have such a profound impact on the field of exercise and sport psychology, but that is exactly what has happened. Individuals who called themselves 'Psychologists' prior to the passage of the relevant legal strictures suddenly found themselves in violation of the law if they had not passed the assorted state and province licensure exams. This situation was equally applicable to those who might have called themselves 'Sport Psychologists.' Calling oneself a sport psychologist without possessing a license is a violation of the law. What recourse was available to sport psychologists trained within a Kinesiology department who were, as stated earlier, the dominant group numbers-wise?

In time, the recourse took the form of credentialing in addition to or instead of licensure. AASP (AAASP at that time) took up the charge in the late 1980s and put in place a process to credential nonlicensed sport psychology professionals, thus giving them a legal and ethical mechanism to continue working in the field. The credentialing process, begun in 1989, has resulted in what is known today as Certified Consultant, Association for Applied Sport Psychology (CC-AASP). The purpose of this credential is to confer an organizational stamp of approval on professionals in the field who have met strict training and applied requirements. The person seeking certification must possess, among other things, a doctoral degree, be in good standing as an AASP member, and complete 400 h of supervised practical experience. In addition, he or she must demonstrate proficiency in a variety of intellectual domains including intervention, performance enhancement, the social psychology of sports, biomechanics, psychological assessment, biological bases of behavior, and research design and statistics. Of the ~1000 members of the organization, 217 members have been accorded certified consultant status.

In summary, the certification allows talented professionals to work in academic and applied settings minus licensure.

The process thus serves a number of purposes including protecting the public, demonstrating that AASP has a strong commitment to quality control within the field, assuring that a system is in place to promote training, assisting in marketing the services of the consultancy, and serving as a stepping stone to being placed on the US Olympic Committee Registry, thus allowing consultants to work with Olympic athletes, coaches, and teams.

Ethics

Briefly stated, the AASP code of ethics consists of an Introduction, a Preamble, 6 general principles, and 25 standards, and they are largely based on the Ethical Principles of Psychologists set forth by the APA (APA, 1992) and amended where needed to address specific ethical issues related to sport psychology. To the credit of the organization's leadership, it is stated that where the AASP code suggests a higher standard than other ethical guidelines or the law, the AASP member should adhere to the higher code.

There is no time or space to deal with all of the facets of the AASP ethics code, but brief discussion of the six general principles is in order. Of paramount importance in any ethical discussion is the licensure and credentialing issue discussed earlier, and once one is on firm ground there, the other six principles become salient. These principles are Competence, Integrity, Professional and Scientific Responsibility, Respect for People's Rights and Dignity, Concern for the Welfare of Others, and Social Responsibility. Restated, these principles require that one practice within one's training and competence, always operate with the highest level of personal and professional integrity, refrain from engaging in any activity that would shed negative life on the profession, respect client confidentiality and privacy, be sensitive to real and ascribed power differentials between oneself and others, and be respectful at all times with regard to one's obligations to one's community and to society as a whole.

One of the training issues confronting the field at present is the institution and operation of academic courses devoted to ethical practice. For example, Watson et al. (2006) reported that two-thirds of the graduate programs they surveyed required such training, though most often the ethical issues were imbedded in the subject matter of other courses in the curriculum. Producing ethical practitioners might be improved upon if courses specifically addressing the topic were implemented in lieu of the more hit-or-miss approach in place today.

Image of the Profession

As noted elsewhere, the profession of psychology was plagued for a time with the poorly trained, the incompetent, and the charlatans, and to some extent exercise and sport psychology got caught in that same net. Promises were made to professional sports teams that could not possibly be met, the public was fed a steady diet of fads and frills about what the field could do, and the end result of this was slow growth in the acceptance of sport psychology as a valid discipline. Even among academic clinical psychologists, there was some agreement with the sentiment of one respondent to our questionnaire

who stated that "Sport Psychology is a Flash in the Pan, Soon to Die" (LeUnes and Hayward, 1990).

There has been an increasing acceptance in the past decade of what exercise and sport psychologists have to offer. Part of this change is due to greater awareness among the general public of what both psychologists and those who work in the subdiscipline of exercise and sports have to offer. Also, there has been a burgeoning interest among professional athletes, particularly golfers, owners of professional teams, and administrators and coaches within university athletic departments in having the expertise of a licensed psychologist or certified sport consultant available within their domains. Newspaper headlines are increasingly making reference to sport psychology applications in a variety of settings, and most of the publicity has been positive. Overall, there seems to be a substantial and positive change throughout sports operations and the general public in their acceptance of sport psychology principles and practice.

Employment Opportunities

It is not unusual for professors with expertise in sport psychology to be approached by students and athletes wanting to know what they can do to prepare themselves for a career in sport psychology. My standard response is to (1) assure them that it is an exciting profession and (2) make sure they understand that job opportunities are, at best, sparse and that there are two major strategies they can employ to carve out their own niche. One is to earn the Ph.D. degree in a Kinesiology of Psychology program and become a professor. The second approach is to obtain the licensure required to become a psychologist, set up a broad practice geared to having enough paying customers to make the practice flourish, devote a part of that practice to athletes, coaches, and teams, and if all goes well over the years, phase out the clients other than those involved in sports, and devote the remainder of one's career to sport psychology. Both of those proposed routes are long term, demanding, and expensive, but afford the greatest likelihood for a sport psychology practice. State laws that allow for subdoctoral licensure, such as Licensed Professional Counselor (LPC), offer an additional opportunity for master's level graduates to eventually set up an independent practice that is psychological in nature while adhering to state law and good ethical practice.

An interesting outgrowth of training in sport psychology is seen in the entrepreneurial efforts of one-time sport psychology professionals such as Dr. David Cook, Dr. Graham Jones, and Dr. Robert Rotella. These three people come from an assortment of training backgrounds but share common roots in sport psychology coupled with a real entrepreneurial flair. They have branched out into the domain of business and industry, taking their sport psychology mental skills package to work with management in corporations such as Bayer, Chrysler, Coca Cola, Compaq, Deutsche Bank, Ford Motor Company, General Electric, Heinz Foods, and State Farm Insurance. Motivating athletes and young management personnel to excellence in performance, however defined, must have some common threads imbedded in good sport psychology practice.

More and more collegiate athletic departments are making use of sport psychological services, and this is opening up some much-needed positions. A leader in this area is the athletic

department at the University of Oklahoma which employs Dr. Nicki Moore as the Director of Psychological Resources for OU Student-Athletes (PROS). Dr. Moore supervises a staff of three doctoral-level personnel, a postdoctoral fellow, and a registered dietitian. Dr. Moore and her staff provide a wide variety of services to include individual, group, and couple counseling, mental coaching to improve performance, coaching consultation, learning disabilities assessment, crisis intervention, career development, and specialized treatment and medical referral. The success of the OU athletic program is legendary, and part of the reason for their success is that they are forward thinking and innovative, placing emphasis on relatively new initiatives such as sport psychology that many other universities may regard as superfluous, too expensive, or not necessary.

The Future of Sport Psychology

The future of the field rests on improvements in training, mentoring, creating additional job opportunities, maintaining and enhancing the image of the field with the various constituencies (i.e., the public, athletes, coaches, athletic administrators, and the larger field of psychology), and being more inclusive and encouraging broader input on the various challenges facing the discipline. AASP and Division 47 are diligent about assessing the current status of the field and where it should go in the future as evidenced by such initiatives as the twenty-fifth Anniversary Survey.

Care should be exercised to ensure that sport psychology is inclusive rather than exclusive. The field is relatively small and everyone tends to know everyone else, and this can lead to insular narrowness of perspective. Care must be exercised by the leadership to make sure these things do not happen. It is tempting to adopt a self-serving 'You scratch my back, and I'll scratch yours' mentality when it comes to choosing the leadership within the two professional organizations, who gets to publish their research in the top journals in the field, and who are the prime movers and shakers. The field will not thrive in the future if it proceeds in this fashion.

The relative paucity of fundamentally sound sport psychology researchers in areas basic to psychology such as conditioning and learning, physiology, biofeedback, and neuropsychological assessment is problematic. A concerted effort should be made to lure some of the better thinkers and doers in these areas into the field. They could provide a breath of philosophical and experimental fresh air and thus infuse new life into sport psychology. The field is blessed with an abundance of good social psychologists of sport, assessment experts, and capable performance enhancement practitioners, but a few hard-core, well-trained psychologists with alternate areas of expertise would be a most welcome addition.

Sport psychology professionals need to be alert to practitioners purporting to enhance sports performance through exaggerated claims about various applications of biofeedback. Where unfounded claims about the efficacy of biofeedback are made, there should be challenges lodged against them at every turn. It is seductive to hook an athlete up to sophisticated electronic devices with their assortment of wires, sensors, electrodes, monitors, and thermometers, and pass off resulting

observations as proof of the efficacy of biofeedback procedures in promoting athletic success. If a procedure is promoted enthusiastically as hard-core science, looks every bit the part, has an element of mystery to it, is couched in fancy scientific terms that laymen or athletes really cannot understand, and produces glitzy visions on a computer screen or a flashy, multicolored digital printout, it must be good. There are instances in which unwarranted claims are made that simply stretch credibility and are inconsistent with good science and practice.

The field of sport psychology is alive and well. Its image is on the ascent, there is some forward movement in the job market, training models are constantly improving, territorial disputes over who 'owns' sport psychology appear to be subsiding, and athletes, coaches, and organizations are increasingly seeking sport psychology services. The future looks bright.

Expectation

V Hoorens, Katholieke Universiteit Leuven, Leuven, Belgium

© 2012 Elsevier Inc. All rights reserved.

Glossary

Affective forecasting The prediction of one's future moods and emotions.

Comparative optimism The belief that one's future will be better than the future of other people or of the average individual.

Confirmation bias The tendency to selectively search or focus on information that is consistent with one's prior expectation.

Expectancy-value model A model that describes human motivation as a function of people's beliefs about the likelihood that actions will create outcomes and about the subjective value or utility these people associate with the relevant outcomes.

Expected utility The expected subjective value of an outcome.

Linguistic expectancy bias The tendency to describe expected behaviors in more abstract terms than unexpected behaviors.

Overconfidence effect An unwarrantedly strong confidence in the accuracy of one's own predictions.

Self-defeating prophecy An expectation that affects the holder's behavior in such a manner that this very behavior prevents the expectation from coming true.

Self-fulfilling prophecy An expectation that affects the holder's behavior in such a manner that this very behavior makes the expectation come true.

Stereotype threat The unfavorable effect on an individual's performance of this individual's awareness of a negative stereotype about his or her group in the relevant performance domain.

Subjective probability The perception of the likelihood by which an event or behavior will occur.

Definition and Types of Expectations

An expectation is a belief about events or behaviors that will occur or that will be revealed in the future. The objects of event-related expectations may be identifiable events (specific expectations, e.g., about an economic recession, about good weather), life in general, or the future in general (generalized expectations, e.g., about whether the future will be pleasant or unpleasant, or about whether important outcomes are generally controllable or uncontrollable). The objects of behavioral expectations may be overt behaviors (e.g., giving money to charity, attending a class) or covert behaviors (e.g., feeling happy, needing company) shown by the individuals who hold the expectations themselves or by third persons.

Behavioral expectations about the self need to be distinguished from other types of future-oriented thinking, such as aspirations, wishes, behavioral intentions, and fantasies. Aspirations and wishes are the goals people hope to achieve rather than the goals they believe they will achieve. Behavioral intentions concern the actions people decide they will undertake rather than the actions they believe they will undertake. In fantasies, people pretend that something happens or that they perform some action rather than believe that it will truly happen or that they will perform it.

Expectations may occur in relationship to various aspects of events or behaviors, such as these events' or behaviors' nature, their likelihood (i.e., the events' or behaviors' subjective probability or likelihood), their subjective value (i.e., the events' or behaviors' predicted or expected [subjective] utility), their consequences, or their duration. All these expectations may be either purely descriptive or normative. Descriptive expectations merely state what, according to the individual holding these expectations, will happen or will be revealed. Normative expectations

also state what, according to the individual holding them will happen yet with the prescriptive connotation that for logical, social, or moral reasons it should happen. Normative expectations are therefore closely related to norms.

Role of Expectations in Human Behavior

Expectations are involved in almost any kind of human behavior. They play a particularly important role in learning, motivation, decision-making, affective responding, and social interaction.

Learning

Signal learning, the prototypical form of classical conditioning, implies learning that the occurrence of a mundane stimulus predicts the subsequent occurrence of another, more meaningful stimulus. Instrumental or operant learning implies learning to expect rewards or punishments for specific behaviors. Signal learning also gives rise to generalized expectations about the predictability of important events, while operant learning gives rise to generalized expectations of controllability. Both generalized expectations have even been shown to crucially affect the well-being of both humans and animals. For instance, at the core of the learned helplessness phenomenon lies a generalized expectation of not being able to control important events in the future.

Motivation

The central role of expectations in behavior is also reflected in so-called expectancy-value models of motivation that assume

that people make choices on the basis of the subjective expectancy of attaining (or not attaining) given outcomes through a behavioral choice and of the value they place on attaining (or not attaining) these outcomes. The individual's motivation to show some behavior depends on the multiplication of these two factors. Some famous expectancy-value models of behavior are Tolman's expectancy theory, Eccles' expectancy-value theory of achievement motivation, and Pekrun's control-value model.

Decision-Making

People make decisions based on their expectations both concerning their future preferences, tastes, feelings, and needs and concerning the likelihood of events, situations, and behavioral outcomes. One theory that formalizes the role of expectations in decision-making is prospect theory. This theory states that people choose between behavioral options on the basis of the expected subjective utility of each alternative's outcome weighed by the subjective probability of these outcomes. An outcome is conceived of as a change relative to a reference point (i.e., as a loss or a gain) rather than as a state. The subjective utility of an outcome therefore depends on both the reference point and on the magnitude and the direction of the change. However, not all differences between outcomes are created equal. The further away two outcomes are from the reference point, the smaller the difference in subjective utility between them normally is. For instance, the difference between gaining \$5 and gaining \$10 'feels' larger (in more formal terms: corresponds to a greater difference in subjective utility) than the difference between gaining \$50 and gaining \$55.

The expected subjective utility of a loss or gain is a function of the outcome's subjective utility adjusted for temporal distance. The more distant an outcome seems, the weaker its positive or negative value is (temporal discounting). Having to wait some time for a pleasant outcome renders that outcome less attractive than knowing that the outcome will arrive any moment. Similarly, knowing that an unpleasant outcome will only happen after some time renders it less aversive than knowing that it will arrive any moment. However, temporal discounting is generally steeper for losses than for gains. Postponing an unpleasant outcome reduces its expected aversiveness to a larger extent than postponing a pleasant outcome reduces its expected attractiveness. By consequence, outcomes that carry both advantages and disadvantages (i.e., outcomes that may be viewed as gains in some respects but as losses in other respects) often seem more attractive (or less unattractive) when they are envisioned in the distant future than when they are envisioned in the near future. This phenomenon may give rise to preference reversals, with one option seeming more attractive than another at some point in time (e.g., with the prospect of helping a friend move some weekend next spring seems more attractive than spending that weekend reading on the beach) but becoming less attractive as the relevant event comes nearer (e.g., with the prospect of spending the weekend reading on the beach becoming more attractive than helping the friend move on the Friday before it is all supposed to happen).

Apart from expected utilities, the subjective probabilities or the expected likelihoods of events and behaviors also affect

decision-making. Various biases occur in people's estimation of these likelihoods. For instance, people tend to overestimate small likelihoods and underestimate high likelihoods. They also associate higher likelihoods with desirable outcomes than with undesirable outcomes and lower likelihoods with undesirable outcomes than with desirable outcomes. At the same time, people seem to be quite able to produce accurate estimates of likelihoods. In general, it seems that people are better able to estimate likelihoods when they are allowed to do so in a format that they would spontaneously use (e.g., by estimating frequencies of occurrence) than when they are forced to use a nonspontaneously used format (e.g., by estimating probabilities).

Affect

In the domain of moods and feelings, it is generally believed that affective responses to events and behaviors sometimes depend on people's expectations about how these events or behaviors will make them feel and on how their actual experiences depart from their expectations (cf. the affective expectation model). According to the affective expectation model, both assimilation and contrast effects may occur. People's affective responses to an event or a behavior may be assimilated to these people's prior expectations about how they will feel if the stimulus information they perceive does not differ too much from the stimulus information they expected. In these cases, people's affective reactions resemble the affective reactions they had expected more than they would have done without the relevant expectations. For instance, an audience may have more fun viewing a moderately funny movie when this audience had previously expected to see a funny movie (and hence to have fun) than when the audience had expected to see a not-so-funny movie. If, however, the stimulus information so strongly departs from the expected information that the discrepancy gets noticed, contrast effects occur. In these cases, people's affective reactions differ from the affective reactions they had expected more than they would have done without the relevant expectations. For instance, an audience may have less fun viewing a moderately funny movie when this audience had previously expected to see a wildly funny movie (and hence to have tremendous fun) and when the audience notices that the movie departs from this expectation than when the audience had expected to see a not-so-funny movie.

This view that expectations influence affective reactions is at the basis of various models of consumer satisfaction in which satisfaction is believed to be a function of the confirmation versus disconfirmation of expectations. These models generally indicate that consumer satisfaction is highest when prior expectations are surpassed and lowest when expectations remain unfulfilled. As such, setting rather low expectation standards may, to some extent, enhance consumer satisfaction, whereas setting high expectation standards may reduce it.

Social Interaction

People's behavioral choices in interdependence situations are affected by their expectations about how the others involved will behave. Interdependence situations occur in group settings when the outcomes of group members' behaviors depend on

how the other group members behave so that each group member affects and is affected by others. For instance, when students work together on a group project, each student's efforts may contribute toward a good grade, yet whether or not the effort of this individual student will ultimately prove useful depends on the work of the other students in the group as well. In interdependence situations like these, expectations about the behaviors of others may affect behavior in various directions. When people share a common good, the expectation that others' contributions will be sufficient to build and maintain the common good may lead them to consume from the common good without contributing to it (free riding). Similarly, when people work on a group task, the expectation that others will work sufficiently hard sometimes leads them to invest less effort (social loafing). Ironically, the expectation that others will insufficiently contribute may also inhibit contributions out of fear of being taken advantage of. Only in specific cases (usually implying strong group cohesiveness) will the expectation that others will perform poorly or not contribute induce harder work and larger contributions (social compensation).

Sources

Expectations about events may derive from an individual's previous experiences with the relevant events or with similar events. They may also be based on verbal or numerical information individuals receive about other people's experiences or even on their purely cognitive constructions or intuitive rules-of-thumb (named heuristics). To estimate events' likelihoods, for instance, people may use statistical information to some extent. However, they also apply heuristics such as the availability heuristic (if I can easily remember or imagine examples of it, it must be likely). Moreover, people sometimes judge an event's likelihood on the basis of whether they can figure a mechanism or scenario leading up to the event. One consequence is that when people are able to causally explain why given events might occur, their likelihood estimates for these events may be enhanced. This effect occurs even when people are aware of the fact that the events they have just explained were purely hypothetical.

Similarly, interpersonal behavioral expectations may derive from the observer's previous experience with the actors (the individuals whose behaviors are being predicted) as well as from implicit personality theories, stereotypes (including those associated with social roles), and projection from the observer's own behaviors. For instance, an individual's social values (e.g., individualism, competitiveness, altruism) have been shown to predict the social values according to which he or she expects others to behave in interdependence situations.

Because people possess an unequalled basis of knowledge about their own overt and covert behaviors as compared to what they know about others, it would seem that their expectations about their own behaviors depend on their actual experiences rather than on stereotypes or on intuitive theories of personality and affect. Yet, it seems that even self-related expectations are based on theories and stereotypes. For instance, women may expect to experience mood swings caused by their hormone cycle because they have heard about the emotional effects of hormone-level changes on women.

Even if people process information without any prior expectations to guide them, expectations that arise online (i.e., while people are encoding the incoming information) may affect their interpretation of subsequent information elements. For instance, when people receive a variety of information about some other individual, the behaviors or personal characteristics that they encounter first may create an initial impression. This initial impression then serves as an expectation about the individual's other behaviors and characteristics. The primacy effect (i.e., the phenomenon that initial information weighs relatively heavily on general impressions) is a case in point. One situation in which a primacy effect may occur is when emerging expectations lead people to interpret subsequent elements in a manner that is partial to their first impression.

Measurement

Expectations are typically studied by asking people about them. Participants in studies are invited to verbally describe (either in their own words or, more frequently, using rating scales) what they think will happen or what they or others will do, how pleasant or unpleasant they think these future events or behaviors will be to them or to others, how likely they believe the events or behaviors are, or how long they think events or behaviors will last. The main problem with this approach is that verbal self-descriptions are vulnerable to self-presentation tendencies (including social desirability). When researchers use rating scales to facilitate participants' responding, their approach is also vulnerable to issues surrounding scale interpretation. People may differ in how they interpret specific response alternatives and hence how they view scale ranges. In addition, these interpretations may change over time. The latter problem is particularly troublesome in prospective studies on the accuracy of expectations.

In prospective studies about how well people's expectations match their actual experiences, researchers ask participants about the events or behaviors they expect. Later on, they either ask participants about the events or behaviors that have actually occurred or collect external data concerning the occurrence of these events or behaviors. To the extent that their original ratings differ from their later ratings, the expectation is said to have been inaccurate. Yet, participants' ratings may differ not because their expectations were off the mark but because these participants' scale use has changed. For instance, maturation may have taught them not to use extreme response alternatives lightly.

In retrospective studies about how well people's expectations match their actual experiences, researchers either ask participants about events or behaviors that have actually occurred or collect external data about the occurrence of these events or behaviors. They then ask participants about what they had expected concerning these events or behaviors. The main problem with retrospective studies is that people's ratings of how pleasant or unpleasant they had expected an event to be may resemble how they rate the event after it actually happened not because their expectation was spot on but because the hindsight bias (the tendency to view past or current events as more predictable than they were before they

occurred, also known as the “I knew it all along effect”) affects their reconstruction of their prior expectations.

Cross-sectional studies compare people’s expectations of how they will experience events in the future with how other people actually experience these events at the same time. When researchers use these designs, they ask one group of participants who face a given event about their expectation and another group of participants who have experienced the same or a similar event about their experience. One weakness of cross-sectional designs is that it may be hard to find comparable samples or to optimally match the expected versus experienced events and that error variance due to individual differences may obscure within-individual discrepancies between expectations and experiences.

Accuracy and Biases

In general, accurate expectations help people to prepare for events and to adequately respond to events and other people’s behaviors. As shown by research within a functional perspective of Pavlovian conditioning, for instance, the most important outcome of signal learning is not that learners develop responses to conditioned stimuli but rather that their responses to the unconditioned stimuli are optimized, with aversive stimuli evoking weaker negative responses and appetitive stimuli evoking stronger positive responses.

However, a few notable exceptions to the rule that expectations help prepare for reality have been identified. In academic learning situations, for instance, expecting recognition tasks negatively affects memory performance both on recognition and recall tasks. The most plausible explanation seems to be that people view recognition tasks as easier than recall tasks. Even though this perception is accurate to some extent, the overestimation of the difference leads people to invest less effort on the preparation (i.e., the encoding and subsequent rehearsal of stimulus materials) in recognition tasks than in recall tasks.

The accuracy of people’s expectations obviously depends on the specific characteristics of the objects of these expectations, of the individuals who hold them, and of the context surrounding the events and behaviors. Despite this variability, however, various tendencies have been identified that generally characterize people’s expectations.

One general characteristic of people’s expectations is that in the absence of any information about upcoming experiences, people tend to expect that these experiences will be moderately positive. Ironically, this expectation creates negativity effects. People’s rosy expectations indeed make negative information stand out and seem both more extreme and more informative, thus allowing this information to disproportionately weigh upon their overall evaluations. In the domain of consumer satisfaction, the consequence of the negativity effect is that the mere expectation of having to evaluate products or services renders people’s evaluation more negative by having them focus more than they would spontaneously do on potentially evaluation-relevant information.

Expectations about the subjective utility of future outcomes are often characterized by a so-called projection bias. This bias implies that whereas people do realize that their future tastes,

needs, and circumstances will differ from their present ones, they underestimate the magnitude of this difference. Hence, they overestimate the extent to which future subjective utilities will resemble current subjective utilities. For instance, in a hungry state, people often prefer candy-like snacks (such as chocolate bars and crisps) over fruit snacks (such as apples or bananas). When people choose a snack to consume in a week’s time, their selection therefore depends on whether they expect to consume the snack at a time at which they may reasonably expect to be hungry (e.g., late in the afternoon) versus at a time at which they may reasonably expect not to be hungry (e.g., immediately after lunch). Interestingly, however, people’s predictions also depend on whether they are hungry at the moment they make the choice regardless of whether they may expect to be hungry at the moment of consumption. This finding shows that people project their current situation (and hence the current subjective utility of outcomes) onto the future.

The projection bias is closely related to biases in affective forecasting. To the extent that expected utilities are directly related to affective responses to events, it may even be viewed as an affective forecasting bias. Another of these biases is the overestimation of the emotional impact of future events. This so-called impact bias has various causes. First, people tend to think about future events as if these will happen in a vacuum rather than in the midst of many other events and experiences (focalism or the focusing illusion). Second, people fail to appreciate the essentially comparative nature of human judgment. On the one hand, people fail to appreciate how strongly their standards of evaluation may change under the influence of their previous experiences (neglect of change in adaptation level). On the other hand, they fail to appreciate how strongly their judgments will depend on social comparison. Third, people also ignore the extent to which they will psychologically transform the event into something less extremely positive or less extremely negative after it happened (neglect of ordinization and of psychological immune reactions). It should be noted that people not only overestimate the impact of events as compared to the actual impact events generally have, they also overestimate the impact of events as compared to these events’ impact on others. People generally believe that bad things will make them suffer more and that good things will make them happier than others.

In the domain of behavioral expectations, people generally underestimate how strongly situational factors will affect other people’s behaviors and particularly how these situational factors will affect their own behaviors. Among the situational influences that people generally underestimate are social influences. People underestimate how strongly others will be affected by a unanimous majority (and hence show behavioral conformism), by an authority (and hence show obedient behavior), or by the mere presence of others (and hence show social facilitation and inhibition).

In addition, people’s expectations about future events are generally overoptimistic, both as compared to these events’ objective probabilities (implying that people believe that desirable outcomes are more probable and that undesirable outcomes are less probable than is objectively warranted) and as compared to how they view the probabilities of these events in other people’s future. Apart from expectations about events,

comparative optimism also characterizes behavioral expectations in that most people believe that they are more likely to perform morally desirable actions in the future than others. The planning fallacy, implying that people underestimate the time they will need to complete projects, may be viewed as an example of overoptimism and comparative optimism at the same time. People indeed underestimate the time they will need to complete projects but do not (or to a lesser extent) underestimate the time other people will need to complete their projects.

Despite biases like these, one intriguing characteristic of expectations is that they tend to get validated more frequently than would rationally be warranted. One reason is the confirmation bias (also known as 'positive test strategy') that leads people to focus on, overweigh, and selectively search information that confirms their expectations. In addition, expectations guide the interpretation of vague or ambiguous information. The process of selectively seeking and interpreting information results in the apparent confirmation of expectations, a phenomenon that is known as perceptual confirmation. In addition, interpersonal expectations may lead observers to behave in such a manner that they evoke the expected behaviors in those about whom the expectations exist. This phenomenon is known as behavioral confirmation.

Meta-Characteristics

Expectations are not only characterized by their contents and their validity. People may hold them with varying degrees of confidence and experience them at varying levels of concreteness and elaboration. Studies on such 'meta-characteristics' of expectations have yielded intriguing insights.

Overconfidence and Inferences of Trustworthiness

One characteristic of many expectations is that they are held in an overconfident manner. This overconfidence effect implies that people generally overestimate the accuracy of their expectations. In addition, people infer the trustworthiness of other people's expectations partly from these expectations' preciseness. For instance, they find communicators more trustworthy if these communicators provide point estimations of probability (i.e., one numerical value) than if they provide interval estimations (i.e., a numerical value accompanied by the range of numerical values between which the probability may vary). This is counternormative because the so-called confidence intervals generally provide more information (namely, by acknowledging the degree of uncertainty surrounding the estimation) and are more likely to be accurate than point estimations.

Abstraction and Temporal Distance

One particularly intriguing characteristic of expectations is that their level of abstraction depends on the temporal distance of the expected events or behaviors. The more distant an event or a behavior seems to be in the future the more abstract or high level its construal tends to be in that it includes general, essential, or overarching characteristics. The nearer an event or a

behavior seems to be in the future the more its construal includes contextual, incidental, or concrete details.

This apparently simple idea is at the core of construal-level theory. It carries a variety of implications. One implication has to do with how the expected event or the expected behavior itself is conceived of. Expectations about the distant future tend to be simpler, more prototypical, and less diverse than expectations about the near future.

In the case of behaviors, it is important to note that behaviors may be described at different levels of abstraction, with trait inferences that are based on them representing the highest level and with mere descriptions of directly observable actions representing the lowest level. Reflecting the more abstract nature of expectations for the distant future than for the near future, people expect that other people's behaviors in the distant future will depend on these other people's traits more strongly and hence show a higher cross-situational consistency than other people's behaviors in the near future.

In addition, people's expectations about the subjective utility of temporally distant events and behaviors mostly depend on these events' and behaviors' overarching and central characteristics. In contrast, their expectations about the subjective utility of temporally near events and behaviors also depend on the events' subordinate and noncentral characteristics. By consequence, changes in evaluation and sometimes even preference reversals may occur as distant events come nearer.

A further and counterintuitive implication of the relatively abstract representation of distant events and behaviors has to do with these events' and behaviors' subjective probabilities. People are more convinced that their expectations for the distant future will be borne out than they are about their expectations for the near future. Finally, the relative abstractness of future expectations affects the expected variability in them. People expect less variability in the distant future than in the near future. When predicting other individuals' behaviors, for instance, people expect these others to behave more consistently across situations in the distant future than in the near future.

Cognitive Effects of Expectations

The Identification of Behaviors and Events: Assimilation and Contrast

Expectations affect the interpretation of information. Their effects have mainly been demonstrated in the field of perception and social judgment. For instance, when observers compare suspects to facial composites, they may expect that a given suspect is guilty (e.g., because witnesses have identified him or her). This expectation can lead them to view a greater similarity between the composite and the suspect, even when they deny that it affects their judgment. Expectations' effects also occur in other domains, such as visual perception (with context-based expectations affecting the interpretation of ambiguous patterns), the perception of physical symptoms (with the expectation of a physical symptom leading people to interpret any physical experience in terms of that symptom), and the perception of covariation (with the expectation that two variables covary leading people to perceive a nonexistent association or to overestimate an existing association, better known as illusory correlation).

When expectations affect information processing in such a manner that the cognitive elaboration of (including perception, interpretation, and judgment) events and behaviors or the affective responses to these events and behaviors is distorted in the direction of the expectation, assimilation is said to occur. Assimilation predominantly happens when the incoming information is vague, ambiguous, incomplete, or mixed. In these cases, expectations are used to clarify or disambiguate the information, to fill in the gaps, or to make a choice between conflicting interpretations and conclusions.

Contrast effects are said to occur when the cognitive elaboration of an event or behavior is distorted away from the expectation. Such contrast effects predominantly occur when the incoming information is clear and unambiguous and when observers strongly focus on the incoming information (e.g., when they are driven by a strong need for cognition). Because most information is open to interpretation, contrast effects tend to occur less frequently than assimilation effects. Yet, contrast effects have been demonstrated in affective responses.

People may be (partly) aware of how their expectations affect their interpretation of incoming information. In these cases, they may try to correct their impressions and responses for the biasing effect of expectations. As a consequence, expectation effects typically occur when people have lowered their defense against them, for example, when they believe that the incoming information is rich enough to overcome undue expectations. When people do try to correct for expectations, on the other hand, overcorrection may sometimes take place. The assimilation effects that would normally occur then give way to contrast effects or vice versa.

One consequence of the predominance of assimilation effects is that they help to maintain and even corroborate expectations even in the face of information that objectively contradicts them or that might be construed as contradicting them. For instance, assimilation has been identified as an important factor in stereotype maintenance. When people believe that men are better professors than women, for instance, they may evaluate a lecture given by a man more positively than a lecture given by a woman even if both performed equally well, thus maintaining and even corroborating the stereotype.

Judgment: Expectations as Descriptive and Normative Standards

Expectations may sometimes serve as descriptive comparison standards by which observers judge the new information. As such, they may affect the subjective evaluation of events and behaviors as well as affective responses to them.

In the domain of consumer psychology, buyers' satisfaction with products and services depends on the confirmation versus disconfirmation of prior expectations. It does so in an asymmetrical manner, however, with negative disconfirmations particularly strongly predicting dissatisfaction.

In the domain of person perception, stereotype-based expectations may serve as standards by which individuals' abilities, behaviors, and life circumstances are being judged. When differential expectations lead to different standards being applied to different individuals, these expectations may codetermine the subsequent judgments, for instance, group stereotypes may

give rise to expectations about how group members behave or about the situations in which these members live. Any individual group member's behavior or situation may then be judged by comparing it to the expectation that is associated with his or her group. When women are expected to show low levels of aggressiveness and men are expected to show higher levels of aggressiveness, for instance, any woman's aggressiveness is judged by comparing it to a low-aggression standard and any man's aggressiveness is judged by comparing it to a high-aggression standard. The same behavior may then seem aggressive when shown by a woman (because it is above the normative expectation for women) or as nonaggressive when shown by a man (because it is below the normative expectation for men).

Group-specific expectations may create paradoxical consequences in the comparison of above-average members of a group that is expected to score low on a given dimension and below-average members of a group that is expected to score high on the same dimension. The former individuals may then be judged to score higher on the dimension than the latter individuals do, even if their score is objectively lower. For instance, women who behave more aggressively than expectations for women would predict may be judged as behaving more aggressively than men who behave less aggressively than expectations for men would predict even if by any objective standards the women's behavior is less aggressive than the men's.

Apart from serving as descriptive standards, it should be noted that expectations may also serve as normative comparison standards. This is particularly evident in the case of behavioral expectations, with expectation-confirming behaviors being judged as normal and appropriate and with expectation-disconfirming behaviors meeting with disapproval. For instance, the expectation that women behave less aggressively than men may give rise to the normative prescription that women should behave nonaggressively and that men should behave aggressively. A woman behaving aggressively and a man behaving nonaggressively may then be socially sanctioned.

Causal Attribution

When their expectations are contradicted, people are more likely to engage in causal thinking than when their expectations are met. Unexpected events or behaviors thus evoke more causal attribution than expected events and behaviors. This particularly holds true for events and behaviors that depart from the prior expectations in an undesirable sense. In this case, causal reasoning often takes the form of counterfactual reasoning contrasting alternative series of events to what has actually happened ('what if...').

One implication of the effect of expectations on causal reasoning is that the extent to which people causally explain events or behaviors reveals to some extent whether they had expected these events or behaviors. Within this context, for instance, the notion 'stereotypic explanatory bias' has been coined to describe the relative tendency to explain stereotype-inconsistent behaviors and to leave stereotype-consistent behaviors unexplained. The stereotypic explanatory bias has been at the basis of the development of a measure of stereotypes that does not require asking people about their stereotype-based

expectations (a so-called indirect or implicit measure of expectations). Like other indirect measures, it is particularly useful to avoid the social desirability concerns that often plague self-report measurements.

Recognition and Recall

In apparent contrast with the finding that expectation-inconsistent information tends either to get overlooked or to get distorted, memory is generally better for expectation-inconsistent information than for expectation-consistent information. This finding holds both for recall and recognition measures. The sole exception consists of recognition measures that are not corrected for response tendencies. Probably due to guessing strategies, these measures show an advantage for expectation-consistent information above expectation-inconsistent information. The advantage for expectation-inconsistent information that all other measures reveal seems to be due to expectation-inconsistent information being processed in a deeper or more elaborate manner than expectation-consistent information.

Expectations and Verbal Communication

Apart from affecting the perception of expected and nonexpected events and behaviors, expectations may affect how observers communicate about these events and behaviors. As compared to nonexpected behaviors, people tend to describe expected behaviors in more abstract terms (the linguistic expectancy bias).

One measurement of the abstractness of a description hinges on the verbs and adjectives being used, with descriptive action verbs (describing an observable overt behavior, usually implying an invariant physical element) representing the most concrete level and with adjectives representing the most abstract levels. The intermediate levels are represented by interpretative action verbs (describing a broader semantic category to which an observable overt behavior belongs) and state verbs (describing internal states) and, in some conceptualizations, by mixed types of verbs. Imagine, for instance, that an observer views a female passer-by slap a male soccer hooligan. The observer may describe the incident as 'she slapped him' (descriptive action verb), 'she abused him' (interpretative action verb), 'she hates him' (state verb), or 'she is aggressive' (adjective). Interestingly, the more the observer had expected the behavior the more abstract his or her description generally is. In the example described previously, the observer is more likely to use concrete verbs to describe the scene than if he or she had viewed a male soccer hooligan slapping a female passer-by.

The effect of expectations on verbal communication is important because it facilitates the interindividual spreading of expectations. As compared to concrete descriptions, abstract descriptions do not only communicate that the speaker or writer expected the event. On an implicit level, it also suggests that the listener or reader should in turn expect the behavior.

Interestingly, the more abstract a description is the more evidence it seems to be based on. As compared to communication about unexpected behaviors, therefore, communication

about expected behaviors suggests that it is based on a larger informational basis. In addition, abstract descriptions are harder to verify or to falsify than concrete descriptions are. Whenever a message refers to a directly observable behavior, readers or listeners may easily determine whether it is truthful or not. If, in contrast, a message refers to a broader semantic category of behaviors, nonobservable behaviors, or personality characteristics, it is much more difficult for readers and listeners to prove that it is true or that it is false. Because people generally assume that interpersonal messages are truthful unless proven otherwise, communications about expected behaviors thus get accepted more easily (because it is more difficult to falsify them) than communications about nonexpected behaviors do.

Apart from affecting the verbalization of behaviors, expectations may also affect how listeners or readers decode verbally described events and behaviors. This effect is particularly well documented in the case of natural language quantifiers such as the ones that are used to verbally describe probabilities. A word like 'probable' may be interpreted as denoting different probabilities depending on whether it is used to describe events that *a priori* seem likely versus to describe events that *a priori* seem unlikely. For instance, the statement that 'it will probably rain tomorrow' may be interpreted by listeners or readers as denoting a much higher likelihood when the forecast is about the weather in Belgium than when it is about the weather in California.

Expectations Affect Reality

Perhaps the most intriguing characteristic of expectations is that they may make themselves come true. Among the best known manifestations of this phenomenon is the treatment belief effect (better known as the placebo effect) that is said to occur when the expectation that a treatment will work in itself induces improvement. However, expectations affect reality in a variety of other situations as well. Interpersonal expectations sometimes lead observers to behave in such a manner that they encourage or even evoke the expected behaviors or performances in others. One well-known example of such interpersonal self-fulfilling prophecies is the so-called Pygmalion effect, indicating that individuals about whom high expectations exist do show an improved performance. The Pygmalion effect has been extensively studied in the context of teacher expectations, with the scientific consensus presently being that teacher expectations do affect pupil performance in a robust manner yet to a typically small extent. Yet, self-fulfilling prophecies are also involved in demand effects (also known as experimenter bias, occurring when an experimenter evokes the expected behaviors in participants) in studies with both human and animal participants.

One particularly intriguing manifestation of a self-fulfilling prophecy is stereotype threat. This phenomenon occurs when a negative stereotype evokes a stereotype-consistent bad performance in members of the stereotyped group. In order for it to occur, a set of conditions must be met. First, group members must be aware of the negative stereotype that exists about their social group (e.g., women must be aware of the stereotype saying that women are worse at mathematics than men are).

Second, their group membership must be salient, either because it chronically is or because situational cues draw the group members' attention to it (e.g., women having heard sexist jokes or having seen sexist commercials). Third, group members must be aware of the fact that the task at hand calls on the ability that their group supposedly lacks (e.g., women knowing that a test they take measures mathematical ability). Fourth and finally, the relevant achievement domain must be personally important to them (e.g., women who wish to pursue a career in mathematics). When these conditions are met, group members may underachieve as compared to a situation in which they are not met and as compared to other groups.

The opposite of a self-fulfilling prophecy is a self-defeating prophecy or an expectation that falsifies itself. Self-defeating prophecies have been studied less intensely than self-fulfilling prophecies. One example of how expectations may both validate and falsify themselves is to be found in the domain of affective expectations. These expectations affect actual emotional experience such that either assimilation effects (with the actual experience being more similar to the expected one than if the expectation had not existed) or contrast effects (with the actual experience being more dissimilar to the expected one than if the expectation had not existed) may occur.

Conclusion

Expectations are ubiquitous in human behavior. The frequently occurring impression that one's expectations are borne out may be due, at least in part, to the sometimes distorting effects of expectations on behavioral, affective, and cognitive processes. However, the mere existence of successful instrumental and classical learning processes reveals that people can and do develop adequate expectations.

Glossary

Correlation A statistical method for determining the degree and direction of relationship between psychological variables.

Extraversion A major personality dimension that includes measurable traits such as sociability, activity, and dominance.

Factor analysis A statistical technique that combines clusters of correlated variables into broader categories.

Personality A field of study that focuses on describing individual differences in human behavior and identifying the causes that characterize our unique ways of thinking, feeling, and acting across situations.

Traits Relatively consistent and enduring ways of thinking, feeling, and behaving.

Extraversion: An Overview

Alison and Milla are a study in contrasts. Both young women have entered their first year of university and have been assigned to share a room in the university residence. Alison is described as a ‘bubbly’ person, full of charm and wit – a real go-getter. She is active in many campus clubs and can always be found with a group of friends. She enjoys dancing and lively music, plays various team sports, loves to travel, and seems willing to try most things at least once. She is well liked and popular and often at the center of events. She has indicated that she would enjoy work that has lots of action and change to it rather than an office job.

In contrast, Milla is a somewhat shy and retiring person who is much more content to work on her studies in the library or at her desk in the residence. She prefers quiet meals and going to movies or reading a book to the more outgoing activities of her roommate. She is not especially well known by fellow students as she tends to move rather quietly from class to class. She has several close friends whom she knows from her public school days. Her expectation is to major in history and English, and author books or work as an archivist.

Whatever commonalities and differences exist between these two people, one particular personality dimension comes to the fore. The various behaviors, actions, and preferences would suggest that Alison and Milla vary along the personality continuum defined as extraversion–introversion. Extraverts, like Alison, manifest a relatively consistent and stable profile, characterized by such descriptors as sociable, lively, active, carefree, and sensation seeking. Milla more clearly falls toward the other end of the continuum, which defines introverts, people who are quiet, reserved, passive, controlled, and less sociable and outgoing.

Extraversion is seen by many psychologists as a major personality dimension that is very important in formulating a description of human behavior and particularly of individual differences. Psychologists have created numerous concepts in an effort to explain, understand, predict, and even change or modify human behavior. But, in order to understand the nature and relevance of extraversion (E), consideration must be given to a number of basic questions that are of critical importance when examining any personality description. The discussion of E that follows focuses on the following themes: historical perspectives, current views of personality, personality measurement, the biological basis of E, cross-cultural studies, and relationships with other human characteristics.

History

Efforts to describe how we both differ from each other and how we are the same certainly predate the development of psychology as a scientific discipline and a profession. In fact, the term personality is derived from ‘persona,’ the Latin word meaning mask that refers to characterization in early Roman theater. Astute descriptions of personality appear in the works of early Greek and Roman philosophers and writers such as Theophrastus and Cicero. The attempt to explain those differences in personality in a systematic way can also be traced to an early period in Roman history, notably in records of Galen of Pergamum (c130–c200 AD), who was a physician to early Roman emperors. The schema that Galen espoused, the humor theory of temperament, was remarkably influential and resilient over many centuries, and indeed, vestiges of this schema are linked to the modern personality description of extraversion.

For Galen, humors were bodily fluids that influenced the health, physiognomy, and character of man. There were four primary humors, *chore* (bile), *melanchole* (black bile), *sanguis*

[†]Deceased.

(blood), and *flegma* (phlegm). These four humors were understood in the context of a general cosmological theory where fire, earth, air, and water were conceived as the four basic elements of all things. As expressions of bodily processes, psychological characteristics were influenced by the particular blend (L. temperare) of the four humors, that is, temperament. For example, steadiness and solidity was thought to depend on black bile (melancholy), whereas simple mindedness came from blood (sanguine). In the analysis of Galen's work that survives today, it is clear that he mainly addressed medical problems. His observations of character were infrequent and bear little resemblance to the adjectives ascribed to the humor categories by later authors. Further, the humor theory as a framework for understanding health issues was displaced by progress in medical science. Nevertheless, as a descriptive personality classification schema, the four temperament categories prevailed during the eighteenth and nineteenth centuries, notably in the work of German philosophers Immanuel Kant and Wilhelm Wundt.

Both Kant and Wundt developed schemas of personality adjectives that expressed the four temperament categories in terms of two concepts. For Kant, the two concepts were feelings and activity. The sanguine temperament was characterized by strong, short-lasting feelings in contrast to the melancholic temperament characterized by weak, long-lasting feelings. The choleric temperament was characterized by intense, but brief activity in contrast to the phlegmatic temperament that was characterized by weak, but enduring activity. This schema yielded four independent temperament categories based on two dimensions. For Wundt, the two concepts were strength of emotion and changeability. Although the two concepts are similar to those employed by Kant, Wundt shifted the emphasis from four independent categories to a two-dimensional system that encompassed the four types. In this schema, the choleric and melancholic are characterized by strong emotion (unstable) in contrast to the sanguine and phlegmatic that are characterized by weak emotions (stable). The sanguine and choleric are characterized by rapid change in contrast to the melancholic and phlegmatic that are characterized by slow change. In terms of semantics, the unchangeable–changeable dimension and the strong–weak emotion dimension in Wundt's schema clearly resemble the extraversion and neuroticism dimensions, respectively, that were developed by Hans Eysenck using modern statistical methods. The relation between the classical four temperament types from Wundt's depiction and Eysenck's results is illustrated, using modern statistical methods of personality description, in Figure 1.

During the early part of the twentieth century, there were significant advances in the application of mathematical concepts to the study of individual differences, which enabled personality description to move from the insightful categorical association of descriptive personality adjectives as discerned by Kant and Wundt to a rigorous, objective clustering of adjectives, using statistical methods. This advance in statistical methods was pioneered by several significant figures, notably Francis Galton, who developed the correlation statistic and Charles Spearman, who developed a procedure, factor analysis, for grouping correlation statistics into a common factor. During this period, the terms introversion–extraversion emerged in the personality description literature, effectively

Figure 1 Representation of the four classical temperaments using Wundt's schema and adjectives from modern descriptions of extraversion (changeable–unchangeable) and neuroticism (stable–unstable).

replacing the terms unchangeable–changeable from Wundt's schema. Although the original introduction of introversion–extraversion in psychological literature is obscure, it is clear that the terms were popularized in the hugely successful writing of the Swiss psychoanalyst Carl Jung. This popularity led several investigators (e.g., J. P. Guilford and R. B. Cattell) to develop psychometric tests of introversion–extraversion. This dimension is prominent in all modern personality classification systems.

Neither Kant nor Wundt offered a causal basis or theory of temperament to replace Galen's humor theory. Early in the twentieth century, there were several scientists who suggested physiological processes to account for differences in the temperament categories. Notably, Ivan Pavlov, famed for his contributions to learning and conditioning theory, applied the neurophysiological concepts of excitation and inhibition to explain the four temperament types. Introversion and extraversion types were included in an all-encompassing theory of personality developed by Carl Jung. In his theory, personality was determined by innate dispositions (instincts), culture, and conscious and unconscious processes. In 1929, from current knowledge of the nervous system, William McDougall outlined a hypothetical chemical theory that presaged our contemporary understanding of the biological basis of introversion–extraversion. In his proposal, greater cortical inhibition, mediated by a hypothetical neurochemical factor, effected the behavioral restraint and reticence exhibited by introverts. A similar course of inquiry blossomed in the biological basis of introversion–extraversion proposed by Hans Eysenck in 1967.

Contemporary Views of Extraversion

Psychologists have been and are still actively engaged in the debate as to whether human personality can be best and most meaningfully described with the aid of only a few or many

'words.' One can very quickly create an exhaustive list of personality descriptors commonly found in the lexicon: for example, happy, bright, friendly, kind, assertive, honest, sullen, patient, etc. At the same time, we can accurately and concisely describe individuals along such major dimensions as extraversion-introversion when we recognize that some human characteristics or behaviors share much in common with others (e.g., shy, withdrawn, nonassertive, not talkative, quiet, loner, etc.). Psychologists' attempts to reduce human behavior to a finite set of descriptions are not an attempt to impose an artificial and nonworkable solution onto a truly complex personality description, but rather, an attempt to find the most meaningful and parsimonious means of representing human personality.

As already described, extraversion has its roots in the early Galen-Wundt theory of the four temperaments but has been more recently elaborated by such notable contemporary psychologists as R. B. Cattell, H. J. Eysenck, L. Goldberg, J.A. Gray, J. P. Guilford, J. Wiggins, and P. Costa and R. McCrae. Extraversion is also included in other personality models but under different names. Further, E scales appear on all of the Eysenck personality measures, beginning with the Maudsley Personality Inventory and Eysenck Personality Inventory to the more recent Eysenck Personality Questionnaire series (EPQ and revised scales such as the EPQ-R and Eysenck Personality Profiler, EPP), where it constitutes one of the three major personality variables.

The description of individuals according to a small number of personality dimensions is frequently referred to as the trait approach. Essentially, through the use of sophisticated statistical techniques, such as correlational and factor analysis, psychologists have reduced the large number of behavioral descriptions to a much smaller number of stable and generalizable characteristics that make possible the explanation and prediction of individual differences and similarities possible. This view rests on the assumption that a meaningful model of personality can be based on a smaller but more powerful set of traits that are remarkably stable across time and differing situations.

Very briefly, E appears as a major personality variable in almost all the current trait descriptions, whether by name or as a result of further research investigations stimulated by these theories. An ongoing debate is whether personality is best described, for example, by the 16 primary traits suggested by Cattell, or the 'big 5' trait dimensions emphasized by Goldberg and Costa and McCrae, or by the '3 super factors' described by Eysenck. A consistent finding from the research studies is the emergence of a robust factor that may be called extraversion. Analysis of large numbers of responses to the various personality questionnaires seems to invariably produce an E factor. The two most influential trait theories today agree that E is one of the major dimensions. Eysenck adds two other major personality dimensions labeled neuroticism (N) and psychoticism (P). Costa and McCrae add neuroticism, openness to experience, agreeableness, and conscientiousness to their extraversion factor to produce the 'big 5' trait dimensions of their Five Factor Model.

Some of this confusion may be clarified by examining how Eysenck has developed his personality model with particular reference to E. His system is a hierarchical one and begins with

single acts or thoughts. The second level focuses on more consistently occurring behaviors and cognitions. Next comes the level of traits and finally types that reflect a composite of various correlated traits. Thus, each level is more encompassing and inclusive than the previous level. With respect to E, it is a dimension that encompasses a number of trait descriptors such as happy, cheerful, sociable, lively, assertive, and carefree. It is the observed intercorrelations between these traits that justify our postulating the existence of extraversion. This structure is shown in Figure 2. Similarly, for the other major high-order concept, neuroticism, traits that intercorrelate and thus define it are shown in Figure 3.

How can we justify such a typology? Table 1 shows six questions supposed to measure E, and six questions supposed to measure N. We can collect large numbers of answers from random samples of the population, intercorrelate the answers, and check whether the patterns of intercorrelations and more parsimonious factor analysis results give us two independent factors corresponding to E and N. Should we obtain the results shown in Figure 4, it is obvious that the results support the theory.

We do not have to rely on self-ratings to obtain such evidence. Figure 5 shows the results of such a factor-analytic investigation of the relation between ratings made of thousands of children in a child guidance clinic, using items of behavior. It will be seen that extraverted children demonstrate conduct problems, and introverted children personality problems. Of course, all of these children are essentially high N scorers; children with low N scores would simply be more outgoing behaviorally when extraverted, and unsociable when introverted.

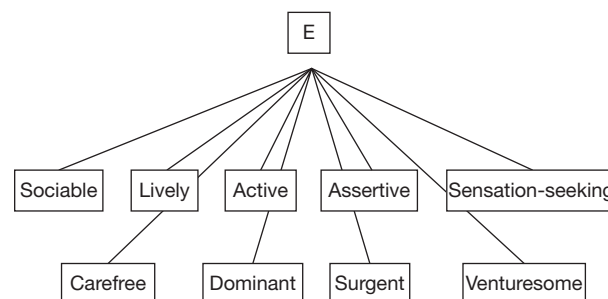

Figure 2 Some traits defining extraversion.

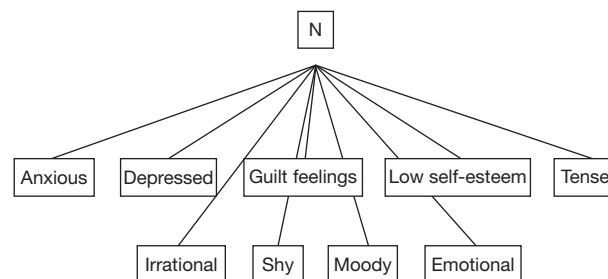

Figure 3 Some traits defining neuroticism.

Table 1 Questionnaire items measuring extraversion–introversion

Questions	Key
1. Do you sometimes feel happy, sometimes depressed, without any apparent reason?	N
2. Do you have frequent ups and downs in mood, either with or without apparent cause?	N
3. Do you worry a lot?	N
4. Does your mind often wander while you are trying to concentrate?	N
5. Are you frequently 'lost in thought' even when you are supposed to be taking part in a conversation?	N
6. Are you sometimes bubbling over with energy and sometimes very sluggish?	N
7. Do you like surprises and spontaneous activities?	E
8. Are you happiest when you get involved in some project that calls for rapid action?	E
9. Do you usually take the initiative in making new friends?	E
10. Are you inclined to be quick and sure in your actions?	E
11. Would you rate yourself as a lively individual?	E
12. Would you be very unhappy if you were prevented from making numerous social contacts?	E

**Figure 4** Relative position in two-dimensional space of six neuroticism and six extraversion questionnaire items.

Jung had earlier put forward the hypothesis that introverted neurotics would present with psychasthenic or dysthymic symptoms (anxiety, depression, apathy), while extraverted neurotics would show hysterical symptoms (hysterical attitude, conversion symptoms). A study of the behaviors and attitudes of hundreds of neurotics bore out this theory as shown in [Figure 6](#). These empirical studies will give an idea of the structure of personality.

A discussion of empirical findings that help us to better understand extraversion follows. It is important to know about the theories and models that psychologists have created to account for and explain extraversion. The most thorough and widely accepted is the theory put forward by the late Professor Hans Eysenck (1916–1997), who spent much of his professional career at the Institute of Psychiatry, University of

**Figure 5** Two-factor representation of conduct and personality problems in children, showing breakdown into extraverted and introverted groups.

London. The ensuing discussion draws extensively from the theoretical and research contributions of Professor Eysenck. A question that is frequently asked is how psychologists measure variables such as extraversion. A number of questionnaires have been developed and are mentioned below. While a description of the structure of personality is important, it is equally important to examine its causes. Extraversion would not be a very useful person description if it only served as a summary label for a collection of human behaviors. Of considerable importance are questions related to whether extraversion is learned or whether genetic factors determine a person's position on the extraversion dimension. What are the biological underpinnings of extraversion, and are there certain brain structures or functions that underlie an individual's behavior along the introversion–extraversion dimension? Further points that must be addressed relate to the robustness of extraversion such as: can it be identified cross-culturally? What extraversion, or any other personality factor, tells us about other aspects of human functioning is of relevance. For example, are extraverts more or less prone to certain psychiatric illnesses? Are there differences in various performance indicators between extraverts and introverts?

Figure 6 Behaviors and characteristics of introverted and extraverted neurotics.

The Measurement of Extraversion

Psychologists employ various procedures for gathering information about human behavior. We may observe a person in a structured situation or in more natural settings. The person may be interviewed or we can ask others to tell us about the person. Various tests can be conducted to determine, for example, how an individual reacts to stressful situations or responds to tasks that require the learning of new behaviors. In some instances, we gather information that tells about the person's internal condition such as the level of cortical arousal (EEG or MRI scans). Various biochemical influences on personality can be examined by extracting samples of hormones such as testosterone and cortisol, or neurotransmitters including monoamine oxidase, dopamine, or serotonin. We may also assess personality with self-report questionnaires. It is this personality test, inventory, or questionnaire method that is most commonly used to assess variables such as extraversion.

Hans and Sybil Eysenck have developed the most well-known and frequently used personality measures of extraversion. Recent versions include the EPQ-R, for which there are both adult and child forms. This questionnaire contains items that are answered with a 'yes' or 'no' and measure the three superfactors of extraversion, neuroticism, and psychoticism. It also includes another scale that measures untruthfulness, faking, or social desirability (e.g., answering questions in a way that presents a supposedly more 'desirable' profile of the

Table 2 Please respond to the following statements with 'yes' if you agree that they more or less describe you. Answer 'no' if the statement is not a reasonably accurate description of you

1. I like loud music
2. I would much prefer a quiet evening at home to going to a party
3. Driving fast cars would appeal to me
4. I am easily bored
5. I enjoy meeting new people and having lots of friends
6. I make decisions in a very methodical and deliberate way
7. I would not enjoy traveling to new and different places
8. Others see me as an easygoing and carefree person

There are no right or wrong answers.

person). More recently, the EPP has replaced the EPQ in both professional and research use.

Since extraversion, in the main, taps traits and behaviors such as those shown in [Figure 2](#), the kinds of items that might be found on such inventories may look like the example questionnaire shown in [Table 2](#).

While these are not actual items from the EPQ or EPP, they do reflect the kind of content and appearance found in measures of extraversion. If 'yes' were answered to questions 1,3,4,5, and 8 and 'no' to questions 2,6, and 7, then the respondent would likely be more of an extravert than introvert.

Many hundreds of studies have been conducted that focus on how useful and 'good' these questionnaires are at assessing

introversion–extraversion. Interested readers may wish to examine the journal *Personality and Individual Differences*, for research papers reporting results of studies with the EPQ, EPP, and related measures. The Eysenck scales show consistently high reliability (an indication of the test's precision, consistency, and stability) and validity (an indication of whether the test measures what it was intended to measure). Unfortunately, in addition to the Eysenck measures, other scales developed to measure extraversion differ in the relative mixture of the affective, behavioral, cognitive, and goal-seeking components, which has caused some confusion in the research and clinical literature.

The Basis of Extraversion

Trait models of personality are sometimes criticized for apparently claiming to explain differences in behavior by simply postulating the existence of traits based on that behavior. How do we describe social shyness? We correlate a number of questions related to that trait, extract the factor of social shyness, and then describe the observed behaviors by the very trait label based on the analysis of these behaviors! But this criticism is incorrect. In the first place, we carry out the statistical analyses in order to discover whether our original notion was correct, that is, that there was in fact only one factor of social shyness. At first sight, it may seem obvious that this is so, but, in actual fact, it may not. When we take a large sample of items relating to sociability, social shyness, and similar notions, calculate the correlations, and factor analyze the resulting table of correlations, we find, not one factor, but two. There is an introverted social shyness, defined by items that tell us that introverts do not particularly like being with other people and prefer being by themselves most of the time. However, they are not worried about being with other people and can perfectly sustain social interactions. There is also a quite independent type of neurotic social shyness, where people are actually afraid of others and avoid them for that very reason. They would like to socialize with others, but are prevented from doing so by their worries and anxieties about social relations. Thus, a statistical analysis of this kind is carried out in the main to see whether our commonsense beliefs are justified or not, and in many cases what is found is that they are not. In other words, we have to solve the problem of personality description before we can go on to attack the problem of causality. Factor analysis and other correlational methods are not meant to tell us anything about causality, but to act as tools for the discovery of a useful personality taxonomy. Having solved the problem, we may then go on to carry out the more difficult task of discovering why some people are sociable, others quite less so, and why some people are extraverted, others introverted.

Hereditary Influences

The first step in such a causal analysis must be to discover to what extent differences in behavior are determined by heredity, and to what extent they are determined by environmental factors. For many years, personality theorists took it for granted

that environmental factors, and particularly the influence of the family, were the major, if not sole, determinants of individual differences in human behavior. Early studies of identical and fraternal twins seemed to support such a view, but improved research methods have challenged this assertion.

There are several ways of assessing the relative importance of nature and nurture. The first, and probably the most important, is to study identical twins (monozygotic (MZ) twins) who were brought up from birth in different environments, that is, were adopted. Identical twins share 100% heredity, being the product of a single ovum, fertilized by a single sperm, and then separating into two separate entities. MZ twins separated at birth share identical heredity, but have completely different environmental influences determining their behavior. We get an accurate estimate of the importance of heredity by looking at the intercorrelations between such MZ twins; if environment were all-important, there should be no correlation at all. In fact, several studies have shown quite high correlations, suggesting that heredity accounted for at least 50% of the total difference observed.

Similarly, we can compare MZ twins and dizygotic (DZ) twins; that is, fraternal twins who share, on the average, only 50% heredity, and are no more alike than ordinary siblings. If heredity was important, we could expect MZ twins to be much more alike than DZ twins, and this is precisely what is usually found. So here again, we have evidence for the importance of heredity. These and other studies, on topics such as whether adopted children are more alike in personality with their biological or their adoptive parents, leave us in no doubt that heredity is extremely important. They also show that the theory implicating only the family is quite wrong. We can divide the environmental factors determining differences in personality into those between families, emphasizing the importance of family upbringing, and those within family, emphasizing the environmental differences between different children coming from the same family, such as one having a good teacher, the other a poor one, or one marrying a kind and loving person, the other an abusive, unsupportive one.

Several very large-scale studies have now shown that it is the within-family environmental factors that affect individual differences in personality between children, not those between families, a finding that demonstrates that practically all the usual theories of personality are in fact inadequate, and have to be revised or replaced. Most current personality theories have now taken the implications of genetics into account. What is important to remember here, however, is that even very high heritabilities do not imply a lack of malleability; nor do they deny the possibility of changes over the life span. Heritability is a within-cohort measure that increases with a lack of environmental variability; heritability estimates say little about mean changes over time or what happens if the environment is systematically varied.

The Link Between Biology and Extraversion

The compelling evidence from behavioral genetic studies confirms the important contribution of heritable, constitutional factors to the development of personality. This evidence endorses the views of scholars, from Galen to McDougall and

Pavlov, who speculated on the physiological determinants of personality. Only physiological processes, under the control of DNA, are heritable. During the twentieth century, there was considerable research that aimed to identify the psychological processes and neurological mechanisms that mediated individual differences in personality. Foremost in this research enterprise was the leadership provided by Professor Hans Eysenck and his colleagues at the Institute of Psychiatry, University of London, in their studies on introversion–extraversion and individual differences in cortical arousal.

From the 1950s, there was widespread interest in the idea that a continuum of neurophysiological states of arousal, ranging from sleep to alertness and excitement, was important in influencing such psychological processes as attention, motivation, and learning. Importantly, it was shown that low-amplitude, high-frequency EEG activity, associated with wakefulness and attention, and high-amplitude, low-frequency EEG activity, associated with sleep and drowsiness, were modulated by activity in the ascending reticular activation system (ARAS). The ARAS is a diffuse network of neural fibers that are innervated by collaterals from the main sensory pathways and that project to the midbrain and higher cortical centers. The discovery of the ARAS provided a plausible physiological basis for the arousal continuum and for the psychological processes involving modulation of sensory inputs that it served. Several of these psychological processes were known to differ between introverts and extraverts. For example, compared to extraverts, introverts tended to be more alert (as indicated by stronger reactions to stimulus change) and to be more vigilant in situations that demanded sustained attention. It was in this context that Hans Eysenck proposed the arousal hypothesis in 1967 as an explanation for individual differences in introversion and extraversion (Figure 7).

The central hypothesis identified individual differences in behavior between introverts and extraverts, with differential thresholds of excitation and inhibition in the various parts of the ARAS. It was suggested that, compared to extraverts, introverts were characterized by higher levels of activity or lower

levels of excitation in the ARAS. In general, it was expected that the responses of introverts and extraverts would be affected differently in psychological processes and psychophysiological measures that were thought to be sensitive to the stimulus-modulation function of the ARAS. The hypothesis inspired hundreds of experiments and continues to guide research on the topic even as personality theory and ARAS brain physiology advances. From this substantial body of work, some induction of the causal bases of extraversion can be made from the reliable effects that were demonstrated and from research employing different methods and paradigms that converge on common processes.

First, there is considerable research, both in the field and in the laboratory, demonstrating that introverts are more sensitive than extraverts to sensory stimulation. This effect can reasonably account for some social behavior that is displayed by introverts, that is, their preference for quieter environments and solitude and avoidance of noisy environments and intense stimulation, such as partying. For example, one project investigated introversion–extraversion and the area where a person preferred to study in the library. Introverts tended to prefer sitting in quieter corners of the library whereas extraverts seated themselves closer to the noisier, well-traveled areas, although there is the view that an impulsivity effect underlies these reported differences. In another example, when given the opportunity to set the volume on the radio to their preferred listening level, on average, introverts set the volume level 20 decibels lower than did extraverts. In the laboratory, under rigorously controlled conditions, introverts exhibited greater sensitivity to sound and taste stimuli, that is, lower auditory and gustatory thresholds. Similarly, introverts show less tolerance for intense sensory stimulation, as evidenced by lower pain thresholds and noise thresholds.

The behavioral differences in response to sensory stimulation are also evident in psychophysiological indices that gauge the physiological response to sensory stimulation. When small metal electrodes are placed on the finger tips to record minute changes in sweat gland activity, the greater sensitivity of introverts compared to extraverts to brief moderate-intensity tones is evident in their larger skin conductance response, that is, greater sweat gland activity. From electrodes placed on the scalp, introverts exhibit larger electrocortical responses (event-related potentials) to simple auditory stimulation. Similarly, with techniques that measure the speed at which eye blinks are initiated, introverts display faster startle reflex responses than extraverts to moderate-intensity noise bursts. It was also found that introverts are characterized by faster brainstem auditory evoked potentials (BAEP) than extraverts. This effect too is indicative of greater auditory sensitivity for introverts. However, BAEP waves develop very early in the auditory pathway, prior to excitation of the ARAS, and they are relatively independent of descending cortical influences (the waves are unaffected by either sleep or arousal). Thus, the BAEP effects cannot be easily accounted for by differences in the ARAS as originally proposed.

It is also important to note that the described differences between introverts and extraverts reflect differences in response to stimulation rather than tonic or base levels of arousal. This conclusion is drawn from the absence of differences when autonomic nervous system measures of arousal, such as sweat

Figure 7 Diagrammatic representation of the interaction between the limbic system (visceral brain) and the reticular–cortical arousal system. Copyright © 1967, H. J. Eysenck.

gland activity (skin conductance), are obtained prior to sensory stimulation and in conditions that have low arousal potential. Notably, differences are seldom reported with EEG measures in low-arousing conditions or during sleep. In effect, it is the reaction to stimulation, rather than endogenous differences in level of physiological activity, that differentiates introverts and extraverts. This conclusion challenges the idea that extraverts seek stimulation in order to achieve an optimum level of arousal.

An important clarification of the arousal hypothesis was the distinction between energetic and tense arousal. Energetic arousal, which contrasts energy versus sleepiness, varies over the day in a clear diurnal rhythm. Tense arousal, reflecting a dimension of tension and worry versus calm and relaxed, varies in response to situational demands. While not differing in their tense arousal, introverts and extraverts do differ in the phase of their energetic arousal. Introverts have a somewhat earlier peak level of energetic arousal than do extraverts. More importantly, high energetic arousal is associated with increased activity and sociability rather than the inverse relationship that would be expected by the arousal-seeking hypothesis.

Introverts and extraverts are also known to differ in a range of social behaviors that can be linked to differences in movement or motor activity. These differences in the expression of motor activity provide a plausible basis for understanding the greater spontaneity, sociability, and liveliness of extraverts. For example, extraverts are more disposed to participate in physical activities and sports than introverts. Extraverts are more talkative and initiate conversation more frequently than do introverts during interview situations, and they are more restless (fidgety) in restricted environments. In controlled laboratory experiments, faster reaction time is commonly observed for extraverts than for introverts. On a task that involves tracking a small target on a revolving disk and requires refined motor control, extraverts show less effective tracking performance than do introverts. In reaction time tasks, where participants are instructed to respond as quickly as possible, extraverts tend to make more false-positive errors than introverts. These effects indicate that extraverts inhibit the initiation and control of movement responses less readily than introverts.

In reaction time tasks, it is understood that the task involves a cognitive decision to respond when a cue to respond is presented and a movement response that typically requires pressing a response button. Decision time and movement time can be separated in reaction time tasks by measuring the time from the onset of the cue to respond to the release of a home button that is, decision time, and by measuring the time from the release of the home button to the press of the response button, that is, movement time. In a series of studies, it was consistently observed that extraverts exhibited faster movement time than introverts, but that there were no differences in decision time. In effect, it was motor activity rather than cognitive activity that was the discriminating factor. Moreover, it was clear that this movement time effect was due to the faster initiation of movement for extraverts than introverts rather than the speed of the ballistic motor response.

The behavioral differences in motor activity between introverts and extraverts were also explored using psychophysiological indices of movement responses. In the recording of electrocortical activity during reaction time tasks, extraverts displayed greater response amplitude than did introverts in

the interval between a warning signal and the cue to respond. This effect is indicative of greater response motor preparation for extraverts than introverts. It has also been observed that extraverts exhibit slower motor-neuronal recovery than introverts following the discharge of motor reflexes, an effect linked to increased dopaminergic activity for extraverts.

Differences in motor activity between introverts and extraverts were also examined with an electrocortical response measure, the lateralized readiness potential (LRP), that directly assesses movement initiation processes following stimulus-related processing. In this procedure, the duration of premotor activity, including stimulus analysis, response preparation, and some aspects of response selection, is distinguished from the duration of motor activity, independent of stimulus processing. With this task, shorter response-linked LRP latencies were found for extraverts than introverts, indicating faster speed of motor processing for extraverts than for introverts. There were no differences between introverts and extraverts, however, for stimulus-linked LRP latencies. Again, it is the motor component of the response process, which favors extraverts, rather than the cognitive analysis component that is the relevant factor in this analysis. Overall, these results indicate that introverts and extraverts are characterized by fundamental differences in the expression of motor activity.

Given the remarkable differences between introverts and extraverts in sensory sensitivity and in the expression of motor activity that were consistently demonstrated, there remains the important question of identifying the neural circuits and neurochemical properties on which these effects depend. The neural generators of psychophysiological response measures have been extensively explored and do provide some insight into the neural pathways that are involved in individual differences in extraversion. Perhaps more importantly, there is good evidence indicating that dopamine, a neurotransmitter that is thought to modulate the probability and strength of behavioral responses to sensory input, may be implicated in variation in extraversion. Dopaminergic activity in the mesolimbic pathway is involved in locomotor activity and reward behavior. Increased dopaminergic activity in the mesostriatal pathway can enhance sensory sensitivity by counteracting the inhibitory effects of the striatum on the thalamus and ARAS. When alpha-methyl-para-tyrosine (AMPT) was used to block the synthesis of dopamine, both decision time and movement time were markedly slower for introverts during a choice reaction time task. However, AMPT had no effect on the response time of extraverts. Similar results were observed when remoxipride, a receptor blocker that selectively inhibits mesolimbic dopaminergic activity, was used. These important experiments pioneered by Thomas Rammsayer at the University of Bern, Switzerland, indicate that the differences between introverts and extraverts in the transmission of sensory input to motor seem to be a clear function of modulation in the dopaminergic system. As an extension to this work, introversion–extraversion differences in dopaminergic activity may also be related to the sensitivity in detecting and learning cues for reward. That is, with more dopaminergic activity, one is able to learn which environmental stimuli lead to future reward. When presented with positively valenced stimuli, extraverts display more brain activation, as measured by fMRI, than do introverts. This is true for reward cues but not true for cues of punishment and nonreward.

Cross-Cultural Research into Extraversion

There are other consequences of the general theory that E and N are determined very largely by heredity, and that their behavior is mediated by biological structures in the central nervous system and the autonomic nervous system. One of these is that E and N should appear not only in those cultures where the original studies were made (essentially the European-North American culture) but should also be equally characteristic of all other countries. What is asserted is not that all these cultures would be equally extraverted, or similar in emotional lability, but rather that the same factors would emerge in these countries as were found in North America, Australia, etc. The experiments were done in over 35 different countries, including a large number of European, Scandinavian, Slavic (e.g., Russia, Hungary), Southeast Asian (e.g., Japan, China), South American, and African (e.g., Uganda, Nigeria) countries. In all these countries, over 500 males and 500 females were administered the EPQ, and the items were then intercorrelated and factor analyzed to see whether the resulting factors would be the same as the ones we found in England and the United States.

It was found that in all these countries, there were practically identical structures of items, verifying the existence of N and E. Of course, not all countries had identical levels of E and N; Japan was very high on N but lower on E. The United States was very extraverted. Thus, the prediction is verified. Identical factors emerged in many different countries and cultures. Of interest is the fact that similar findings have been obtained across large samples of children from different countries such as Canada, Denmark, Greece, Spain, and Singapore.

Drug Studies and Extraversion

There is another way of testing the hypothesis that personality is mediated by biological mechanisms in the central and autonomic nervous systems. If this is true, then it should be possible to shift the person on the various dimensions involved by means of drugs known to be relevant to the hypothetical underlying structures. Thus, stimulant drugs should make people more introverted because they are known to raise the cortical arousal level, while depressant drugs should have the opposite effect, making people more extraverted. It is well known that alcohol, which is a depressant drug, does make people more extraverted (except in excessive doses, of course), while stimulant drugs have the opposite effect. Similarly, adrenergic drugs lead to greater neuroticism, anxiolytic drugs to greater stability. **Figure 8** illustrates these effects. Also shown is the third major personality dimension, psychoticism, which is increased by hallucinogens and diminished by antipsychotic drugs. A great deal of work conducted along these lines has yielded positive results.

Extraversion and Other Personality Factors

E as a dimension of personality is never found in isolation but is always interacting with other dimensions of personality and with intelligence. Thus, an intelligent extravert behaves very

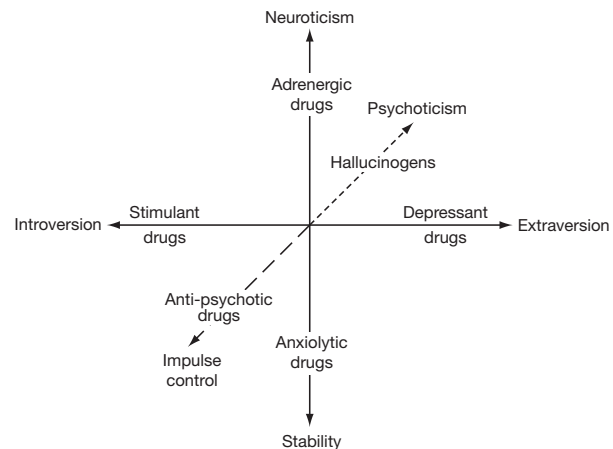

Figure 8 Psychotropic drugs and personality.

differently from a less intelligent one, and a neurotic extravert very differently from a stable one. Furthermore, while extraverts may have the same score on the E scale of the EPP, they nevertheless differ to some extent from each other because they may be characterized in the main by different traits. The sociable extravert is not necessarily assertive, the carefree one not necessarily dominant. These traits are all intercorrelated, but the correlations are far from perfect. Different extraverts may sometimes show different facets, and therefore subtle differences. It should never be assumed that knowing the main dimensions of personality of a given person tells us all there is to know.

The hierarchical system outlined earlier simply tells us that knowing the position of a person on the major dimensions will tell us more about that person than any other similarly restricted data set. If we know a person's IQ score as well as degree of E and N, we will know more about him or her than any other three figures could tell us. This does not mean that there is not a great deal more to be known; if we characterize the person in terms of 40 or 50 traits, we would certainly have a much more detailed picture. But much of this information would be redundant, and we would have great difficulty in absorbing it all. Having a hierarchical theory means that for different purposes, we may choose different levels of analysis. We may be particularly interested in one aspect of E, say sociability, or dominance, and under these conditions, we would obviously prefer to make use of a questionnaire that measures sociability or dominance. Thus, a hierarchical system is very flexible, for it is not committed to working only at the highest level. R. B. Cattell, for instance, preferred to focus on his 16 personality factors, although these are intercorrelated and give rise to higher-order factors very similar to E (which he called 'envia-exvia') and N (which he called 'anxiety'). There is no essential contradiction between the Cattell and Eysenck systems. For all practical purposes, they simply lay emphasis on different levels of analysis; however, the relative weighting of the lower order factors, facets, or aspects does lead to somewhat different conceptualizations of extraversion.

Essentially, what a proper theory of personality must do is look at all the steps, from distal causal factors, such as heredity, to proximal causal factors, such as differences in the

functioning of the limbic system or the ARAS, to the major dimensions of personality like E and N. The theory must then proceed to the study of proximal consequences, such as the study of changeability already mentioned, which is best done in the laboratory. And finally, it must proceed to distal consequences, mainly in the social field, such as sociability or differences in sexual behavior. In the case of E, we have a complete chain, from DNA, through ARAS, to E, to laboratory behaviors, and then on to social behavior. It is not suggested that each element in the chain has been finally located and that no further progress is either required or possible. The concept of cortical arousal presents many difficulties, and there are many anomalies in the experimental analysis of extraverted behavior in those terms. These will be analyzed and solved in future research; at the moment, all we can say is that the theory has much going for it.

Extraversion and Social Behavior

In a complete chain of events, our main interest of course is in the final link, that is, social behavior. An examination of the current research literature implicates E in a wide variety of real-life behaviors including social interactions, sexual activity, work performance, school achievement, psychiatric disturbance, and antisocial and criminal behavior.

For example, it has been shown that traffic accidents are much more frequent in people who are high N and high E. It has also been shown that by using this knowledge in the selection procedure for drivers, the accident rate can be halved. A rather different field is education. There has been a great deal of interest in the last 20 years in the so-called 'discovery learning' or inquiry-based methods, in which students are encouraged to discover basic principles and rules. It has been found, by comparing classes taught by either discovery or reception learning methods, that there is little difference in achievement. This may be due to the fact that both methods are equally good, but it may also be that extraverts learn better by means of discovery methods, and introverts by means of reception methods, as predicted on theoretical grounds. Figure 9 shows the results of one such study, where pupils were taught by one method or the other and then were separated into introverts and extraverts.

Figure 9 The performance of introverts and extraverts using different learning methods.

The posttest was done after 1 week, and again after 5 weeks. It does show that extraverts do indeed benefit more by discovery learning, and introverts by reception learning.

Conclusion

Most people underestimate the very large individual differences in personality, which heredity has created. We tend to think that most people are like us, just slightly different because of environmental events, particularly events characteristic of a given family. Such a view underestimates the very real differences, which are largely genetic, or, if environmental, have little to do with the way children are brought up in a given family. Theories of personality characteristic of the last 60 years have now been shown to be essentially contradicted by the facts of behavior genetic research. We will have to develop new theories in order to do justice to the facts as described. The above descriptions of extraversion are contemporary. While there is good reason to suggest that E will continue to be recognized as a major personality dimension, the specific findings reported here, ranging from its biological basis to behavioral manifestations, are currently being examined and reexamined.

Glossary

Accommodation Change in focus of the lenses, normally accompanied by a vergence eye movement.

Conjugate Both eyes moving with the same speed and direction at the same time.

Extraocular Outside the eye, usually referring to the six muscles that move the eye.

Fixation Steady gaze at an object or texture in the visual world, maintained by compensatory eye movements.

Fovea The retina's area of best detail and color vision, at the fixation point.

Microsaccade A small, abrupt eye movement taking place during fixation.

Oculomotor Referring to the muscles that move each eye, and the neurological system that controls them.

Pursuit Smooth, conjugate eye movements that track objects on the fovea.

Saccade A rapid change of visual fixation from one point to another, accompanied by a suppression of vision.

Vergence A horizontal rotation of the eyes toward or away from one another, to track targets in the third dimension.

Vestibular The sensory system that detects postures and accelerations of the head, with sensors connected to the inner ear.

Eye movements have two functions – making the eyes jump to a new fixation point and steadying the retinal image between jumps. The jumps are called saccadic eye movements, oculomotor sprints that bring the eyes to a new location as quickly as possible, with vision inhibited during the movement. Thus all vision occurs during steady fixation. The steady fixation periods are necessary because the retina processes visual information relatively slowly, and the information smears out if a visual image moves too fast across the retina.

Functions of Eye Movements

During visual fixation, the eyes are seldom at rest. They are continually compensating for movements of the head, movements of objects in the visual world, or both. A family of reflexes holds the retinal region of sharpest vision, the fovea, steady with respect to the visual image. The fovea is a tiny region, about 1° of arc in size, that gives the eyes their best acuity and their best color discrimination. It almost covers the area of the full moon. Outside this region, acuity and color discrimination rapidly decline, though movement discrimination hardly decreases at all if the moving objects are large enough.

The fovea has a unique role in movement perception as well as in acuity and color discrimination, for despite our constant perceptions of movement, objects hardly ever sweep across the fovea. It is essential to stabilize the image on the fovea because the receptors there are so tightly packed that even a slow drift causes the contours of an image to move across the retina at a rate of many receptors per second. At the same time, the stabilization should not be perfect, because visual receptors that receive a constant stimulation adapt within a few seconds and cease responding. So the image should not move too fast or too slowly across the retina. Usually the problem is to keep the image from shearing too fast. A number of physiological mechanisms cooperate to stabilize the fovea against the world.

Types of Eye Movements

Pursuit

A mechanism specialized for stabilizing the image on the fovea is visual pursuit. As soon as a visual target begins to drift away from the fovea, an involuntary movement (one that cannot be willfully prevented) is generated in ancient subcortical brain centers to move the eyes in a direction that reduces the drift. The delay in initiating this compensatory pursuit movement is about 0.1 s, a significant part of which is due to the time required to transduce the visual signal from light to neural activity in the retina. For about another 0.1 s the pursuit system calculates the direction but not the velocity of the drift, so the system generates a stereotyped movement in the direction of the target, but with a constant velocity. This is called an open-loop movement, because the control loop from retinal drift to visual movement detection to motor compensation is broken. Feedback control closes the loop after this interval, so that tracking responds to the speed and direction of the motion.

The pursuit system has a speed limit, however; it can accurately track image movements only up to about 30° per second relative to the head. Because tracking is never perfect, there is usually some remaining drift that is not compensated for. Above this speed the pursuit system continues to generate compensatory movements, but they fail to keep up with the stimulus. Tracking in this mode can continue up to 80° per second for brief periods, but only if driven by a target that is moving substantially faster than this.

When a target begins moving relative to the eyes, the delay in pursuit means that the eyes are already behind the target by the time pursuit tracking begins. If the error is small, pursuit will be a little faster than the target to catch up. Larger errors are cancelled by a saccadic eye movement that makes the eyes jump to the target location, where error feedback maintains accurate position. To study pursuit movements in isolation from the saccade, a target is first jumped by a small amount in the direction opposite to that of its smooth motion. Smooth

target motion begins immediately after the jump. Then, when the delay in the pursuit system is over, the fovea finds itself fixating the moving target.

In the real world, visual targets seldom move with constant velocity and direction. As a target changes its motion, the pursuit system compensates this with its closed-loop feedback control, but always with a delay. If the movement is repeated and predictable, however, the visual system creates an internal model of the motion and feeds its prediction to the pursuit system. As a result, tracking of a predictable target (such as sinusoidally moving point) can occur without delay. The prediction takes over quickly – tracking a sinusoidal oscillation shows a phase lag initially, but within a few cycles the lag disappears as the predictive controller takes over.

Pursuit movements result in perceived motion of the tracked target. If a small target is tracked in darkness or against a uniform field, the perception of motion corresponds to the motion of the target relative to the head, not to the small and variable errors in the positioning of the target on the fovea. The perception corresponds to the innervation sent to the eye muscles by nuclei in the brainstem, not to the motions on the retina, and thus is due to an extra-retinal signal, a copy of the oculomotor innervation (efference copy or corollary discharge) that is sent to centers controlling visual perception. Similar signals inform perception about head movements. These signals convey a smaller amount of motion than the true head-centric motion, however, so that target motion seems smaller and slower than it really is.

Vergence

Oculomotor function can be seen as directing the point of sight, the place where the lines of sight from the two eyes converge, so that tracking takes place in three dimensions. This requires control over convergence and divergence, collectively termed vergence movements. Vergence has a separate neurological controller from pursuit; it moves the two eyes horizontally in opposite directions. The movements are normally accompanied by accommodation of the lens, and since accommodation involves changing the shape of a highly viscous lens, the process must take place slowly. To maintain clear vision, then, vergence movements need not be any faster than accommodation. They are driven by drift of a target away from the foveas in much the same manner as pursuit, except that the target drifts in opposite directions in the two eyes, indicating a change in depth. Visual stimuli that are not imaged on the fovea have little effect on vergence movements; those stimuli will be blurred in any case because of the poor spatial resolution of the peripheral retina. Vergence and pursuit movements can take place simultaneously while tracking a target in three dimensions. The dynamics of vergence are shown in **Figure 1**; the vergence movement to a sudden target appearance is slower than a saccadic movement, and after the target disappears the eyes gradually diverge again, maintaining the point of sight at a 'dark focus' about 1–2 m from the eyes. Normally there is some 'hunting,' oscillations of vergence to find the optimal eye position.

The effect of vergence movements on perception can be isolated by projecting corresponding images into the two eyes from separate sources, and moving the sources separately.

Figure 1 Vergence eye movements (E) in response to a near target (T). The target remains visible for 5 s (A to B).

As the eyes converge and diverge to track these images, the perceived size of the target changes correspondingly.

Vestibular and Optokinetic Systems

Two additional systems supplement pursuit and vergence in maintaining clear vision on the fovea. Whenever the head turns, the vestibular organs connected to the inner ear detect the acceleration of the head and feed a signal forward to the eye muscles to compensate for the predicted slip of the image against the retinas. This reflex is active even in darkness, when vision cannot control corrective movements. It is a feedforward rather than a feedback. In the vertical direction the compensation is called the 'doll reflex' because the eyes, like those of a doll, roll downward when the head tilts back, and roll upward when it tilts forward.

Vestibular reflex compensation functions in all directions, though. Tilt of the head forward and back is the pitch dimension, compensated vertically by the doll reflex. Yaw is rotating the head left and right, compensated by horizontal movements; and roll induces torsional eye movements (the eye rotating about its own line of sight as an axis) to compensate for tilting the head toward one shoulder. An analogous reflex compensates for linear motions of the head by exploiting signals from the vestibular system's gravity receptors, the utricle and saccule. Again these movements are involuntary and cannot be inhibited; most people do not know that the movements exist, though they work almost constantly to stabilize vision. The reflexes are ancient in evolution; they function in sharks in almost the same way as in humans, solving the same problem.

The vestibular reflexes are very quick, sending signals to the eye muscles within 15 ms of the start of a head movement; they rely on hair-cell receptors similar to the auditory receptors. The neural pathway is among the shortest in the brain, a three-neuron arc. The signals adapt quickly, however, because the immediate stimulus for activating the vestibular acceleration receptors is motion of fluid in the three pairs of semicircular canals. When the head starts moving, the fluid remains in place, so that it flows through the semicircular canals and stimulates the vestibular receptor cells. Within less than a second, however, the fluid also begins to move, weakening the stimulus to the hair cells. Once the fluid is moving as fast as the head, stimulation ceases and the vestibular receptors respond as though there were no head movement at all. In this sense the receptors detect acceleration rather than rotation of the head. There is some integration of the acceleration signal, maintaining compensatory eye movements, but eventually the reflex fails to keep up with predicted image movements.

Fortunately another reflex takes over the job of compensating for movements of the entire visual field, the sorts of

movements that are generated by movement of the head and body rather than by movement of objects in the world. This is the optokinetic reflex, a visual feedback that works on the movements of the entire image across the retina. This contrasts with pursuit, that is stimulated only by movements on the fovea. Again it is an ancient system, acting in sharks in much the same way as it acts in humans to compensate for the retinal slip caused by locomotion. The reflex sums up slips of the image across the entire retina, and compensates for the average motion. Thus it is little affected by motions on the tiny fovea, and is dominated by the retinal periphery.

This system too has its limitations, however. Its activity builds up gradually, so that at the start of a movement there is no compensation. Part of the delay is due to the time required to transduce the visual signal, conduct it to the relevant areas of the brain, and generate the appropriate compensations.

For head rotations, the optokinetic and vestibular reflexes work in concert to maintain compensation for the resulting retinal slip. The rapid, feedforward vestibular reflex reaches the eye muscles even before the motion signal leaves the retina. As its contribution declines, the slower optokinetic reflex takes over the job of counterrotating the eyes, resulting in a rapid but continuous compensation.

Though these systems seem primitive, they also show cooperation and adaptation. One complication of compensation is that head turns in the presence of a close target require a larger oculomotor compensation than is needed for distant targets, because turning the head also moves the eyes left and right. The optokinetic system can track this required increase in gain (output/input) because it is controlled by error feedback, but the vestibular system cannot. After extended exposure to a close target while turning the head, though, eye compensation increases even in darkness. This means that the higher optokinetic gain was transferred to the vestibulo-ocular reflex, the only compensation system that functions even in the dark.

These evolutionarily ancient systems are built deeply into all vertebrates, working mostly from the oldest parts of the brain. A conflict arises, however, when the newer pursuit system, functioning only in animals such as humans that have foveas, tracks motion across a fixed background. The pursuit system then drives eye movements, while the optokinetic system works to hold the eyes still. In this case pursuit dominates, but to overcome the optokinetic reflex, it must generate a stronger signal in the presence of a textured background than it would with a uniform background. This is one of the reasons why objects moving against a textured background seem to be moving faster than objects moving across a uniform field. Further, the pursuit signals are registered in perception as object motion while the optokinetic signals are not.

Saccades

If all of these reflexes together constituted the entire oculomotor control system, we would live in a peculiar world, trapped forever by whatever happened to appear on the fovea. To jump to another target, the newer saccadic system suppresses the reflexes briefly to allow a rapid movement to a new fixation point.

The saccadic system is binocular – both eyes move simultaneously to the same extent. During these jumps, the eyes move

so quickly that no useful visual information can be picked up. The shearing image motion is so rapid that the receptors cannot transduce a signal before the next parts of the image interfere. To solve this problem, the visual system actively suppresses vision during saccades. Saccadic suppression is selective – motion is suppressed much more strongly than brightness, because it is apparent motion that must be suppressed, and gross features are preferentially inhibited because fine features will be lost in any case by the rapid retinal image motion.

Saccadic targeting

A saccadic eye movement is ballistic in the sense that once started, it cannot be stopped. Launching a saccade is like throwing a ball; once the ball leaves your hand, its path cannot be altered. Analogously, if you begin a saccade and then change your mind, the movement must be completed anyway, and a second saccade must be planned to reach the new target. During the saccade planning process, you are committed to making a saccade before the eyes begin to move. For example, if you are instructed to simply track a target that jumps away from fixation and then jumps to a new location 0.2 s later, your eyes will remain at their original fixation point when the target jumps, and will still be there when the target jumps again. Just as the target makes its second jump you will execute your saccade to the first target position, because you are already committed to an eye movement. You will wait there for 0.2 s while your brainstem calculates a new saccade, and then fixate the target at its new position (Figure 2).

Since saccades are preprogrammed, they often do not reach their targets exactly. Small saccades tend to overshoot slightly, while saccades of more than about 6° tend to undershoot the target (seen in the first saccade of Figure 2). If the saccade is accurate enough to bring the target into a saccadic ‘dead zone’ less than about 1° from the target, the eyes will simply drift into place, just as pursuit movements can ‘catch up’ to a target when they lag behind. Larger errors are corrected with a second saccade about 170 ms later. People are never aware of this corrective saccade, even if the primary saccade was voluntary.

When both the eyes and the head are free to move, most large saccades are accompanied by a head movement in the

Figure 2 The ballistic nature of saccadic eye movements. The eye must jump to its originally targeted position, even though the fixation target jumps away from the goal location just as the eye begins to move. The target remains at position a_1 for 0.2 s.

Figure 3 Saccadic eye movements (a) with the head fixed and (b) with the head free to rotate. Gaze is the sum of eye motion and head motion. The small corrective saccade occurs one-sixth of a second after the end of the main saccade.

same direction. Since the head rotates much more slowly than the eyes, there is a quick saccade that brings the eyes to the target just as the head movement is beginning. Then, to keep the eyes fixating on the target, a compensatory eye drift begins in the direction opposite to that of the head movement. As a result the gaze position relative to the target remains stable while the eyes and the head rotate in opposite directions at equal speeds. As the process concludes, the eyes are again centered near their original position in the orbit, but the head is deviated to one side (Figure 3).

Anatomy of Eye Movement Control

As specialized, stereotyped movements, saccades have a fixed relationship between their magnitude and their peak velocity. The eyes are driven as fast as the physics of the oculomotor system allows. At the start of a saccade the agonist eye muscles (the ones pulling in the direction of the movement) receive a pulse of innervation. The magnitude of the pulse is always maximal, even for small saccades; the size of the intended movement affects only the duration of the pulse. About halfway through the movement, the innervation drops back to the level required to hold the eyes in the new position, a pulse-step pattern of innervation. It allows the eyes to accelerate much faster than vergence or pursuit movements. For large saccades, a braking pulse in the antagonist muscles slows the eyes near the end of the movement. This helps to keep the rapidly rotating eyes from overshooting their target.

The strategy of the saccadic system is like an automobile driver's strategy in entering a crowded freeway. To reach the cruising speed as quickly as possible, the driver presses the gas pedal to the floor. The faster he wants to go, the longer the pedal stays on the floor. This is the pulse of the pulse-step strategy. When the cruising speed is reached, the driver lets back on the pedal to maintain a steady speed, corresponding to the step of innervation.

Dual initiation of saccades

Normally only one conscious decision is possible in oculomotor behavior – the initiation of a saccade. Even this is usually automatic, without the owner of the saccadic system thinking about its behavior or even being aware of its actions. Accordingly, two separate brain systems can initiate saccades. One, the superior colliculus, resides in the evolutionarily ancient midbrain. The other is located in the newest part of the brain, in the

dorsolateral frontal lobe of the cerebral cortex. The midbrain branch initiates automatic actions such as the return jumps that must be generated during continuous locomotion; when the optokinetic and vestibular reflexes have moved the eyes as far as they can comfortably go, a saccade is generated to make the eyes jump in the direction opposite to that of the continuous movement. The result is a nystagmus, a continuously repeated pattern of eye movement. The frontal cortex system is responsible for jumping to a new target determined by a motivation for visual exploration. We know that these are the only two saccade initiation areas, because removing both of them causes permanent loss of all saccades even though all of the nuclei containing the motor neurons for the ocular muscles remain intact.

The function of these systems can be observed by recording from tiny electrodes that pick up discharges from single nerve cells. For a long time it was thought that the cells in the frontal cortex played little role in initiating saccades, for most of them fired only after the beginning of a saccade. These recordings were made when a monkey was casually looking about a laboratory. But when the animal made a deliberate saccade, for instance to obtain a reward, many cells in a part of the lateral frontal cortex called the 'frontal eye field' became active just after the change in the visual stimulus but before the eyes began to move. The frontal eye field would be better named the frontal attention field.

Control of the eye muscles

Downstream from the cortical and midbrain saccade initiation centers, eye movements are organized in the brainstem, the oldest part of the vertebrate brain. The eye muscles are innervated by three nerves, the third, fourth, and sixth cranial nerves, with brainstem nuclei driving each of them. A common path to saccade execution begins with 'long-lead burst' neurons, followed by actions of a sequence of more specialized neurons organizing the saccadic pulse and step.

Pursuit, optokinetic reflexes, vestibular reflexes, and vergence each have specialized control centers in the brainstem contributing to the final innervations. The eye muscles are the most finely controlled in the body, with each nerve fiber controlling fewer muscle fibers than in any other muscles. This allows very precise control of eye posture.

Eye Movements and Attention

Scanpaths

When a human observer encounters a new visual scene, the eyes saccade first to the area of greatest interest, where the information density is greatest. Then they jump to another location determined by information content, distance, and one's own interests. A series of such jumps generates a scanpath, a pattern of exploratory eye movements.

The scanpath is the meeting point of oculomotor physiology and cognitive psychology. Decisions about where to move the eyes are made with great rapidity, up to 5 per second during reading, and usually without awareness of the decision process, yet they involve sophisticated use of information. Reading presents highly structured eye movement patterns achieved after extensive practice, but other patterns are less fixed.

After the identity of a scene is established, higher-level questions govern visual scanning patterns. Russian researcher A. L. Yarbus showed subjects a painting, Repin's 'Returning Stranger,' while asking them questions about the people in the painting; the scanpaths depended on the question being asked. When estimating the material circumstances of the people, for example, observers fixated largely on the clothing and furniture in the painting. When asked about their ages, though, they fixated mostly on the faces. Observers still scanned the most information-rich regions of the painting, but the definition of what provides the most information changes with the question being asked.

Attention Shifts

When a person shifts attention from one location to another, the first thing that usually happens is that a saccadic eye movement shifts the eyes to the new location. People seldom look in one place while processing information in another (except in psychologists' laboratories). The shifts are very frequent – the eye normally generates about three to four saccades each second. Even when the eyes are not actively exploring, small drifts in fixation are punctuated by 'microsaccades,' tiny saccadic movements that occur during what seems to the observer to be continuous fixation. This makes saccades, unaccompanied by other behaviors, by far the most frequent of all human behaviors. As such they are of central interest to psychologists who study behavior. During a lifetime, a person generates more saccades than heartbeats.

There are three parts to shifting attention: attention must be disengaged, shifted to a new location, and reengaged. The process is analogous to shifting gears in an automobile with a manual transmission. Stepping on the clutch pedal corresponds to disengaging attention, moving the shift knob is the transfer to the new location, and releasing the clutch is the reengaging. Each step takes time, and has a corresponding process in oculomotor control. The disengagement is the active inhibition of the tracking systems that automatically lock the fixation point to the foveal image. If tracking were not disengaged, the start of a saccade would trigger the fixation reflex and the two systems, tracking and saccadic, would fight against one another. The saccade itself corresponds to the shift of attention, and reestablishing fixation occurs at the end of the saccade. Though vision is inhibited during and just before the saccade, it is more sensitive immediately after the eyes come to rest. If the new fixation target is found within a spatio-temporal window following the saccade, space constancy (the perception of a stable world despite eye movements) is maintained, even if there are small errors in fixation.

The attention shift and the motor execution of the saccade are not simultaneous – attention leads the physical action. Two targets can be briefly flashed to the left and right of fixation, but only the one that is the target of an immediately following saccade can be identified, even though the targets disappear before the eyes actually begin to move.

Reading

One of our most highly practiced oculomotor skills, reading can be considered as a specialized and stereotyped scanpath

made on a particular kind of visual pattern (printed text). Experienced readers normally fixate a new word on each fixation, with a saccade between fixations. Small words such as 'of' or 'but' are frequently skipped. Occasionally a reader will look back to a previously fixated word, especially if the text is difficult (a 'reverse saccade'). At the end of each line, a large saccade returns the eyes to the beginning of the next line. This pattern is called a staircase, since it looks like a staircase in an eye movement record when the position of the eyes is plotted against time.

Since they are exploratory saccades (not driven by an abrupt event in the visual world), eye movements of reading are limited to about 5 per second, with a fixation period of about 0.2 s between them. On average, readers normally make about four saccades per second. With these physical limitations, how can one read faster? The only way is to make larger saccades, skipping more words. Especially if the text is easy or redundant, the reader can often fill in the context even if some words are not picked up by the visual system. This requires extra effort, though. The trick of tracking a finger, advocated by some speed-reading techniques, results in pursuit eye movements that make it difficult to see any of the text. Programs that advocate such methods should be avoided.

Dyslexia, a severe reading deficit in a person who is otherwise normal intellectually, is often accompanied by abnormal saccadic patterns during reading. One symptom is a 'reverse staircase,' repeated eye movements in the wrong direction. The input to the brain from such a sequence must be difficult to interpret.

Evolution and Anatomy of the Eye Movement System

The Shark

The oculomotor system evolved along with the earliest vertebrates. To understand the structure of the eye muscles and the orbits, we can examine the basic vertebrate pattern in sharks, in which each extraocular muscle has a simple job. The six muscles are arranged in three opposing pairs; one member of each pair pulls in one direction, while the other pulls in the opposite direction. One pair of muscles pulls the eye up and down (pitch), another pair turns it left and right (yaw), and a third rotates it like a wheel with the line of sight as the axle (roll). The eyes point in opposite directions from each side of the head. The muscles serve to stabilize the retinal images during a shark's locomotion.

The Human

Humans have the same six muscles as sharks, but their arrangement and functions are more subtle and flexible. Over the course of evolution, the orbits have moved to the front of the head to facilitate binocular vision. The muscles that move the eyes are always activated to some extent. A lateral set pulls the eye left and right; a vertical pair pulls up and down, and a little inward at the same time; and an oblique set twists the eye in a complex motion. All eye movements can be resolved into actions of these three pairs of muscles in each eye.

The three dimensions of space are built into the human eye movement control system. Consider the double-eye as a single

organ, managed by a single neurological control system. The double-eye controls the point of sight. Thus, each direction of visual space is represented by a pair of muscles, operating in various combinations. Rectangular coordinates were not invented by mathematicians; they were there all along in the oculomotor control system.

Eye Movements in Sleep

Slow-Wave Sleep

The eye movements of slow-wave sleep, sleep characterized by large slow waves in the EEG that occurs just after going to sleep, are simply slow drifts of the eyes and a general trend upward. In another phase of sleep, named rapid eye movement (REM) sleep, spectacular eye movement activity appears. REM sleep begins about 1½ h after falling asleep, and has several signs. The body becomes paralyzed, the brain shows signs of intense activity, thermoregulation ceases, and the eyes begin to move vigorously.

Paradoxical Sleep

REM sleep is also dream sleep; sleepers awakened during REM usually report vivid dreams, while those awakened during slow-wave sleep seldom do. Not all dreaming occurs during REM sleep, however; it is now almost certain that some dreams occur in other sleep stages. Toward the end of a night of sleep, the distinction between dream reports from REM and from slow-wave sleep begins to break down, but for most of the night REM dreams are the most common and the most vivid.

Dreams are maddeningly subjective as objects of experimental inquiry. Some techniques have been successful in revealing their characteristics, however. For instance, we can ask whether the subjective impression of time in dreams matches the actual duration of the dream. Because dreaming often starts along with a REM episode, sleepers can be awakened after varying durations of REM sleep and asked to relate their dreams. Later awakenings result in longer dream reports, but the effect peaks about 15 min after REM; awakenings after longer intervals lead to about the same length of dream report. The dreams seem to occupy about as much time as it would have taken to act out the action in real life, but apparently memory for them stretches back only about 15 min.

A further step toward relating the content of dreams to the physiology of sleep is to relate the scanpaths of dreams to their contents. Early studies reported such a relationship, but replication has been inconsistent. Interpreting such studies is difficult: how strong must a relationship be between dream reports and eye movements to have significance?

Another way to examine the relationship between dreams and scanpaths considers not the scanpaths but the eye movements themselves. If the eye movements of REM sleep are exploratory movements driven by visual imagery, they should have the characteristics of normal waking eye movements: saccades, pursuit, and vergence movements. These movements are driven by specialized control systems, permitting only a few kinds of activity. Saccades have a fixed peak velocity for each amplitude of movement. But pursuit movements cannot exceed a velocity of about 80° per second. Convergence

and divergence are even slower. These restrictions create an intermediate 'forbidden zone' for eye movements, consisting of movements that are faster than 80° per second but slower than saccades for the corresponding amplitude of movement. Such movements can be neither saccades nor pursuits.

To learn whether REMs of sleep are exploratory, one can look to the forbidden zone of large eye movements too fast to be pursuits but too slow to be saccades. The electrical method usually used in sleep studies cannot measure the dynamics of movements with the necessary precision, and most other methods require the eyes to be open. One technique, however, fulfills all the requirements. The procedure is to sew a small coil of fine wire into the sclera surrounding the cornea of a monkey's eye, leading the two ends of the wire out to a recording apparatus. Using the same principle as a conventional transformer, alternating currents are induced in this coil with three pairs of huge induction coils surrounding the monkey. Eye movements can be recorded quite accurately, with eyes either closed or open, by measuring the amplitudes of the induced alternating currents.

Sleep studies with implanted search coils show that the fastest REMs of sleep matched the dynamics of waking saccades. This is not surprising, since saccades are the fastest possible movements that the oculomotor muscles can generate. Other movements were slow enough to be pursuits. Many so-called REMs, though, fell into the forbidden zone, movements not related to visual exploration. Cats also have REMs inconsistent with visual exploration, for a different reason: all of the movements are in the same plane.

The eye movements of REM sleep are not continuous, but occur in bursts of a few minutes' duration. A typical burst in humans begins with slow movements, continues with more rapid movements up to saccadic velocity, and concludes with slow movements. All of these observations contradict the idea that REMs are exploratory saccades.

Do dreams help to review the experiences of the day? If this were their main function, we should expect to see less REM in organisms with fewer experiences. REM sleep is seen even in unborn fetuses, however. Shortly before birth, fetuses spend most of their time in this state, perhaps to suppress a maturing thermoregulation system that should not be activated until after birth. If they are dreaming, it is difficult to imagine what they are dreaming about.

If dreams review or consolidate a day's experiences, we should be able to manipulate the amount of eye movement allowed during the day and find a corresponding change in REM that night. In fact the opposite change occurs: people induced to make smaller eye movements during the day make larger ones at night. So the evidence does not support a role of eye movements in dream experiences.

Glossary

Double-blind A research study paradigm wherein the person administering a test or a treatment does not know if the subject is receiving an active treatment or placebo.

Live lineup A procedure where a witness views actual potential suspects, often through a two-way mirror.

Photo lineup A procedure where a witness is shown photos of potential suspects.

Sequential lineup A lineup (photo or live) in which persons are presented to a witness one at a time and a decision as to inclusion or exclusion should be made before moving to the next subject.

Showup The practice of showing a witness only one person. This often occurs shortly after a crime when a suspect has been apprehended.

Simultaneous lineup A lineup (photo or live) in which all persons are viewed at the same time. Such a procedure invites so-called comparison shopping, the tendency of a witness to choose the person who resembles the suspect most closely, whether the suspect is present in the lineup or not.

Weapon focus The phenomenon of a witness concentrating attention on a weapon during the commission of a crime.

Introduction

Eyewitness identification, along the bedrock of legal systems throughout the world, is surprisingly vulnerable to attack, although the courts often shield it from appropriate scrutiny, not unlike the situation with fingerprint evidence. Prior to the introduction of the forensic sciences into the trial arena, eyewitness testimony was often the only evidence introduced at a trial. Clearly, the veracity of the witness must be reliable for a criminal justice system to function fairly. To protect the reliability of trial verdicts, courts can impose sanctions (i.e., perjury charges) against a witness (eyewitness or otherwise) who lies in court. Such prohibition is longstanding and encoded in the Judeo-Christian ethic as *Thou Shalt Not Bear False Witness Against Thy Neighbor*.

The recollections of a (truthful) witness who either observed a crime or was the victim are presumed to be accurate by fact finders. Yet there has been, until the turn of the twentieth century, little research into proving that hypothesis. In fact, even with much current research casting doubt on the reliability of eyewitness memory/testimony, the criminal justice system had preferred, for the most part, to ignore such research until DNA science began to lead to the exoneration of many whose conviction resulted from faulty eyewitness testimony as either contributory evidence or the only evidence presented at trial. Eyewitness identification in a courtroom can lead to a conviction even when the defendant has significant alibi evidence in his or her favor. In spite of research findings that ...

- Witnesses can be less accurate when involved in a stressful situation
- Witnesses have difficulty with cross-racial identifications
- Witnesses tend to focus on a weapon rather than a face
- Memory begins to decay immediately
- Witnesses have memory gaps that are filled through confabulation and/or suggestion
- And that there is no necessary correlation between witness proffer of certainty and accuracy of recollection

... some courts insist that a jury's general knowledge is adequate to determine the probity of eyewitness testimony.

(Melton et al., 2007: 190–192)

The problem with eyewitness testimony is usually not that the witness is lying, but rather a far more insidious issue where the witness is testifying to facts they believe to be true, but which in fact are not. With the advent of DNA exonerations, faulty eyewitness testimony has emerged as the leading cause of wrongful convictions, being a factor in 75% of cases (innocence project).

Memory

Before discussing eyewitness testimony it is important to understand the basics of memory. Memory (and therefore recall) was presumed for some time to operate like a movie camera. An individual observed something and since it was initially recorded in the brain, it could be recalled accurately at a future time. Research from the 1970s to date has shown repeatedly that this is far from true.

While scientists are far from understanding memory in its entirety, some useful paradigms of memory have been developed. In possibly the simplest description, for a person to remember something certain processes must occur. First there must be a stimulus in the environment, such as a car passing close by. Second, the individual must perceive the stimulus. Having perceived it, the person must register it in short-term memory. Third, the perception must be transferred or encoded into long-term memory. Fourth, at some future time the memory will need to be retrieved or brought from long-term memory storage to consciousness. It is likely that different areas of the brain are repositories for different aspects of the memory. For example, one area holds the memory of the sound of the car, one the visual of the car passing by, another

the smell of the exhaust and another the emotion of fear or annoyance that the car was so close. To accurately recall the event all aspects of the memory must be laid down accurately and recalled accurately. There is much room for error.

In addition to room for error in recollection, the mind is quite adept at filling in the blank spaces of a poor memory. This can occur without the awareness of the witness and can be recalled and presented as an accurate recollection when it is not. It is very possible that the witness never saw (perceived) the face of the car's driver. Yet weeks later, shown the driver's photograph, the witness might believe he or she saw the driver's face. If presented with covert or overt coaching, the witness may actually describe the face and exhibit significant certainty (and therefore credibility) in the accuracy of the recall. At times attempts are made to use hypnosis to refresh memories of past events. Research into such hypnotically refreshed memories was able to show that the memories produced (created) were often unreliable due to suggestibility and confabulation. Due to this, some states (as well as the military) have banned hypnotically enhanced memories from the courtroom, while others have insisted on various proffers of reliability or adherence to strict protocols for the use of such testimony (Miller, 2003). It is important to note that focused/ritualized enhancements such as hypnosis are not required to create a false or inaccurate memory. As shown by Loftus and Ketcham (1994), simple suggestion can be enough.

Aside from problems related to faulty recall, with or without enhancements (such as hypnosis), there can be problems in perception of the stimulus in the first place. The witness may not have been paying attention and simply failed to initially perceive the information necessary for a complete memory. The witness may have been experiencing other stimuli (internal or external) that interfered with accurate perception, for example fear, anger, confusion, or distraction. Or the witness may have simply inaccurately perceived an event. For example, it is not uncommon for a car to appear one color under certain lighting conditions and another color under others. Also, observers can be inaccurate when judging speed and distance between vehicles, and these inaccuracies can be enhanced due to weather and lighting parameters. Observing two vehicles ahead on a highway can (due to the angle of observation) make it appear that the two cars are actually much closer than they are. Yet it is very possible for an eyewitness to be certain that their misperception is an accurate recollection of an event in question. Also, the wording of questions can effect the reported recollections and additionally, prescribed medications, as well as illicit substance use, can affect one's ability to accurately perceive environmental stimuli.

General Overview

Problems with eyewitness memory have been recognized for quite some time. At the turn of the twentieth century many studies on recall and witness issues had already been performed. Describing such studies, Hugo Munsterberg spoke of "the treachery of human memory" and the fact that the administration of an oath in court adds to the problem as the "... seriousness and solemnity suggest that the conditions for complete truth are given if the witness is not ready to lie"

(Munsterberg, 1908: 46–47). In his book *Criminal Investigation* (1934), Hans Gross, felt by many to be the father of the field of criminalistics, discussed issues of witness perception of events, recall, and eyewitness reliability. Soderman and O'Connell (1936) noted that any of the stages of forming or retrieving a memory leave opportunity for distortion and further noted that there is also opportunity for others to influence the recollections of a witness. They identified a scenario regarding a 'unanimous statement' in which several witnesses are allowed to spend time together telling each other their recollections of a crime. The witnesses will influence each other and this may lead to a collective statement (given individually) where all the witnesses agree on certain facts, lending the facts a more reliable basis than they may deserve.

Stern (1939: 4) pointed out that little attention had been paid to eyewitness testimony in America, highlighting that a "perfectly correct remembrance is not the rule, but the exception." And, "... subjective sincerity does not guarantee objective truthfulness." (p. 13) He noted that when a witness was allowed to relate his or her story as a free-flowing narrative, the result was more accurate than when the witness was constrained, as by cross-examination.

More recently, probably the most well-known researcher on false memories and eyewitness memory is Elizabeth Loftus a research psychologist (Loftus and Ketcham, 1991). Her work publicized the inherent problems with memory as evidence. A problem with most research related to eyewitness memory/testimony is that it is not 'field' based and usually relies on simulated crimes that do not replicate the actual levels of witness and/or victim involvement, stress, and motivation present in actual crimes. Interestingly, *Criminal Interrogation and Confessions*, 4th edn (2001), the most widely used text to teach interrogation, while discussing problems inherent in eyewitness testimony, fails to mention potential contamination of the witness by law enforcement personnel. This is striking, considering that law enforcement is the presumed target audience of the text.

What follows is a review of modern research on the subjects of weapon focus, effect of stress on eyewitness memory, malleability of witness recall, confidence in recall, facial recognition, line up issues, and the inadequate court remedy available. Clearly, these areas of research will overlap.

Weapon Focus

When an offender confronts a victim or witness with a weapon, especially a firearm, accurate recall of the events decreases. It appears the witness selectively focuses on the weapon to the detriment of other pertinent details (Loftus et al., 1987; Loftus, 1996a,b). A 1992 meta-analysis of 12 studies (Steblyay) found a small effect related to lineup identifications and a moderate effect for feature accuracy, for example, clothing and/or facial features.

Stress

Research seems to indicate that the relationship between stress and memory is nonlinear, but results often vary from study to

study, with confounding variables difficult to control for. It seems that, allowing for individual variations, up to a certain point stress enhances memory, but once a certain level of stress is experienced, memory subsequently declines. Yuille and Cutshall (1986) were able to conduct a real life study, whose findings differed from laboratory-style studies. After interviewing 13 witnesses 4–5 months after a homicide, they found that stress levels at the time of the incident did not have a negative effect on memory and, importantly, that the witnesses resisted leading questions.

Valentine and Mesout (2008) produced anxiety artificially (in the Tower of London), but measured it accurately and found that as anxiety increased, accuracy of descriptions and lineup identifications decreased. A 2004 (Deffenbacher et al.) meta-analysis of 24 studies, including 27 tests of the effect of stress on eyewitness recall and 36 tests of crime detail recall, found ‘considerable support’ for the hypothesis that high stress levels negatively affect both eyewitness identification and memory for crime details. Interestingly, it was found (similar to Munsterberg’s commentary noted above) that stress affected interrogative recall much more than it did narrative or free recall. It was noted that a confounding variable (in most studies) is the conflation of findings related to ‘neurotic’ (i.e., more anxious at baseline) individuals with those who do not tend to experience anxiety unnecessarily. This could tend to make it appear that nonneurotics perform more poorly than they actually do.

Confidence/Malleability

It is generally accepted that eyewitness confidence in recall of events and identification often has no clear relationship to accuracy (Odinot et al., 2009) and is subject to overt and covert influence. Yet, the one thing that is likely to impress the trier of fact is the confidence an eyewitness places on his or her identification and testimony (Cutler et al., 1988, 1990). Research has shown that older adults are more prone than younger adults to either remember an event that never occurred, or to recall an event that occurred, but to do so inaccurately (Dodson and Kreuger, 2006) and maintain confidence in the misremembered recollection.

Eyewitness confidence in identification of a suspect is quite malleable. Luus and Wells (1994) staged a theft for 70 pairs of eyewitnesses who then were subjected to a photo-lineup. After an initial identification, witnesses’ confidence was easily manipulated by either telling the witness another witness made the same identification or did not. Surprisingly, one study found that immediate recall after an event did not protect from later incorporation of false details into a recollection. This so-called reversed testing effect is significant to understand in regard to eyewitness testimony and though already recognized, the malleability of eyewitness testimony may be even greater than previously suspected (Chan et al., 2009). In a real life crime scenario (Wright and Skagerberg, 2007) post-identification feedback had a significant effect on eyewitness confidence. This underscores the need to assess witness confidence after identification before they give any further information.

One concern regarding witness confidence in identifications is the confounding factor of a confession. Hasel and

Kassin (2009) conducted a staged theft and later gave information to subjects regarding confessions or denials of guilt, after an identification had or had not been made. More than 60% of subjects changed their identification when told a different lineup member had confessed. Just as problematic, 50% of subjects who had not made an identification chose the lineup confessor when his identity became known to them. Identifications were clearly affected by this information, which highlights the problem with presenting witnesses with such information not only before lineup identification, but also after.

Facial Recognition

It is presumed by many that a human’s ability to recognize a face seen at a prior time and to accurately recall the parameters of the original event are good. What is often misunderstood is that while our ability to recognize a known face may be good, the ability to recognize an unfamiliar face is actually not impressive. Megreya and Burton (2009) performed three experiments designed to test the ability to recall (identify) unfamiliar faces. Performance was poor across the testing paradigms, indicating that witness ability to recall faces is both generally poor and independent of the usual eyewitness memory problems. Both live and still videos were used. Performance under both conditions was poor. When the target was present, a correct choice was made 70% of the time, meaning three out of ten identifications were wrong. When the target was absent, a wrong match was chosen 35% of the time. This was across both photo and live presentation. As expected, there were large variations in performance among subjects.

Also of interest is the fact that interracial facial recognition tends to be poorer than intraracial facial recognition (Marcon et al., 2008) and that women seem to have better ability to recognize female faces than men (Lewin and Herlitz, 2002), although they may not recognize more faces in general than men and men may be better at opposite sex facial recognition (Winters, 2009).

Lineups

Lineups have been problematic from the time they entered use in law enforcement and are subject to contamination at several junctions in the lineup process. Except for rare circumstances, law enforcement personnel want to identify and charge the person or persons whom they believe committed a crime being investigated. In light of this, one would expect law enforcement to eagerly adopt procedures to minimize false identifications as such errors not only can result in conviction of innocents, but also because such errors allow guilty persons to remain in the community, capable of committing new crimes. Yet it has taken considerable time for some jurisdictions to recommend standard procedures for lineups.

A lineup is the presentation of a suspect to an eyewitness for the purpose of determining whether the witness can identify the suspect. Witnesses can receive potentially contaminating information overtly or covertly before, during or after a lineup. A live lineup can be performed after a photo identification, or a photo lineup can be used alone. At any step of the process it is

possible for a false identification to occur. Even when lineup administrators give unbiased instructions to witnesses, influence is measurable and most witnesses do not realize the extent to which they have been influenced (Clark et al., 2009). This is compounded by the fact that humans are not particularly good at identifying unknown faces in the first place.

Several lineup guidelines were offered since 1957, but all suffered various weaknesses. In 1998 Wells et al. reviewed prior guidelines and offered their own. These included double-blind lineups (lineup administrator does not know who the suspect is), advising witnesses that the suspect may not be present, distracters chosen according to eyewitness descriptions, and documentation of confidence at the time of the identification. Several states (most notably New Jersey) have issued guidelines for lineups with mixed acceptance, although most jurisdictions that have adopted recommendations have been happy with the results.

Current recommendations (The Justice Project, 2006) endorse the following:

1. Standard instructions to eyewitnesses
2. Double-blind administration of lineup
3. Random sequential presentation
4. Appropriate use of decoys
5. Immediate documentation of witness confidence and procedure for lineup

Standard instructions are important so that each eyewitness is told the same thing regarding what they will be doing, how it will be done, and what the expectations are. For example, part of protocol would be advising the witness that the suspect may or may not be in the photo array or the live lineup. The potential witness must feel comfortable not making an identification. Investigators may not realize how much a potential witness may want to help solve a crime, leading the witness to override doubt in an effort to avoid disappointing an investigator. Also, using standard instructions minimizes subtle cues that could inadvertently be given to a witness. All investigators must warn against comments that might be overheard during a lineup, such as 'he' or 'she' has been arrested for similar crimes in the past.

The importance of a double-blind presentation cannot be overemphasized. The officer or personnel administering the lineup should not know who the suspect is. Tone of voice, body language, even rate of breathing, can subtly influence a witness to what the desired response is. If it is not possible to use a double-blind technique (due to staffing or other issues) the lineup administrator should take every precaution to avoid seeing what the witness is seeing. For example, in a photo lineup the suspect and decoy photos can be placed in folders (one to a folder) and the folders shuffled. The folders are then given to the witness to look through without the administrator seeing the photos. Also, it should be possible to set up a computer program that can randomly show photos to a witness, and record identifications and witness confidence.

Random sequential presentation is important for two reasons. First, when presentations are random the (blind) lineup administrator will not know which photo or person is the suspect. Second, presenting all individuals together invites so-called comparison shopping by the witness. A witness will be more inclined to pick the person who appears closest to the

perpetrator, regardless of whether that person is in the lineup. With a true sequential presentation the witness must offer a yes or no to each photo or individual before the next person is shown.

Important for the integrity of the process is that any decoys (also known as distracters, fillers, foils, etc.) used must resemble the suspect, especially as to witness reported features. If the witness said the offender had a certain hat or clothing on, then all persons presented in a lineup must have the same hat or clothes on. If the witness reported that the offender was bald, then all persons in the lineup must be bald. The same goes for any type of facial hair or feature, as well as height, weight, and general body build. It would not be fair if a witness reported the perpetrator was very muscular and all the decoys resembled Barney Fife.

Documentation of lineup protocol is important to allow subsequent evaluation of the adequacy of the protocol. Video-taping of the entire process would be a gold standard, but unlikely to be implemented to any significant degree. At a minimum a record should be kept of what was said to the potential witness and how the lineup was conducted. In addition, documentation of witness confidence at the time of an identification is crucial to avoid later bolstering of the confidence level due to information the eyewitness may later learn that can affect confidence, such as the suspect has been arrested for similar crimes, a confession was obtained, etc. The identification must stand on its own. To allow otherwise invites error.

Complicating the picture is a field study conducted in Illinois (Mecklenburg, 2006). The study was a year-long pilot study completed with the cooperation of the Illinois State Police and three local police departments (Chicago, Joliet and Evanston) to assess the sequential double-blind lineup procedure under real life conditions. Results of the study did not support the belief that such a paradigm would result in decreased false identifications, with lower rates of false identifications found in the simultaneous lineups.

But there has been much criticism of the study structure. Wells (2006) states that the study cannot draw any clear conclusions due to the fact that the sequential lineups always used a double-blind structure, while the simultaneous lineups never used one, leaving unanswered whether simultaneous lineup administrators could have suppressed false identifications. Schacter et al. (2008) conclude that this design essentially negates its findings. Also, behind the scenes were such issues as at least one participant (Chicago Police Department) having publicly opposed testing the sequential lineups. Another confounding issue is that the very people opposed to sequential lineups were trained on the nature and purpose of the research (O'Toole, 2006) putting them in an excellent position to bias the study. Interestingly, as pointed out by Schacter et al. (2008), if the Mecklenburg (2006) study had found that sequential double-blind lineup administration decreased false identifications we would not know if it was because of the double-blind or the sequential administration.

One type of lineup is what is known as a showup. Only one photo or individual is presented to the witness. This is a very suggestive procedure. An example would be a suspect apprehended near a crime scene and brought in the back of a police car for viewing. Another example is walking the witness past the suspect at the police station, or asking a witness if he or she

recognizes 'the man sitting over there.' While such a practice may be of some utility immediately after a crime, the more time that passes, the more suggestive it can become.

Court Remedies

Courts have generally been reluctant to allow expert testimony on the problems inherent in eyewitness testimony, framing it as invading the province of the jury. What is unspoken is the practical issue of harm to the ability of prosecutors to try cases. This issue is not to be ignored as many court decisions regarding the use of various types of evidence, although legally framed, are designed to protect the prosecutorial side of the court equation. If eyewitness testimony were allowed to be scientifically challenged at trial it would create a significant barrier to prosecutorial efforts. Expectations that legal safeguards, such as suppression hearings and cross examination, are adequate to protect the defendant from miscarriages of justice are naïve.

In *Neil v. Biggers* (1972) the US Supreme Court offered criteria to assess the reliability of eyewitness identification even when it could be shown that the identification procedure was suggestive of an individual's guilt. Apparently loath to exclude suggestive identifications, the Court offered an examination considering the 'totality of the circumstances' which could include:

- The apparent opportunity of a witness to see the offender during the commission of the crime
- The degree of attention the witness was able to maintain
- The accuracy of the witness' original description of the offender
- Witness proffer of certainty when identifying the suspect
- The length of time that had passed from the occurrence of the crime to the identification

Subsequent research has shown that this paradigm is inadequate to protect against false identifications, if only because there is no reliable correlation between witness confidence and witness reliability.

In spite of an accumulating research body highlighting the problems with eyewitness testimony, the US Supreme Court revisited the issue in 1972 (*Manson v. Braithwaite*) and reaffirmed and clarified the *Neil v. Biggers* decision. The Court reiterated the 'totality of the circumstances' paradigm with the same criteria, but made it clear that if the identification was not unnecessarily suggestive, no further inquiry was required. In other words, unless it could be shown that the identification process was unduly suggestive, the defendant couldn't even take advantage of the flawed criteria offered from the *Neil v. Biggers* decision. The US Supreme Court has yet to revisit the issue of suggestive eyewitness testimony. What the Court failed to appreciate is the inherent unreliability of eyewitness testimony, regardless of whether the police were openly suggestive or not.

In April 2001 the New Jersey Attorney General (Farmer) sent guidelines for suspect identifications to state law enforcement and prosecutors. While a major step in the right direction, the guidelines allowed for both sequential and simultaneous lineups, inviting comparison shopping, as noted above. Since then,

some states, but not all, have adopted similar guidelines. In June of 2010 a Special Master (Gaulkin), assigned by the New Jersey Supreme Court to review eyewitness testimony issues, released his report. It has yet to be acted upon. After reviewing case law and hundreds of research articles, the Special Master advised that the State's proffer that juries can sort out the good from the bad identifications is not accurate. He recommends the State require pretrial hearings to evaluate the reliability of all eyewitness identifications with the burden of proof on the prosecution to establish the reliability of the identification. He further recommended that steps should be taken to ensure that judges and juries are both informed of and guided by the available scientific research.

Summary

Along the presumed bedrock of the Criminal Justice System, eyewitness identification has been shown to be often unreliable. Both at the time of initial identification and later in the legal process, eyewitness testimony is subject to influence. Legal safeguards currently in place are inadequate to protect against miscarriages of justice. In spite of the known problems with eyewitness evidence, it enjoys an unwarranted currency in the courtroom, similar to that of uncorroborated confession evidence.

The best-informed research suggests that minimally, the following procedures should be adhered to when conducting lineups: standard instructions to eyewitness; double-blind lineup administration; random sequential presentation; appropriate use of lineup decoys; and immediate documentation of witness confidence, as well as documentation of the overall procedure.

Facial Expression of Emotion

A Freitas-Magalhães, University Fernando Pessoa Health Sciences School, Porto, Portugal

© 2012 Elsevier Inc. All rights reserved.

Glossary

Culture A set of meanings, attitudes, and behaviors specific to a given cultural group.

Emotion Spontaneous and intense neuropsychological reaction which makes the organism produce an action.

Facial expression Neuromuscular activity via which messages and signals are emitted.

Nonverbal communication The expression and perception of nonlinguistic signs between individuals.

Introduction

The face is the most visible part of the body. Hence, it has vital importance in the psychosocial development of an individual. The face is a complex and many-dimensional system, which has been extensively studied over the years. It is capable of expressing over 10 000 different emotions. Early research on facial expression of emotion concentrated on identifying and characterizing the structural nature of facial movements. Later, attention shifted to identifying and characterizing the functional nature of these same facial movements. Researchers in the field of facial expression of emotion have now turned their attention to the implications and applications of facial expressions in diverse social contexts (e.g., healthcare, justice, and education). Every face is unique, the stamp of the individual, and no two faces are identical. However, many patterns of facial behavior are shared and passed from one generation to another. Facial expression functions as a form of adaptation. So, is the face like a genetic code which we gradually decipher in our social exchanges over the course of our lives? That is a question which continues to provoke scientific debate. Current scientific research on the facial expression of emotion owes much to the work of researchers like Bell, Darwin, Duchenne, Schlosberg, Landis, Hjortsjö, Tomkins, Ekman, Fridja, Izard, Osgood, Fridlund, Russell, and Camras. The identification and recognition of a facial 'program,' with consequent measurability, have preoccupied many researchers over the years. For example, Bruce and Young analyzed face processing as a set of seven types of information code. It is a theoretical model that involves neuropsychological dissociations to access specific semantic information on facial expression recognition. Other theoretical approaches (i.e., of Burton) suggest the involvement of artificial neural networks derived from complex systems. Emotion may or may not provoke a facial expression and facial expression may or may not be prompted by emotion. This is why it is so important for us to understand the brain–emotion–face process. Each emotion (and its accompanying perception) has its own associated neural circuits. It is essential, therefore, to understand the traits on the human face put there by the emotions generated in the brain. Human facial expressions are the result of muscular movements, which express emotional states or signals. Behaviorist and geneticist approaches examine the use and meaning of the muscular movements of the face – eyes, nose, mouth, eyelids, eyebrows, forehead, and neck. Reading the map of the face remains a

challenge to modern science. Facial expression of emotion can have a contagious effect among individuals in their social interaction. The debate on facial feedback and learning, their cerebral, physiological, and situational aspects, is well documented in the literature. The face has always been seen as a mechanism of adaptation and survival, a view borne out by empirical research. Of the various theories on the facial expression of emotion, the holistic approach, which postulates that facial expression is the result of diverse and complex moderating variables, currently has the most followers.

Emotion: A Complex and Multidimensional Phenomenon

Over two centuries have passed since Bell published his anatomical groundwork of facial expression, a work which was to form the foundations for later scientific research and even today is frequently cited. Bell was the first researcher to offer a definition, albeit tenuous, for emotion. The definition of emotion is not consensual, as it is a complex and multidisciplinary phenomenon. For example, some feelings are associated with emotions. But even if all emotions generate feelings, not all feelings derive from emotions. The difference lies in duration, intensity, and frequency. Despite the difficulties in arriving at a consensual definition of emotion, the literature does agree on the importance of neuron, motor, and experiential processes. Emotion is an automatic, intense, and rapid response – either conscious or unconscious – to the world around us, and a neuronal impulse, which induces the organism to perform an action. The functions of emotion are associated with adaptation and expression. Emotion functions as a catalyst between conduct and the environment, and is a prelude to action. Emotion plays a crucial role in the learning process. Experiencing emotion allows us to learn emotionally, so we can deal with future situations, and emotion is a means of preparing us for action. Emotion manifests itself in the form of kinesic and kinetic processes in the scope of the repertoire of nonverbal communication. It contributes to the expression of feelings and may also reflect social status and power in terms of facial configuration. The different types of emotion help make communication more fluent and also assist in the identification and comprehension of defense mechanisms and rules of interaction. The components of emotion are *conscious experience* (sensation), *physiological reactions* (organs and

systems of emotional activity), and *expressive behavior*. Emotional systems have been extensively discussed in the literature and include cognition, facial expression, and the activity of the autonomous nervous system (ANS). The universal recognition of facial expressions derives from an innate program for each of the basic emotions. However, changes in expressivity change what is felt. The characteristics of emotion spread the distinctive pancultural signal for each emotion, universal facial expressions being determined phylogenetically with the involvement of various signals, the duration of which is limited; facial expression reflects aspects of emotional experience; with the different degrees of intensity for measuring the subjectivity of experience, facial expressions can be inhibited, and expressions can be faked; each emotion has its own aspects, and each activates an alteration pattern on the level of the ANS and central nervous system (CNS).

From the Brain to the Face: An Emotional Journey

The general theory is based on the premise that emotion has evolved in accordance with everyday activity; its adaptation implies differentiated patterns for each emotion and that cognition and physiology play a part in the activation of emotion. Emotion is activated in the brain circuits and involves *lateralization*; positive emotions are governed by the left hemisphere and negative emotions by the right hemisphere; *efferece*, the emotion program, implies distinct expression via movement of the facial muscles; and *facial feedback* that relates to the proprioceptive, cutaneous, and vascular dimensions of facial expression is influenced by emotion. Facial expression of emotion lasts from 1 to 5 s. The vascular theory holds that emotion and cognition functions operate via different mechanisms and that changes in facial expression change what we feel, creating or influencing emotional experience. Emotion causes physiological alterations which prepare us for action and which, over the years, evolve on the adaptive and expressive levels. Emotion is a brief reaction, but it can form the basis for the formation of feelings or other conducts. Emotion is a neurophysiological reaction to stimuli which mediate situations of danger and satisfaction. Not all of the emotions occurring in the cerebral structures are conscious. There is an extensive literature attesting that emotion develops in the limbic system, a set of structures located below the cortex and related with the cortical zones. The interaction between the limbic system and the cortex makes us aware of emotion, which may then act as a moderating variable. Emotional processing activates different cerebral structures, such as the hypothalamus and the pituitary gland, whose primary physiological functions are to regulate cardiac and muscle movements. Over the years, the emotional system has evolved to place greater emphasis on the consciousness of emotion. However, no significant evolution has occurred in the primary *pulsions*. Take, for example, the processing of fear: in the first place, the amygdala registers the stimulus almost automatically, without any interference from conscious mechanisms. The amygdala then notifies the hypothalamus, which triggers a set of physiological reactions. This process occurs almost instantaneously, with interaction between unconscious reaction and conscious response which is not fully understood. Studies have clearly shown that the

amygdala is one of the key centers for the processing of emotion, for it is the amygdala that issues instructions to other brain areas for the appropriate emotional response to be made. The brain functions, therefore, as a kind of dressing room for the expression of emotions which subsequently appear on the *stage*, that is, the face. The amygdala plays a crucial role in the emotions, and damage to it can cause selective deficits in the recognition of facial expressions of fear and also other emotions. The amygdala comprises the nuclei, which are responsible for differentiated reactions. For example, while the central nucleus triggers the immobilization reaction in the presence of a phobic situation, the basal nucleus stimulates the flight response. The different ways in which men and women react can be explained by the way these nuclei are affected by the sex hormones. The amygdala is a repository of experience. It operates unconsciously, involving various brain structures (e.g., the thalamus, hypothalamus, hippocampus, cerebral cortex, etc.). This is one reason why it is difficult to treat phobias in a clinical context. However, we can – and should – learn how to deal with the stimuli and in this way mitigate the intensity of phobic reactions. In the case in point, the amygdala captures the facial expression and produces a certain reaction. Scientific discussion continues on the issue of whether the activation of emotional reactions is a conscious or unconscious process. Much literature contends that emotion is initially a physiological reaction to, for example, a threat to the integrity of the system. Once the amygdala has relayed the signal, conscious feeling, involving the orbitofrontal and cingulate cortex, emerges.

Facial Expression: From Universality to Cultural Influences

The research of Ekman and Friesen just over half a century ago made a considerable contribution to our knowledge of the facial expression of emotion. Until then, the study of facial expressions had enjoyed little prestige among psychologists, despite the contributions of Allport et al. At this time, the work of Schlosberg on the representation of the information exhibited by the face drew most attention. Still, very little extended research was dedicated to it. The much needed paradigm shift came with the work of Tomkins, for whom nonverbal communication – namely facial expression – was a superlatively rich source for the study of human behavior. Ekman and Izard were influenced by Tomkins' work, particularly with regard to the planning and execution of intercultural studies, in their examination of questions such as the following: Do facial expressions convey universal emotions? How do we interpret facial expressions? The work of Ekman in New Guinea in the late 1960s reinforced the view that, contradicting Mead, spontaneous expressions are universal, while also showing that facial expressions can be influenced by the so-called *rules of exhibition*, which are specific to a given culture or social context. Ekman's findings were backed up by the evidence gathered in anthropological studies. Psychologists such as Fridlund and Russell, however, have questioned this evidence as well as the methods used in arriving at judgments on the display of facial expressions. Expressions of fear, anger, disgust, sadness, and joy register values of intercultural

congruence. Discovery of the universality of facial expression triggered the need to devise methods and techniques of scientific measurement for the evaluation of facial movement. Thus, in the 1970s, there emerged the Facial Action Coding System (FACS) for the classification of muscular movements, and the Maximally Descriptive Facial Movement Coding System (MAX) for the verification of the most important muscular movements in the identification and recognition of a given emotion. Also, at this time the first scientific findings on the measurement of the electrical impulses associated with movements of the facial muscles began to appear. Measurement of the facial expression of emotion continued to be a challenge for researchers. And the principal problem affecting measurement methods already devised was how accurately and objectively these methods could measure. The identification and recognition of facial movements and their association with certain emotions have provoked extensive and heated scientific debate. The techniques and methods devised by Izard, Ekman, and Friesen (the FACS was updated in 2002) in the late 1970s were based on the research of Hjortsjö into the workings of the facial anatomy. The identifying Affect Expression (AFFEX) by holistic judgment, the Facial Affect Scoring Technique (FAST), the Facial Expression Coding System (FACES) and EMFACS (which converts action units (AUs) into emotional states), the FACS Affect Interpretation Dictionary (FACSAID), electromyography (EMG), functional magnetic resonance imaging (fMRI), and baby FACS and FACEM (which measures facial movements in terms of a dozen basic states) are some of the instruments now used in measuring the meaning of facial movements. Current research also draws on databases (e.g., F-M Portuguese Face (F-MPF) and pictures of Facial Affect and Karolinska Directed Emotional Faces) and software (e.g., Micro Expression Training Tool (METT), Subtle Expression Training Tool (SETT), FaceReader, FaceXpress, i-Brain, i-Emotions, i-Smiles).

Facial Expression: Its Contribution to the Study of the Emotions

The evidence for the universality of facial expressions has led research to extend into other areas, such as healthcare, justice, and education. The scientific community now sees facial expression as a psychobiological phenomenon of considerable interest to the comprehension of human attitudes. Given that each expression is associated with a particular physiological activity in turn associated with a particular emotion, the idea of interaction between a given emotion and the CNS gained increasing numbers of supporters, especially in the early 1990s with the work of Davidson and Cacioppo among others. Spontaneous facial expressions are the result of a subjective emotional experience. Typical emotions appear in response to given situations, which bears out the claim that events precede emotions. Facial expression is the mirror of our ontogeny. The ability to give facial expression to our emotions appears at an early stage of infancy. Thus, the face is a fulcrum element in human interaction from a very tender age – and indeed is the first means of communication from which we can draw. Emotions occur according to a special process. There are various expressions for each emotion. For example, Ekman catalogued over 60 expressions of fear, which reflects the intensity

of this emotion. Each emotion is comprised of specific affective states, and it is the composite nature of these states which determines the differences between the emotions. Facial expressions are seen as evidencing subtly positive or negative states. Emotions may vary in terms of vocal expression, but not in terms of facial expression. And some expressions, such as smiling, are used in various states.

Positive Emotions and Negative Emotions

Negative emotions trigger serious problems, which may take the form of, for example, phobias, anxiety disorders, aggression, violence, depression, suicide, and eating disorders. For Tomkins, negative emotions produce a specific signal. However, research conducted in the 1990s failed to confirm this theory, pointing instead to the existence of various templates, which supports the differential theory of emotion. Positive emotions represent the satisfaction of the individual. The limbic system is related with sensations of pleasure, diminishing other types of activity which may influence the normal course of satisfaction. According to the literature, there is an association between emotional states of pleasure and zygomatic muscular activity. It also shows that happiness is not always signaled by a smile. For example, the smile of a child is more evident in the context of social interaction than in situations of happiness and can also be observed more in situations of discomfort. The smile is coordinated by the ocular function and success in a sports competition is not evidenced when receiving the prize. The smile is in fact a specific phenomenon of the facial expression of emotion and one of the paradigmatic features of the study of facial expression of emotion, as a multidimensional phenomenon which is at the source of much disagreement among researchers with regard to its causes and functions. One type of smile which has attracted much scientific attention – and yet elicited little agreement – is the so-called Duchenne smile, which is characterized by zygomatic activity in combination with the orbicularis oculi.

Basic Emotions

The human face exhibits basic universal emotions with a muscular configuration specific to each: joy (corners of the mouth raised), disgust (cheeks raised, nose puckered, upper lip curled), anger (eyebrows lowered, eyes narrowed, lips compressed), contempt (chin raised, part of corner of mouth raised slightly), fear (eyebrows raised, eyes wide open, mouth open), surprise (eyebrows arched, eyes wide open, jawbone slack), and sadness (eyebrows slanting from center to edge, mouth slack).

What Does the Face Show?

Facial expressions are the reflection of the experiences and messages of the endogroup (the group of belonging) and the exogroup (the comparison group). The terms we use to describe emotions are not unique or unequivocal. Once again the intercultural question comes into play. The message generated by an emotion has to be captured instantaneously. The start, duration, and end of the movement are the stages that have to be taken into account. Involuntary and momentary expressions activate a particular muscular contraction, giving

indications on the type of associated emotion. Positive emotions share a particular expression (e.g., the smile), which can be observed in terms of time, intensity, and context. Negative emotions (e.g., sadness) also exhibit a particular morphology of expression (e.g., corners of the mouth, eyebrows) characteristic of unhappy states. Some emotions are given no expression on the human face. This means we are unable to identify a facial expression, vocal expression, or bodily behavior associated with them – no discernible pattern or sign of distinction exists. This is a legacy of ontogeny and phylogeny. There is a template at the CNS level which is unique for the emotions. The fact that an emotion is not linguistically coded does not mean that the emotion does not exist. There can be emotion without facial expression. Research using EMG has detected alterations in the pattern of facial activity. This would seem to contradict Tomkins, who asserts that facial expression is always part of emotion, even when it is not visible. Voice and posture (e.g., head and hand movements) also contribute to the configuration of the emotions. Isolated head movements do not by themselves communicate emotions. It may be possible that emotion can be characterized by vocal expression but not facial expression. Ekman agrees with Tomkins in contending that each emotion has its facial expression and its vocal expression too. The existence of emotions with no expressive or auditory signal has occupied many contemporary researchers. Ekman maintains that we must bear in mind certain discrepancies in the mode of facial expression of emotion (e.g., anger as a result of irritability), emotional state (anger as a result of hostility), and affective disorders (sadness as a result of depression).

Facial Expression Without Emotion

People can fabricate and feign the facial expression of emotion, but this occurs when they are not in any emotional state. The literature attests to the distinction between genuine and false expressions. Some muscular movements cannot be made voluntarily. In the latter half of the nineteenth century, Duchenne identified the orbicularis oculi, the muscle which surrounds the eyes. This muscle contracts in involuntary smiles but not in voluntary smiles. The orbicularis oculi comprises two portions: the central and the lateral. The first portion can be contracted voluntarily, but the second cannot; and it is the contraction of this second portion which is absent in 'false' smiles. Duchenne's theory now enjoys global consensus. Expressions such as anger, fear, and sadness also involve specific muscular configurations that cannot be exhibited voluntarily.

A Special Phenomenon: The Human Smile

Not all smiles are the same. Laboratory analysis of the human smile has established a reference framework which distinguishes between true and false smiles, and which involves identical asymmetry and different amplitude and duration. Distinctions are established between true smiles and false smiles, spontaneous smiles and intentional smiles, as well as Duchenne smiles and non-Duchenne smiles. The Duchenne smile and the social smile are extensively documented in the literature. The first is spontaneous; the second intentional. The Duchenne smile – named after the French neurologist Guillaume Duchenne, who was the first to identify it – involves

muscles activated by an unconscious cerebral process. With the Duchenne smile, the lower eyelids dilate and the corners of the eye wrinkle. The smile is an indicator of what its wearer is feeling and reveals the emotional state ascribed to it. Forced smiles point to low levels of happiness. The smile is controlled by emotion. A true smile, which involves activation of the muscles around the mouth and the eyes, reveals joy and involves the motor cortex, the muscle around the eye (which controls movement of the eyelids), and the amygdala. A false smile, however, involves conscious brain structures and the motor and premotor cortices, with the eyes averted and deliberate contraction of the muscles around the mouth drawing the lips outwards, and also involves the premotor and motor cortices, the frontal cortex, and the lesser and greater zygomatic muscles.

Gender and Age: Differences and Implications

Women are more attracted by faces exhibiting positive emotions in men than in women, regardless of age, while men are more attracted by negative emotions without distinction of gender. This is one of the conclusions of research into facial attraction and the effects of the emotions. The procedure consisted of displaying images of faces exhibiting basic and secondary emotions and judgments on identity and attractiveness made by individuals. The findings suggest that women feel more attracted by the faces of men exhibiting positive emotions and belonging to the 18–25 age group, with levels of attractiveness decreasing as age increased. Men feel more attracted by negative emotions in the 18–25 age group, and again the level of attractiveness decreases with age. The findings also suggest that distinct perceptions of attractiveness vary according to the type of emotion exhibited on the face, and that such perceptions vary also according to gender and age. The conclusions also suggest that facial expressions reflect and determine how emotions are expressed. They confirm the principal effect of the facial muscles in the representation and determination of the emotions, while differences according to age and gender were observed. Women claim to feel emotion more intensely than men. Individuals in the 40–60 age group also claim to feel emotion with greater intensity. The findings corroborate the facial feedback theory, according to which the facial expressions exhibit not only emotional experience but also determine the way the basic emotions are lived and labeled.

Emotion Manifested on the Face: Some Theories Compared

The new scientific approach accepts some associations between facial expression and emotion, but insists that the central question is not the associations themselves but their nature. This is the real core of the debate on the facial expression of emotion. The facial expression of emotion is influenced by culture, age, and gender. It makes reference to multiple standards within the scope of nonverbal communication, which reinforces the behavioral ecology view of the emotions. Spontaneous expressions are rather the reflection of phylogenetic criteria. The smile, according to this theory, appears from the

experience of an affective state. It is not an intention of friendship, but a positive feeling. The emotions do have social intentionality, as rational behavior does, but we must take into account a behavioral disposition characteristic of a certain receptor. Facial expressions can occur when the emitter is alone. With regard to facial expression and the effect of the intensity with which the basic emotions are exhibited, the literature observes that the human face is incapable of displaying two emotions at the same time. The research procedure consisted in collecting information on the intensity of the seven basic emotions (joy, sadness, anger, fear, surprise, disgust, and contempt) exhibited by individuals. Muscular-skeletal movements were measured in terms of microexpressions in fractions of a second. Participants were unable to exhibit two basic emotions (e.g., joy and anger) on their face at the same time when asked to do so. The findings show that the brain processes the exhibition of the basic emotions sequentially. The findings also suggest that women exhibit the basic emotions quicker and more intensively than men, regardless of age. Surprise and fear are the basic emotions that both women and men are quickest to exhibit, while contempt and disgust are those which take most time to appear on the face. The literature also shows that the right hemisphere is more associated with negative emotion than the left hemisphere. For example, the identification and recognition of the basic emotions of fear and sadness tends to activate the structures of the right hemisphere more than the left, while the signals produced are received and processed by the left hemisphere. These signals must circulate in that order if we are to be conscious of the emotions. Facial expression of emotion also activates the right frontal cortex. Emotional information is processed in neuronal circuits and the reaction and response to them depends on the type of stimulus. For example, the positive emotions follow a different path from the negative emotions, for they are intimately linked to the cerebral artery which segregates dopamine, the neurotransmitter responsible for feelings of satisfaction and pleasure. The consciousness and evaluation of the intensity of emotion is the responsibility of the thalamus. fMRI enables us to identify the course of the reaction and response of brain structures. The literature attests that the facial expression we know as the smile is more rapidly identified and recognized (i.e., consciously) than a neutral expression, and that the brain needs only 350 ms for the global perception of emotional interpretation. Emotion is characterized by duration and intensity. It is a guide for adaptive behavior. It is consensually described as a neuronal impulse which causes the organism to produce an action. Modern evolutionary theories are concerned with the identification of the functional axis of the emotions, arguing that just as emotion can be the cause of facial expression, the latter can be the cause of emotion. And the recognition of discreet or subtle emotions is a fundamental question in the evaluation of this process. Approaches toward the facial expression of emotion have changed since the late 1970s. Traditionally, expressions such as the smile have been considered as facial expressions. But this is where a range of differences begins to emerge. The new approaches focus on the expression-emotion pairing. The facial movements are called signals. Facial expression is viewed as a heterogeneous phenomenon and the point of analysis is the emotional state of who is emitting and who is receiving the message associated with a given facial expression. The communication process is considered, and analyzed, in its

entirety. The modern era of the study of the facial expression of emotion began in the 1960s with the work of Tomkins, which was later an influence on Izard and Ekman, among others. Tomkins's theory holds that each basic emotion is associated with a unique cerebral emotional process. The basic emotions vary in their degrees of intensity. This theory of the basic emotions has received criticism, however. The new approach to the facial expression of emotion stresses the multidimensional character of the emotions, paying particular attention to the components underlying emotional processes. One of the criticisms leveled at the theory has to do with the fact that research into the facial expression of emotion is centered exclusively on the judgments made by the receiver of messages. The momentary emotional state of the receiver of these messages is not taken into account. And the judgments made by the receiver do not necessarily correspond with the emotion as lived. This view of the facial expression of emotion stresses the idea that the receiver does more than merely receive and decode the expressed message. The facial expression of emotion involves the emitter in a range of effects. For example, when detecting a lie, the receiver is not merely detecting the lie but also verifying a standard of truth. For the person receiving the message, more than merely verifying the traces of the lie, he/she verifies the truth-framing process. Can the facial expression of emotion predict human behavior? The traditional theory of the basic emotions is now being reexamined in the light of new approaches, which stress the dynamic processes of the various components involved, with particular emphasis on the social context and its relationship with cognition and activation. Social learning is a dimension which must be taken into account in the process of construction and exhibition of the facial expression of emotion, as the communication process involves both sender and receiver and it is not essential that an emotion be attributed to the message. What is at stake is the universality of this process. In the traditional view, facial expression is always a particular signal of emotion, with the consequent process of decoding on the part of the receiver, regardless of gender and age variables. The process is innate and immediate. It is precisely in regard to the processing of the comprehension of facial expression that the debate and the different approaches emerge. According to the traditional view, the facial expression of emotion occurs according to an innate standard shared by all cultures. According to the modern view, social influence has a considerable effect on this process. In other words, the signal manifested on the human face is interpreted according to different perspectives, as a range of facial traits can be observed for each emotion. No rational evidence for the existence of such a range is known. The research is extensive and the findings are not consensual, principally with regard to the facial expression of spontaneous emotion. And this is a result of the components involved in the cognition process. For example, some emotions are more easily recognized than others. The basic premise is that this process requires that the emotion is part of the stimulus and as such must be immediately recognized, as if it were part of a congenital standard. Now the attribution depends not only on the genetic process but also on the cultural background of the individual processing and emitting, and the individual receiving and perceiving. For example, the literature observes that a smile is not always a sign of happiness, and that the ways we recognize a smile are not in fact consensual. Hence, modern theory on the facial expression of emotion argues for

the existence of what it calls a minimum universality, pointing to the fact that facial expression can occur in any place at the instancing of a psychological process, that is, people make inferences based on facial traits. However, judgments reveal discrepancies with regard to identification and recognition. The judgment that the receiver makes of facial traits is summarily expressed as a specific emotion. Yet, this process is influenced by our surroundings. The judgment of a given facial expression of emotion is not as simple as it might at first glance appear to be. The process – often the immediate identification of a signal – involves complex variables such as gender, age, affective state, and social context. The idea is that the recognition of the facial expression of emotion is not just the recognition of a signal but the result of a learning process of the utility of such a signal in the dyadic process of human communication. In the light of the above, and despite previous research, further intercultural investigation is required, for the effects of the facial expression of emotion are diverse.

Macroexpression and Microexpression

The analysis of the facial expression of emotion, spontaneous or intentional, addresses amplitude, asymmetry, duration, onset, offset, intensity, and head movements. Macroexpressions last between half a second to 4 s and can be observed in everyday conditions. Microexpressions last less than half a second and occur when the individual is concealing or repressing his/her feelings. Microexpressions are not immediately detected by the observer. However, with a little training, we can learn to express and recognize microexpressions. ‘Subtle’ expressions are related with the intensity of the emotion and occur only when an individual is undergoing the onset of an emotion. They also appear in response to another individual in contexts of reduced emotional intensity. We can observe a strong correlation between the degree of identification and recognition of subtle expressions and the degree of detection of falsehood or deception. The time taken for macroexpressions to appear and disappear varies between 0.5 and 4.5 s, and occurs as part of a normal process of the exhibition of the emotions. The time taken for microexpressions to appear and disappear is less than half a second, and frequently as short as 1/5 or 1/15 of a second. Some expressions involve the whole face, that is, enlist all the facial muscles at the service of a certain pattern, including the forehead, eyes, cheeks, and lower jaw. Facial expressions that involve all the associated components are observed only in the eyebrows or eyes and cheeks or lower jaw. Analysis can be made in terms of angles (frontal, whole face frontal; 3/4 angle where the face is seen from an angle of 45°, and in profile, where the face is seen from the side, at an angle of 90°). The intensity of macroexpressions can be moderate or strong, corresponding to codes C to E of the FACS. Microexpressions are of low intensity, corresponding to codes A and B of the FACS. Facial expression is also measured in terms of distance (short, as in social interaction between close friends or family members; medium, as in social interaction among known and unknown individuals; and long, as in the identification of a face in the crowd or at a considerable distance). Recent research has revealed that subtle expressions, but not microexpressions, are a more accurate and

useful tool for the detection of falsehood and deception. Thus, learning how to identify and recognize subtle expressions helps us learn how to detect lies. Subtle expressions occur only when an individual is beginning to feel a given emotion and in low-intensity contexts. When we identify and recognize a subtle expression, we are identifying the emotion that our interlocutor exhibits and the subtle variations in its expression. To identify and recognize a microexpression, we need to be able to verify an expression visibly replete with emotion in a short space of time (1/2 s or less). In the laboratory analysis of facial expression, a range of methods and techniques are used. For example, Psy7Faces is a method devised for detecting subtle expressions and microexpressions. The METT, SETT, and SubX are computer programs designed to train us in identifying the basic emotions. The most commonly used instrument for measuring facial expression is the FACS, which provides a scientifically rigorous method of classifying the movements of the facial muscles. Current research suggests that traits can be identified and recognized for lie detection purposes. The basic premise is simple enough: if there are different ways of expressing the content of the basic emotions, then profiles for psychophysiological alterations can be devised. The research manual, published in 2002, lists 44 AUs for evaluating facial expression via combinations. For example, the expression of joy maps to AUs 6 and 12. The intensity is measured on a scale of a (trace) to e (maximum evidence). Onset, apex, and offset mark the stages during the muscular movement evaluation process.

Neuromuscular Structure and Facial Expression

The way the brain constructs emotion has been the subject of much in-depth research in recent years. The brain is divided into two hemispheres, and processes information cross-wise: each hemisphere controls the opposite side of the body. Each half of the cerebral cortex has four lobes (frontal, parietal, occipital, and temporal), each with a specific function. The temporal lobe regulates certain emotions (joy and anger); the frontal lobe regulates movement and reasoning; the parietal lobe regulates touch, sensations of heat, cold, and pressure; and the occipital lobe interprets the information sent it by the optical nerve. As for the nervous system, of the 12 pairs of cranial nerves it is the facial nerve (VII) which controls the movements of face and neck, as well as the sense of taste. The motor fibers drive the facial muscles and in this way allow us, for example, to move our eyebrows, open and close our eyelids, narrow our nostrils, smile, pull faces, and kiss. The muscle around the eye allows us to close our eyes (voluntarily, when we want to sleep, and involuntarily, to blink); the muscle around the mouth allows us to close our mouth or stick our lips out (e.g., to give a kiss); the frontal muscle allows us to raise our eyebrows and frown our forehead; the masseter muscle allows us to chew; the nasal muscle allows us to open and close our nostrils; and the temporal muscle allows us to move our temples. Another example of the differentiated movement of the muscles is that the expressions made by humans are not exactly the same as those found in the chimpanzee (humans configure joy differently from chimpanzees; when the latter show their teeth they are revealing fear).

The Face: Moderating Variables

The Effect of Visual and Auditory Stimuli

Visual stimuli exercise more influence on emotional perception than auditory stimuli, and there are gender and age differences in emotional reactivity when the neuropsychophysiology of the emotions is examined via the verification of the visual and auditory effects of positive and negative emotions. The effects of visual stimuli are more visible than those of auditory stimuli both in positive and negative emotional reactions. Regardless of their age, women are more influenced by the visual stimuli of the basic emotions of joy, sadness, and surprise. Men are more influenced by visual stimuli of the basic emotions of anger and joy, decreasing in intensity from age 45 onward. Research has revealed that visual stimuli of fear and sadness are mentioned by participants aged 65 and over.

Effect of Skin Color

According to the literature, skin color affects the psychological perception of the smile. The expressiveness of the smile reveals that women are more influenced by skin color when they see a smile. Research has demonstrated that our perception of smiles in individuals of a different color of skin reinforce attachment to the endogroup in relation to the exogroup and facial stereotypes in the context of the rules of social exhibition and theories on the facial expression of emotion. The Smile Perception Scale (SPS), devised by this author in 2003, comprises 19 opposing pairs and measures the factors evaluation (Ev) and expressive movement (EM) in two types of facial expression: the broad-type smile (lips apart, corners raised, both rows of teeth on show, the whole face exhibiting significant physiological alterations, accompanied by muscular movements) and the neutral or unsmiling face (lips together, corners not raised, teeth not displayed, no physiological alterations of face, and no muscular movement).

Facial Feedback

The facial expressions reflect and determine how emotions are expressed, that is, the psychological construction of the emotions and the effect of the movement of the facial muscles. The research procedure involved asking participants to use their facial muscles to express the basic emotions. One of the examples used was fear ('Raise your eyebrows and knit them'; 'Stretch your lips horizontally toward the ears'). The participants later noted whether they had felt the emotion represented, and with what intensity. The findings confirm the principal effect of the facial muscles in the representation and determination of the emotions, and age and gender differences were observed. Women say they feel emotions more intensely than men. Participants in the 40–60 age group also claimed to feel emotion with greater intensity. These findings corroborate the facial feedback theory.

The Effect of Stereotypes

Facial expression and the effect of the smile on the psychological perception of stereotypes show that an individual who smiles is perceived as intelligent and attractive. Smiling people

were perceived as happier than those with a neutral expression. The broader the smile, the happier its wearer. Women were perceived as more intelligent and attractive when wearing a superior or closed smile than when with a neutral expression. There were no significant differences in perceived intelligence in men. The findings suggest that smiles affect men's perception of beauty. A smile makes a woman more attractive, and attractiveness increases in linear fashion from a neutral face to a broad smile. The 60–70 age group makes no significant distinction in its perception of the different types of smile and associated psychological characteristics. But this difference is significant in the 18–25 age group. Women tend to underestimate the effect of a smile in other women, attaching greater value to the smile of a man. A smile in itself is the expression neither of intelligence nor beauty – its effect depends on variables such as the gender and age of its wearer and observer.

The Smile of Criminals

Criminals who smile are more favorably perceived, and seen as less responsible for the crimes they have committed, than criminals with a neutral expression, especially among women. Analysis of facial expression and the effect of the smile in psychological perceptions of criminals revealed the same. The conclusion is that women and male criminals are perceived more favorably, and seen as less responsible, by women, while men only make such a distinction in relation to women. Research has also revealed that the age effect is operative in men aged between 18 and 50, for whom there are no significant differences in their perceptions of the facial expressions of criminals. The more serious the crime committed, the less the importance attached to the smile, both by men and women. The findings reveal that this significant reduction in the smile effect is more pronounced in men.

Activation and Perception

Findings on the psychophysiology of the smile and the construction and effect of the emotions reveal that the smile not only reflects certain emotional states but can also help to produce them. Women and men attest to experiencing positive emotions when they smile, and this experience varies according to gender and the type of smile exhibited: women say they feel happier when they wear a broad smile and men when they wear a superior smile, as the literature records. For example, the muscles which are activated when we smile send a message to the brain informing it of the experience of happiness, even when context and circumstance have not actually produced this particular emotion. This is the premise on which the theory of facial retroaction is based. Conversely, neither women nor men say they feel any emotion when they wear a neutral expression. A closed smile is the first indicator of the feeling of happiness, although it has little intensity either in men or women. None of the participants said they felt any kind of negative emotion when exhibiting one of the smile types studied. The findings suggest that wearing a smile has strong therapeutic effects in the induction of positive emotions in diverse social contexts. The smile has been classified into four different types: the broad-type smile (lips apart, corners of mouth raised, both rows of teeth on show, the whole face exhibiting significant

physiological alterations, and accompanied by muscular movements), the superior smile (lips apart, corners of mouth raised, upper teeth on show, the whole face exhibiting significant physiological alterations, and accompanied by less intense muscular movements), the closed smile (lips together, corners of mouth raised, teeth not on show, no significant physiological alterations to the face as a whole, and limited muscular movement), and the neutral or unsmiling face (lips together, corners of mouth not raised, teeth not displayed, no physiological alterations of face, and no muscular movement).

The Effect of Visual Memory

Women reveal better visual memory in the identification and recognition of human faces, as shown by research into the effect of memory on the psychological perception of the face over different periods of time (5, 10, and 30 min). The ability to remember a face decreases significantly as more time elapses between exhibition of the face and the request to identify and recognize it at a later stage. The eyes, mouth, nose, and facial shape are the elements most cited as facial identifiers. Regardless of their age, women are more assertive in the identification and recognition of faces, but especially in the 45–65 age group.

The Effect of Facial Deformation

There is a pattern of construction of facial expression associated with each basic emotion, as discovered by recent research into the effect of facial deformation in the psychological perception of the basic emotions. The research procedure consisted in the identification and recognition of the basic emotions (joy, sadness, surprise, fear, anger, disgust, and contempt) via the exhibition of purposely deformed faces extracted from F-MPF, a database compiled by this author in 2003 and spanning ages ranging from 18 to 80 years. Degree of assertiveness in the identification and recognition of the facial expression of emotion diminishes as movement decreases and deformity increases. Sadness and contempt, two emotions that require little muscular movement in a subject of purposeful deformation, are the emotions that register the lowest identification and recognition ratings. Joy, anger, disgust, fear, and surprise were more assertively perceived, and in the order given. Regardless of their age, women are more assertive in the identification and recognition of the basic emotions in deformed faces, especially in the 45–65 age group.

The Effect of Tears

Research into the psychophysiology of weeping and the effect of tears on emotional experience has found that women on average cry two or three times a week and more frequently show their tears than men. The procedure consisted in the gathering of information (via questionnaire) on the frequency and intensity of weeping and the emotional and physical circumstances in which weeping occurs. The findings suggest that while women cry more than men, the latter cry more intensely when they do. Age differences were observed in the manifestation of tears: women in the 18–30 and over 60 age groups cry more frequently, but more intensely in the 35–55 age group. With men, weeping is more common in the 18–30 and over 60 age groups, but more intense in the 35–50 age group.

Women tend to cry in their bedrooms and with their female friends, while men claim not to choose the location and place the emphasis on the circumstances which incite their tears. Both sexes are in agreement with regard to the reactive nature of tears, that is, weeping is provoked by external factors; however, women also noted that sometimes they cry without knowing why. The death of kin, family breakups, loss of employment, and the detection/treatment of illness are the most important causes for the production and manifestation of tears. The findings also indicate that women have (or claim to have) no shame about crying in public, while men are more withdrawn and only cry in public in exceptional circumstances. Both sexes see weeping as a reactive mechanism, a compensatory phenomenon which offsets the tribulations of life.

Facial Symmetry

The classification of faces as ‘more masculine’ or ‘more feminine’ depends on the degree of symmetry they present, a phenomenon related with the mechanisms of attraction. According to research, symmetry is related to biological processes, where it functions as an indicator of attraction and the genetic suitability of a prospective partner. According to the findings of research into facial expressions and the recognition of the basic emotions, women can more readily and more consistently identify the basic emotions via facial expression – a faculty they retain over the course of their lives. Research involved individuals aged from 18 to 70. Joy, anger, sadness, surprise, disgust, and fear were the emotions studied. In women, the standard for the perception of the basic emotion of joy is in the 18–25, 40–50, and 60–70 age groups. Women perceive this emotion more spontaneously, frequently, and rapidly than men. No homogeneous pattern can be identified for men, although anger and disgust are the emotions they identify most frequently and rapidly. Research revealed that men in the 60–70 age group identify sadness and fear more frequently and spontaneously. Women in the 18–25 age group perceive joy and sadness more frequently and spontaneously, while men more readily identify anger and rejection. Men in the 40–50 age group perceive sadness and surprise more frequently and spontaneously, while women more readily identify joy. While women frequently and spontaneously identify all the emotions, regardless of the age or gender of the individual exhibiting them, men more frequently and spontaneously identify the emotions exhibited by females. Perceptions are not linear across all age groups: the 60–70 age group had difficulty in correctly identifying the emotions expressed. The METT and the SETT, devised by Ekman in 2003, were the instruments used in the collection of empirical data. The facial expression of emotion was exhibited for only one quarter of a second, with participants subsequently asked to identify the emotion exhibited.

Expression and Twins

The smile and its effect on the psychological perception of twins. The objective of this research was to determine whether, in controlling the face variable by the presentation of twins, people are perceived differently because of their gender. The broad smile was the smile type which exerts most influence on the psychological perception of the person, followed by the superior smile, closed smile, and neutral expression. A gender

effect is also observed in the comparison of smiles in twins: women identify more with a smile by the female twin, while men make no distinction.

Perception of Facial Expression in Babies

Women are more spontaneous and consistent than men in the perception of the basic emotions conveyed by the facial expressions of babies aged 1 year, as research into the facial expressions and the recognition of emotions has shown. Joy, anger, sadness, surprise, disgust, and fear were the basic emotions studied. The findings merely confirm that the identification by women of the basic emotions is the result of bonding interaction from the first 3 months of life, intensifying from 8 months without gender distinction. Men are less spontaneous and less consistent in their identification, manifesting errors of emotional perception in babies of both sexes between 5 and 6 months of age. Women are also better able to spontaneously identify positive emotions than negative emotions. Gestational age is a moderating variable in emotional perception. The 18–35 age group registers the least discrepancies in emotional perception, regardless of gender, while the 35–50 age group exhibits alterations, inaccuracies, and errors in its emotional perceptions, a phenomenon especially marked in men.

Truth and Falsehood in Facial Expression

Expressing and reading the emotions on the human face are two verbs which should be conjugated in the present, as they contribute to healthy interaction. Expressions are not merely signals – they are also freighted with emotional content. Persons who are blind from birth never change their facial expression. Learning seems to have little influence. Observation of the expression of the emitter presupposes that the receiver gets it immediately. Inhibition, via intentional muscular configuration, is performed consciously. The literature shows that individuals unable to imitate facial expressions after cerebral stimulation are unable to identify and recognize them to the same extent as those able to imitate. Facial expressions can be false, and this falsity can be detected. When we express an emotion we are creating that emotion, so when we attempt to fake an emotion we fall prey to emotional conflict because of overlapping emotions. This process involves the secondary motor cortex (responsible for the alternative expression), the upper temporal sulcus (responsible for evaluating the effect of the forced expression), and the orbitofrontal cortex (responsible for inhibiting the natural expression). When we attempt to display an emotion which we do not feel, diverse cerebral structures are involved. With true expressions, the left hemisphere controls movement on the right side of the face, while the right hemisphere, more emotional, controls the left side. Take for example the eyes and the importance of their movement. The eyes can be a major giveaway in lie detection, and women are more assertive in this procedure, according to the conclusions of research into the effect of the eyes in lie detection. The procedure consisted in the identification and recognition of falsehood via true and false stories with which a certain look was associated (direct, evasive, objective, right, left, straight ahead, profile, miosis, mydriasis, normal, upwards,

downwards, or/and level). The standard for identification of falsehood was the more frequent exhibition, in this order, of intensity (mydriasis and miosis), incidence (averting the eyes), inclination (up, down), and laterality (profile). Regardless of their age, women are more assertive in the identification and recognition of falsehood, especially in the 25–45 age group. Research has also shown variations in the types of look associated with falsehood from 45 years of age onward.

Psychosocial Implications and Applications

The facial expression of emotion has diverse psychosocial implications and applications, for example, in the fields of healthcare and justice. In healthcare, the applications are in physiognomy and pathognomony, that is, verification that the patient is transmitting a true emotion: subtle expressions and microexpressions in the context of clinical supervision, emotional expressiveness as an indicator of psychological state and social cooperation, and the study of pain via detailed mapping of facial expressions. Some current lines of research are examining pain in terms of its facial manifestations. Identifying and recognizing the neuro-anatomical features of the expression of pain facilitate productive interaction between patients and doctors in healthcare settings. Mapping the features of pain allows us to immediately detect discomfort and to take more assertive action, as the face is like a fingerprint of suffering. The neurophysiological mechanisms of pain give us valuable information about the face and its ability to convey the state of health of an individual, and this information is of great value in the prevention and treatment of pain. Meanwhile, technology is also making its contribution to the study of the human face, with attention focusing on sufferers of, for example, Alzheimer's and Parkinson's diseases. The objective here is to allow sufferers of degenerative diseases of the brain to improve their ability to identify and recognize faces, thus improving their quality of life. Memory loss is the principal symptom of such diseases as Alzheimer's, so the challenge is to create signals which assist memory, and the human face is a reactive mechanism which can play a decisive role in this process. As for Parkinson's disease, the strategy is to give patients the chance to identify and recognize faces with the objective of facilitating interaction via the mapping of facial movements. Loss of the expressive faculties is a recurrent symptom of this disease, so the challenge is to create signals which assist memory, and again the human face is a reactive mechanism which can play a decisive role in this process. All aspects of the expressive powers of sufferers of Parkinson's disease are worthy of scientific analysis, for knowledge of the facial movements is a valuable asset in the development of a healthy society, as it clarifies the mechanisms of communicative interaction. In addition to four-dimensional imaging technology for the verification and evaluation of the muscular movements, other techniques can be used for scientifically verifying the functionality of facial expression in sufferers of Parkinson's disease.

The Smile and Its Therapeutic Effects

The literature confirms that the broad smile and superior smile are the two types of smile which exert the greatest therapeutic effect. The effect of these two types of smiles is more

frequent and more intense in women than in men. It was also observed that the therapeutic effect of the smile varies according to age group: members of the 45–60 age group registered clear improvement in their mental health in relation to the 25–44 age group, and participants attached increasing importance to positive thoughts when exposed to broad and superior smiles.

Forensic Psychology: The Value of Facial Expressions

The adoption of methods and techniques for the analysis of the facial expression of emotion within the legal system. Analysis of the effect of the smile in lie detection represents one more attempt to raise awareness in legal circles of the need to adopt scientific procedures for the analysis of the facial expression of emotion. The lines of research have shown that the legal system stands only to gain by using facial expression analysis techniques. One example is questioning by police and legal representatives, during which the use of scientific methods for interpreting facial movements and facial language can be decisive in determining the truth, and one more contribution, therefore, to the body of evidence. Like DNA analysis, the science of the human face also employs the concept of markers of trust in analysis of facial expressions. Training police agents to detect emotional incongruities using scientifically proven techniques and methods is one potential application. The ‘autopsy’ of facial expressions could prove decisive in solving certain crimes, as some muscular movements are totally involuntary and as such escape the control of an individual who might, during questioning, attempt to conceal them. The face is a laboratory of scientific analysis which could be put to the service, in this case, of justice.

Emotion and Psychopathy

Research has examined the relationship between psychopathy and the emotions. The objective is to understand the cerebral processes involved in the neuropsychophysiological reactions of the facial expression of emotion and to establish a standard which facilitates treatment and the prevention of crime. The ability to identify a psychopathic state is a vital predictor for treatment and the prevention of violence. Science has suggested that psychopaths process emotions in a different way from normal persons, and therefore the manifestation of emotions in the form of facial expressions is likely to be different too. The ability to identify and recognize emotions and the frequency of their manifestation could form the basis for the creation of a database for forensic use. To verify and analyze the brains of psychopaths and the relationship with facial expression, research laboratories use fMRI, neurofunctional psychometry, and computer programs which stimulate the cerebral systems, especially the limbic system.

Conclusions

Debate on the facial expression of emotion continues to revolve around the questions of universality and cultural specificity. This involves determining whether expressions of emotion really are expressions, and the emotions are not an easy subject to study. Research continues. The different aspects of facial expression are universal or culturally specific. The facial expression of emotion

is a complex and multidisciplinary domain, which requires, after verification of the structural and functional axes, refinement of analysis methods and techniques. Computer programs will play a decisive role in the future, as the science of facial expressions finds more and more applications in a range of psychosocial contexts. The emotions play essential roles in human development. For example, they prepare individuals for action and help mold behavior. The emotions are a mechanism of social interaction, promoting development in the scope of the neurocultural theory advanced by Ekman. No one will dispute that the human face is a rich repository of information and communication. However, analyzing the face is not as easy as it might sometimes appear. Superficial analysis of the face leads us into error, and this error can become a serious one in cases where the information emitted is incorrectly assimilated and interpreted – or where the information in question is actually false. Interpreting the signals put out by the human face is a line of research which has occupied many scientists in the last two decades. But what is the ultimate objective of this research? To answer this question, we have to identify and understand the psychological states that underlie the facial expressions; however, these expressions are configured. The codification of such work is the next step in the construction of a theoretical groundwork for the development of a reliable and workable scientific technique for the mapping of the human face. In psychology, the study of the human face is now a wide-ranging field which occupies large numbers of researchers. Review of the literature is vital, given the countless studies carried out and their greater or lesser practical feasibility. The study of the face, insofar as it is a measurable and quantifiable phenomenon, is now a vital condition for research in the domain of the facial expression of emotion. In early studies, the face was seen, and studied, as an independent variable. The objective was simply to study the effect of the face on other associated variables. Nowadays, however, the face is seen and studied as a dependent variable in its relationship with other variables in the context of human systems of communication. From situations of social confrontation (e.g., embarrassment) to the study of facial expressions in forensic, healthcare, school, etc. contexts, the face is a constantly changing repository of information which requires refined theoretical and practical analysis if the scientific interpretation of it is to be put at the service of society at large. Over the course of history, basic research on the emotions has involved the analysis of emotional experience, the neurological control centers of facial expression, and the difference between voluntary and involuntary expression. Meanwhile, applied research has shown how useful it can be to identify and recognize movements of expression and has pointed to the social implications of such knowledge – for the brain, not the face, is the actor.

Glossary

Cybernetics The study of systems that change themselves, or the science of self-regulating systems – that is, systems that attain or maintain a particular endpoint or goal, despite changing conditions, through a process of feedback, thereby permitting self-correction. An interdisciplinary field that began in the 1940s. Norbert Wiener, one of several founders of the field, coined the term, coauthored seminal papers, and authored a best-selling book, *The Human Use of Human Beings: Cybernetics and Society*, which applied the concepts of cybernetics to human systems.

Double bind A verbal command or request that is contradicted nonverbally such that regardless of response, a failure occurs. For example, a mother tells her son to give her a hug, tensing when he draws near. A father insists that his son become a basketball star yet becomes furious whenever his son beats him. Double binds are said to have a pathological impact if the relationship is important and the recipient is not permitted to comment on the contradiction.

Genogram A family tree that includes information about significant events in the family history, qualities of relationships (e.g., enmeshed, close, cutoff), emotional triangles, unresolved conflicts, etc. Such mapping can highlight relational imbalances in the extended family, transitional conflicts, repeating patterns across generations, and also allows consideration of the entire family at one glance.

Reactivity Internal reactions driven by unresolved emotional issues, disguising themselves as reasonable responses justified by circumstances. Overreaction occurs usually when an area of vulnerability or sensitivity is touched.

Second-order cybernetics The study of systems that change how they change themselves. Also referred to as learning systems, these systems change the feedback loops themselves based on feedback about how well those loops are helping the system maintain its desired goal.

Family Systems Theory

Family systems theory is an approach to understand human functioning that focuses on interactions between people in a family and between the family and the context(s) in which that family is embedded. Family systems theory has been applied to a wide variety of areas including psychotherapy in general and family therapy in particular (working from a systems framework with emotional, behavioral, or relational symptoms in individual, couples, and families); school systems; community problems (e.g., working with polarized disputes and facilitating ‘difficult conversations’ as in the Public Conversations Project, peace studies, nonviolence training); organizations (consulting, leadership training, coaching); and health care (medical family therapy – tracking the emotional dynamics of illness and facilitating collaboration among patients, families, providers, and health care systems).

According to a family systems perspective, an individual’s functioning is determined not so much by intrapsychic factors as by a person’s place in the system(s) in which he or she finds himself or herself, subject to the pushes and pulls of the system, including competing emotional demands, role definitions and expectations, boundary and hierarchy issues, coalitions and collusions, loyalty conflicts, family and institutional culture and belief systems, double binds, projective identifications, and systemic anxiety. In addition, self-correcting and self-reinforcing feedback loops in a system can either facilitate or hinder pathology or health, breakdown or resilience.

A thorough understanding of family systems theory requires an elucidation of the foundational contributions of systems theory itself.

Systems theory is a field that informed and inspired the founders of the family therapy field and upon which family systems theory is based in many important respects. Unfortunately, as the field of family therapy has developed, the important contributions of systems theory to the theoretical foundations of the field have too often been neglected, undervalued, or only dimly understood. The following discussion will review the key concepts of systems theory that are most relevant to family systems theory and family therapy, followed by a description of the primary schools of family therapy and enduring family systems concepts and family therapy techniques. The concepts throughout will be illustrated with both actual and hypothetical clinical case examples.

Systems Theory

Systems theory is an interdisciplinary area of study that developed around the same time as family therapy, in the 1950s, with particular roots in biology. (An allied field, cybernetics, developed out of engineering around the same time and focused on how mechanical systems control and change themselves. Cybernetics has also had a major impact in family systems theory and therapy.) Systems theory seeks to understand the dynamic behavior of complex systems, including how components of a system interact to affect the behavior of the system in often unexpected, nonlinear ways.

There are actually many schools of systems theory, each with its own focus, methods, and applications. This discussion will focus on concepts common to most. Important contributors to the development of systems theory include

economist Kenneth E. Boulding and biologists Anatol Rapoport and Ludwig von Bertalanffy (general systems theory); mathematician Norbert Wiener, psychiatrist Ross Ashby, and anthropologist Gregory Bateson (cybernetics); computer engineer Jay Forrester (systems dynamics); and others. Systems theorists whose work has found particular application to family systems theory and family therapy include Gregory Bateson, biologist Humberto Maturana and Francisco Varela, and chemist Ilya Prigogine.

Initial proponents argued that system theory could be used to understand any type of system (hence, *general* systems theory), be it biological, physical, electrical, ecological, conceptual, social, or psychological. Systems theory has been applied to various disciplines such as engineering, physics, biology, computer science, ecology, and the social sciences to study a wide variety of systems, including ecological systems, industrial systems (e.g., the oil industry, or coal, fishing, agriculture), monetary systems, stock markets, business cycles (economic models), local and global climate systems (climate modeling), political systems, population systems, corporations and organizations, (organizational theory, management science), society (sociological theory and sociocybernetics), communities (community ecosystemic models, urban dynamics), and families (family systems theory and therapy, systems psychology).

The Nature of a System

A system is a collection of parts – people, cells, organizations, planets – that are interconnected in such a manner that they produce their own pattern of behavior over time. Systems are self-organizing. When perturbed by external forces, the resulting behavior of a system is determined by the structure of the system. To a significant extent, a system causes its own behavior. A system is more than the sum of its parts, and so the properties of a system cannot be predicted from an analysis of its constituent members. A pile of wood chips is not a system. A tree is a system. A collection of books is not a system. A library is a system. Systems can be biological or nonliving – frogs, families, factories, clocks, guided missiles, the water cycle. From a systems perspective, the world is a continuum; there are no ‘separate’ systems. All systems interconnect. Where to draw a boundary around a system and what to include as its constituent elements depends on the purpose of the discussion. A family is a system. A family is also a part of multiple larger systems – neighborhoods, schools, religious institutions, medical, workplace – with which it interacts in significant ways.

There are three components to any system, including family systems: (1) elements – the roots, branches, and leaves of a tree; the components of a TV; the people in an organization or a family, (2) interconnections – the flow of water through the trunk, the flow of electrons through circuits in a TV, the flow of information in an organization, the flow of emotional information in a family, and (3) a function or purpose – of a tree to grow and reproduce, of a TV to inform and entertain with moving images and sound, of an organization to provide a specific product or service, to make money and/or contribute to the social good, and of a family (usually) to nurture and protect its members.

It is easier to spot the elements of a system than it is to see the interconnections among the elements. The difficulty in recognizing interconnections in a system can lead to misattribution of the causes of behavior of the elements of the system, or faulty prediction about probable outcomes of interventions in a system. It is harder still to grasp the function or purpose of a system – the best way to do so is to observe its operation over time. Purposes of a system are inferred from behavior, not from the system’s professed goals or intent. This point is especially relevant to family systems. A family systems analysis of any presenting problem begins with the assessment of both how the system organizes itself and what its underlying purposes are. The latter is best assessed by examining the results of the system’s behavior rather than the professed intent of any of the system’s members. An adolescent may protest that he wants his parents to let him make his own decisions, yet behaves in such a provocative way as to make that impossible, suggesting that his behavior is organized by a wish to remain dependent. This wish, in turn, may derive from the parents’ deep anxiety about the prospect of his leaving home (contrary to their professed wish to grant him independence once he begins behaving responsibly). The purpose of such a system can be understood as keeping everyone safe by preventing members from leaving.

Systems are self-organizing and are often self-repairing and resilient, at least to a point. Systems are often composed of various subsystems, which may compete and pull in opposite directions from each other or from the purpose of the larger system. Sometimes this competition can benefit the larger system, as is intended in our governmental system of checks and balances, or in the capitalist theory of competing self-interest adding up to maximum prosperity for the greatest number. Other times, subsystem competition can result in disorganization and undermine the purpose of the larger system, as when departments in a university wage war over limited resources, eroding morale and encouraging talented people to leave or stay away.

Due to the interplay of the parts of a complex system, understanding the system structure and predicting a system’s behavior can be anything but straightforward. Attempts to alter a system’s behavior may lead to unanticipated consequences. A classic example of such unintended results is the introduction of cats to Australia to control the rabbit population (rabbits having been introduced as a food source by sailors in the 1800s) with the result that the cats have become pests, decimated native fauna, and had little appreciable impact on the rabbit population. The field of ecology now involves the modeling of complex, interconnected environmental systems in an attempt to understand more completely the factors involved in managing the structure and predicting the behavior of ecosystems, including national parks, agricultural systems, forests, and other important natural resources.

Feedback Loops

The fundamental control mechanism in systems – the way a system runs itself – is the feedback loop. In human terms, a feedback loop is a systemic process whereby one’s behavior is influenced by the system’s reaction to one’s behavior. When A is friendly toward B because of B’s warmth, and B is warm

toward A because of A's friendliness, a reinforcing feedback loop is set in motion that encourages more of the same, and is resilient over time. If A is having a bad day, B's expectation of A's friendliness pulls warm behavior from B and tends to elicit friendly behavior from A anyway. Thus, self-reinforcing feedback loops, which increase a given behavior in an individual or system in response to that same behavior (friendliness begets more friendliness), may eventually trigger self-correcting feedback loops, which counter a given behavior if it strays too far from the norm or goal of the system (unfriendliness begets its opposite, as when a sudden absence of friendliness in a resilient system prompts greater warmth in the rest of the system in an effort to restore the balance of friendliness). Likewise, when pushed past a certain point of vulnerability, a self-correcting feedback loop may reach its limit and give way to a self-reinforcing feedback loop – if A's absence of warmth is not changed by B's increase in friendliness, B may give up and angrily withdraw, reinforcing A's unfriendliness, which further reinforces B's withdrawal.

In general terms, a feedback loop is the mechanism by which any system alters the flow of resources depending on the level of the resources available, or alters the behavior of the system in response to feedback about the state of the system relative to the goals of the system. A feedback loop is formed when changes in the supply of resources in a system affect the flow into or out of those same resources through a set of operations based on a rule, decision, emotion, physical law, or action relating to the level of resources.

Balancing and reinforcing feedback loops

Feedback loops can be either balancing (negative, stabilizing, or goal seeking) or reinforcing (positive, amplifying, self-multiplying, escalating, runaway, snowballing). A balancing feedback loop reduces change to keep levels in check around a specified system state or goal. A reinforcing feedback loop magnifies change – rising levels increase the ability of the system to raise levels still more, and falling levels not only decrease the levels of resource but result in ever accelerating outflows.

A balancing (or negative) feedback loop is in operation whenever a system is able to maintain a steady state despite changing outside conditions. The process of a system maintaining a steady state in the face of changing conditions as a result balancing feedback loops is known homeostasis. An example of a balancing feedback loop is a home heating system. The thermostat monitors the changes in the level of heat in the room and alters the output of the furnace in order to maintain room temperature within a certain range. When system resources fall above or below a certain level, the system tries to change the level of resources in the opposite direction. For this reason, balancing feedback is also called negative feedback; it negates change, reducing the discrepancy (error) between the state of the system and the goal of the system.

A reinforcing (or positive) feedback loop amplifies the direction of change in a system, either positive or negative, so that the more the system changes, the more rapidly or forcefully it changes, resulting in vicious cycles or virtuous circles. Any system that behaves in an escalating fashion contains a reinforcing feedback loop. An avalanche is one example. Upward mobility is another – success begets additional

resources that increases chances of still more success. Warming global temperatures melt arctic tundra, releasing trapped CO₂, increasing greenhouse gasses, and escalating global warming which melts exponentially more tundra. The distancing of the husband makes the wife anxious so she pursues contact to feel better, he feels intruded upon and increases his distance (and her anxiety) until the escalation results in a system locked into a rigid distance or tumultuous contact. Reinforcing feedback is also known as positive feedback because it responds to whatever changes occur in a system by adding to it.

All systems exist as elements within larger systems and coexist with complementary and competing subsystems, so all systems are surrounded by limitations and by other feedback loops. Escalating feedback loops often trigger balancing feedback loops in the larger system, so 'trees don't grow to the sky' – swelling populations trigger increase in predators or exhaust the food supply; stock market bubbles burst; banks fail or new system-protective regulations are imposed; successful companies reach the limits of growth when they have recruited all potentially available customers; escalating conflict in families often leads to divorce or cutoff, ending the escalation.

Feedback loops are ubiquitous in nature, in human functioning, and at all levels of the biopsychosocial continuum, from the cellular and physiological (balancing feedback loops – blood sugar levels, body temperature; reinforcing feedback loops – tumor growth), to the intrapsychic (mood levels, perceived happiness; addiction, impulse control problems) and the social/interpersonal (levels of intimacy and independence in a couple; mutual criticism, self-fulfilling prophecies, prejudice) to the ecosystemic (P/E ratios of stocks, employment levels, diplomacy; capital investment, arms races).

Feedback loops in human systems often function through the flow of information – for example, about the state of the system, along with some 'rule' about how to alter the behavior of the system accordingly to change the state of the system. When one shifts one's weight to maintain one's balance, one does so in response to information fed back into the body about the location of the body in space. When deprived of visual feedback, maintenance of balance becomes far more difficult, as can be observed by standing on one leg and then closing one's eyes.

Systems Thinking and Family Assessment

Appreciating the operation of feedback loops is critical to becoming a family systems thinker – someone who understands the unexpected, counterintuitive ways all systems, including family systems, function. Effecting change in a system is rarely simple or straightforward. An intervention can have unanticipated consequences and may even reinforce the problem it intends to correct, or set in motion cascades of behavioral reactions that lead to new problems. Systemic change is often slow and/or nonlinear – if some intervention produces one result, twice the intervention may produce half the result or 100 times the result, the opposite result, or no result at all.

Due to the interconnecting nature of feedback loops in a system, causality in systems is said to be circular rather than linear. While mother's overinvolvement with the children may

put father on the periphery, it is also true that father's retreat to the periphery pushes mother toward overinvolvement with the children. If A causes B, it is often just as true that B causes A, or the effect of A on B and of B on A in turn may influence, and be influenced by, a third element, C. A child's oppositional behavior may be 'caused' by the parents' controlling behavior, or the parents may become controlling in response to an oppositional child, or the child may be aligned with a grandparent who is critical of the parents and gratified by the child's demonstration of the parents' 'incompetence' – the reactions of each person exacerbates the corresponding reactions of the other.

Since a system causes its own behavior by the operation of feedback loops, the cause of the behavior can never be determined to have an originating point – or rather, the originating point becomes irrelevant once the self-maintaining cycle has begun. The relevant point is the cycle itself: system behavior → feedback → change in system behavior → feedback → change... If a system, including a family system, causes its own behavior, then solving problematic system behavior must first begin with analysis of the structure of the system itself rather than searching for some internal or external cause. When systems thinkers encounter any particular symptom or behavior in a system, they automatically seek the interconnections with other elements in the system that may be influencing that behavior, and also look to understand how that behavior may be influencing itself or generating supportive or opposing feedback from other parts of the system. If outside elements are deemed relevant to the system's behavior, the boundaries of the system under consideration must be redrawn to include that element and its reciprocal interaction with the family. An example of this would be considering the impact on families of the larger contexts of community, schools, health care systems, social service systems, employment systems, etc.

The Development of Family Systems Theory

Unlike traditional psychoanalytic or behavioral approaches to therapy, family system theory drew intellectual inspiration from a wide variety of fields in addition to clinical psychology and psychoanalysis, including social psychology, anthropology, communication theory, hypnotherapy, linguistics, philosophy, mathematics, biology, zoology, and particularly cybernetics and systems theory. Like systems theory itself, family therapy developed initially in the 1950s as an interdisciplinary field with psychiatrists, psychologists, social workers, and other clinicians and scientists in various parts of the country experimenting with seeing families together in contravention to the then-prevailing psychoanalytic orthodoxy that dictated that therapists should have minimal contact with family members of the patient lest the transference relationship become irrevocably tainted. Also, in contradistinction to the traditional psychoanalytic focus on internal processes and psychopathology seen as arising from repressed drives and maladaptive defense mechanisms, the family systems perspective focused on interpersonal processes, developing models for how interactions among family members give rise to or maintain pathological behavior. A family systems perspective even led to the question of whether such problematic behavior, if understood

as arising from systemic attempts at adaptation, could rightly be termed pathological, especially considering the potential of labels such as 'pathological' to affect the behavior of others in the system through reinforcing feedback loops in such a way as to call forth more pathological behavior.

The development of new theories regarding human functioning based on a family systems perspective suggested new approaches to therapeutic intervention, whether one worked with individuals, couples, or families. The 'patient' was not the source of the difficulty; the problem was in the system. The word 'patient' was put in quotes, and the terms 'identified patient' and 'symptom bearer' came into use, reflecting the belief that a patient was merely the person in the system who was the most vulnerable to system pressures and therefore the first to develop emotional, behavioral, or relational symptoms as stress in the system increased. Therapeutic change therefore became a matter of changing the system rather than changing the patient, or rather, seeking to change the patient through bringing about change in the system.

Schools of Family Therapy

Various schools of family therapy developed in the latter half of the twentieth century. Over time the distinctions among different approaches became less important and integrated models of family therapy were developed. Some of the major family therapy approaches will be briefly described below, followed by consideration of the enduring family therapy concepts and techniques common to various approaches.

Structural family therapy

One of family therapy's most influential approaches, structural family therapy was developed by Salvador Minuchin and colleagues at the Philadelphia Child Guidance Center at the University of Pennsylvania, which Minuchin directed for many years. Structural family therapy draws from systems theory the idea that the behavior of a system is a result of the structure of that system, and that a system's structure is gleaned from observation of the behavior of the system over time. Structural family therapy looks for misalignments in the structure of the system as reflected in the nature of the boundaries, hierarchies, and cross-generational coalitions in the family. How all family members respond to events in the system is also carefully tracked. Minuchin posited that healthy families have a clear hierarchy with the parents in charge (neither anxiously seeking guidance from the children nor rigidly commanding them), and with clear but flexible boundaries demarcating the family as a whole, the parental and sibling subsystems, and the personal boundaries of individual family members, promoting flexible interdependence and autonomy rather than an over-involved, emotionally fused enmeshment or a disconnected, underinvolved disengagement.

Strategic family therapy

Strategic and brief therapy approaches grew out of the influential work in the 1950s and 1960s of a group in Palo Alto, CA, led by Gregory Bateson, an anthropologist, and including Jay Haley (communications theorist), John Weakland (engineer turned anthropologist), Don Jackson (psychiatrist), and Paul Watzlawick (philosopher and Jungian therapist), among

others. The group applied communications theory, systems theory, and cybernetics to the understanding of schizophrenic communication, family interaction, and therapeutic communication. Don Jackson and others formed the Mental Research Institute in Palo Alto in 1959, to develop treatment approaches based on the theoretical formulations and findings of the Bateson project, including concepts deriving from their study of the creative, unconventional hypnotherapeutic approaches of psychiatrist Milton Erickson. Landmark articles from this collaboration include 'Toward a theory of schizophrenia', which introduced the concept of the double bind, and 'The question of family homeostasis'. Both strategic family therapy and brief therapy approaches emphasize a here-and-now, problem-centered focus and development of strategies that interrupt the problem-maintaining interactions in the family system. Dramatically brief and counterintuitive interventions became the hallmark of this approach, which is one of the more theory driven of all the schools of family therapy with the notable exception of Bowen family systems therapy.

Bowen family systems therapy

Murray Bowen, a psychiatrist who worked initially with schizophrenic families at NIMH and eventually settled at Georgetown University, developed a comprehensive theory of emotional functioning in biological systems, including family systems and organizations. At the center of his theory is the concept of differentiation of self, which refers to an individual's ability to maintain a self-directed, principle-driven course of action while maintaining contact with emotionally significant others. Lack of differentiation is reflected in a tendency when anxious either to give up self to maintain togetherness (e.g., emotional fusion, placating, conflict avoidance), or to give up togetherness to maintain sense of self (emotional or geographical distance, disengagement, stonewalling). Differentiation also has an internal aspect: the ability to distinguish in oneself thought (reflection) from feeling (emotional reactivity). Lack of differentiation is reflected by an inability to recognize when one is overreacting, and a corresponding conviction of the reasonableness of one's behavior. The emotional dynamics of a relational system – family or organization – is a function of the level of differentiation of the systems' members, especially of the leadership. Bowen contends that working on one's own level of differentiation is key to resolving problems in the family system. He argues that this can be best accomplished by working through unresolved emotional issues with one's family of origin, particularly with one's parents, and improving one's ability to maintain a sense of self while in contact with the family emotional system. Michael Kerr, a student and close associate of Bowen, has taken up the mantle at the Bowen Center since Bowen's death in 1990.

Experiential family therapy

This approach is most closely associated with the work of psychiatrist Carl Whitaker (symbolic-experiential family therapy), but also includes others who emphasize the importance of working directly with emotional experience of the family in the here-and-now: Virginia Satir (humanistic), Walter Kempler (gestalt experiential), Leslie Greenberg, and Susan Johnson (emotionally focused couples therapy). Hallmarks of experiential approaches include a reverence for authenticity,

directness, awareness (of emotions, cognitions, and physical sensations) and attention to nonverbals as clues to what is being left unsaid, use of nonverbal techniques with the family to capture systems dynamics, including sculpture, role play, empty chair work, visualization, and imagery.

Narrative family therapy

The rise of postmodernism as an intellectual force in virtually all academic disciplines has found expression in the field of family therapy in the development of narrative/hermeneutic/language-based models, which are seen as an antidote to the mechanistic metaphors of cybernetics and systems theory, metaphors that omit much that is uniquely human. Narrative therapy focuses on how all people assemble internal narratives of their lives, summarizing and compressing the richness of lived experience into dominant themes deriving feedback from family, culture, and society. These dominant narratives go on to impact the individual in countless ways and become self-reinforcing. Narrative therapy seeks to assist people in breaking this self-reinforcing loop by reauthoring the stories of their lives through the integration into their narrative of formerly overlooked truths about themselves (unique outcomes) that could not have been predicted by the dominant narrative. Narrative therapy returns meaning and a focus on the experience of the individual to the center of psychotherapy, all of which, ironically, are hallmarks of insight-oriented therapies of all stripes, from psychoanalytic to Jungian to existential-phenomenological, from which family therapy initially distinguished itself. Michael White is the most well-recognized developer of this approach, though many others have also contributed including David Epston, Jill Freedman, and Gene Combs.

Enduring Family Systems Concepts

As the family therapy field matured, a number of key concepts and interventions became widely recognized as core family systems theory ideas and techniques. Most were originally associated with a certain school of family therapy but over time have become recognized as having merit independent of any particular theoretical formulation.

Biopsychosocial model

The biopsychosocial model is a broad framework for understanding the interaction of all levels of life, from the most simple (molecule) to the most complex (biosphere), developed by George Engel at the University of Rochester as an antidote to the reductionism inherent in the prevailing biomedical model, which omitted psychosocial factors from consideration in analysis of the etiology and course of physical illness. In the biopsychosocial model, all levels of biologic complexity are organized on a continuum from the somatic to the intrapsychic to the interpersonal. When arranged vertically, each of these levels can be seen as embedded in the ones above and containing the ones below, from the level of the molecule, cell, and organ system to the level of individual, dyad, family, community, culture, nation, and biosphere. Events at any one level in the hierarchy are influenced by interactions with those levels above and below. The biopsychosocial model provides a systemic framework for integrating biological, psychological, and social domains of human functioning by affirming the

centrality of each. The biopsychosocial model continues to play an important role in family systems approaches as a foundational framework for the field of medical family therapy, which is an application of family systems theory to the psychotherapeutic treatment of chronically and terminally ill patients and their families.

Circular causality

Circular causality refers to the idea that causes of behavior in a system cannot be located in any one person or interaction but instead occur as a function of recursive feedback loops in the system, in contrast to the typical human preference to see causality as linear (A causes B causes C...). Circular causality refers to the understanding that A's impact on B is affected by B's impact on A, so that an individual in a system unwittingly tends to bring about the very behaviors which he or she finds problematic. The following case example illustrates how an undesired behavior in Person A can be unwittingly triggered by family members who seek to 'fix' the behavior: The family of an autistic young man was referred to me because his highly agitated reaction whenever his parents (with whom he lived) went on vacation was becoming increasingly disruptive to his day treatment program. All attempts by his parents and the program staff to correct this problem over several years had been unsuccessful. In our first session, I asked the parents about their understanding of the problem. They suspected he was becoming upset whenever they left town because it made him think of their 'abandonment' of him as an adolescent when they had, at the advice of his doctors and with deep reservations, put him in a residential facility for a year, which had proved to be extremely painful for them all. The parents were asked if they themselves had associations to that painful time whenever they were planning and packing for their trips. They tearfully agreed, noting that their anxiety level increased significantly before every trip. It became clear that their son was reacting to their anxiety and becoming agitated in turn, which further worried the parents, increasing their guilt and further increasing his agitation. Targeting the parents' anxiety for intervention proved far more successful than targeting the son's.

Once a cycle of interactions has become self-sustaining, any attempt to define 'cause' in terms of one part of the system's impact on another is an arbitrary punctuation of only part of the cycle and is therefore incomplete. This can often lead to causal misattribution and misguided interventions. Each interaction is dependent on and caused by the interlocking interactions in the rest of the system: father criticizes mother as incompetent, mother deflates and withdraws, daughter comforts mother and acts out against father, who blames daughter's behavior on mother's incompetence, etc. The 'cause' of this cycle cannot be said to originate in any single member of the system, or any single interaction. A therapeutic implication of circular causality is that strategic intervention at any point in a system can lead to change in the entire cycle of interaction since the change ripples through the entire system, each part in turn.

Emotional cutoff

Emotional cutoff is the refusal to have any contact with a family member(s), often for years or decades, typically with the perception that the other person is impossible to deal with, toxic, or dangerous. Cutoffs tend to be replicated in families

across the generations. Cutoffs rarely succeed in resolving relational difficulties as it makes future cutoffs more likely and permits both parties to avoid the hard work of reconciliation, boundary management, definition of self, differentiation, and tolerance of difference. Resolution of a cutoff is facilitated if at least one of the parties makes genuine ongoing attempts at reconnection without the demand for capitulation or apology. Major emotional events in families' lives such as births, marriages, funerals, and catastrophes often provide openings for reestablishing contact and resolving cutoffs as a result of the significant changes in the emotional states and proximity of estranged family members that such events often provide.

Family life cycle

The family life cycle is a model of the stages family systems go through in their course of development: marriage → childbirth → children starting school → entering adolescence → children leaving home → caring for aging parents → the arrival of in-laws and grandchildren → retirement → death. Transitions between stages are inherently stressful as they require shifting previously stable routines, roles, and expectations from the former stage to adapt to the requirements of the new stage. Symptoms often develop at these transition points, especially if there was an unsuccessful adaptation to a previous stage of the life cycle. For example, if a husband was unable to adjust to the idea of marriage, the arrival of the first child may intensify the problem and result in depression, substance abuse, or an affair. If parents were unable to adjust to the increasing capabilities of their school-aged children, the children's entry into adolescence can become highly problematic as the children press for greater age-appropriate independence and the parents are unprepared to allow it. Symptoms can also develop if there was an unsuccessful adaptation to the same stage of the life cycle in a previous generation. For example, symptomatic behavior in an adolescent getting ready to leave home often matches an analogous difficulty one or both parents had when they were leaving home, with fears of abandonment or dependency conflicts rippling down through the generations at similar developmental junctures.

Function of the symptom/communication value of the symptom

Symptoms can be understood as the system's attempts to solve a problem or send a message. The function of the symptom can best be discerned by carefully inquiring about how family members respond to the symptom or by looking at the pragmatic impact of the symptom over time. For example, an adolescent girl had significant anxiety and difficulty sleeping, prompting her parents to bring her to see me for therapy. The initial interview revealed that, as a result of the symptom, mother soothed daughter by lying down with her at night so she could fall asleep, with the result that mother herself often fell asleep in daughter's room. Husband complained that his wife no longer sleeps with him since this problem began. I observed that the symptom functions to keep mother from the marital bed, and inquired about the quality of the marital relationship, which was highly (though quietly) conflictual, something the couple avoided facing. Another example, drawn from my practice: A young woman's suicide attempt, of which she is deeply ashamed, is reframed in a family therapy session as her way of communicating to herself and her family

the intensity of her distress as well as her recognition of the hidden distress in her parents' lives – all difficulties which the loving but minimizing family had been loath to recognize.

Homeostasis

Literally 'standing in the same place,' homeostasis is the process by which a system maintains stability (and so resists change) by making internal adjustments in response to changing external conditions through the operation of balancing feedback loops. In family therapy, homeostasis is the term for 'resistance,' or the process by which a family or other human system will tend to return to any established way of functioning even if that functioning is problematic to the participants. A family may respond to an alcoholic member's sobriety with behavior designed to encourage return to alcohol abuse. Relief over a decrease in chronic fighting in a couple may be accompanied by increased anxiety as they struggle with the unfamiliarity of warm intimacy and so find themselves reverting to the former hostility, a territory with which they are intimately familiar. Elimination of a symptom in the family scapegoat may be followed by development of a symptom in the formerly 'perfect' child.

Identified patient/symptom bearer

The symptomatic member of a family can be understood as expressing the stress or pathology in the system, sometimes on behalf of others. Consequently, he or she is identified by the family as the sick one, though the entire system is responsible. In this sense, the patient is bearing the stress for the rest of the family through the development of symptoms. This systemic understanding of symptom development stands in marked contrast to an intrapsychic perspective, which understands symptoms as arising from within the individual due to individual psychopathology. Illustrative case examples: A conflict-avoidant mother who could never stand up to her ex-husband brought her son to see me because he had become highly conflictual and unmanageable at father's house, alarming both parents, who see him as the patient. I point out that he is fighting mother's battles with father on her behalf, something she could never bring herself to do. Mother's willingness to assume more responsibility for her feelings about her ex-husband allows her son to stop arguing on her behalf and the tension subsides markedly. A 7-year-old was brought to me for therapy because he had developed severe obsessive preoccupations at bedtime and at the end of school breaks. His mother, a self-sacrificing woman with obsessive tendencies, had three young children at home. His father had recently begun graduate school and was increasingly unavailable in the evenings to help with the children. The child's symptoms quickly remitted when the parents were coached about (1) dealing with personal and family stress more effectively, (2) not reinforcing the identified patient's anxiety by anxiously overreacting to it, and (3) providing extra contact with the child when he is not exhibiting symptoms rather than when he is.

Isomorphism

Literally 'same shape,' isomorphism refers to the tendency of interlocking levels of a system to mirror each other, or take on similar characteristics. The supervisor criticizes the therapist for criticizing the mother for criticizing the child for criticizing the

younger sibling. These behaviors are isomorphic. Intense alliances and dramatic battles between an adolescent and her parents are mirrored by alliances and battles in the extended family, and then between the family and various providers, and then among the providers themselves. Isomorphisms multiply through a system, including biological systems – for example, roots, branches, and leaf veins of a tree have similar branching forms.

More of the same solution

According to strategic family therapy, people come to therapy not because they are stuck with an insoluble problem, but because they are stuck in escalating attempts to apply a solution that is not working and that they cannot stop using, which elicits more of the same problem in a reinforcing feedback loop. Therapeutic interventions in such situations should focus on finding ways to get people to stop using their unhelpful solutions so that a new solution might emerge.

Polarity

A polarity is a tension between two extremes of a continuum. A central polarity in therapy is between the need to change/grow and the need for stability/safety. Any system seeks a balance between these two poles. Too much of either will threaten the viability of the system. People will usually respond to a pull toward either end of any continuum by moving in the opposite direction, and will tend to move away from an extreme position in response to someone advocating an even more extreme version of the same position. A therapist advocating for change more strongly than the family desires will arouse their anxiety about loss of stability and change will slow down; conversely, a therapist pushing for the status quo beyond the family's comfort level will enhance their desire for change.

Triangles

Triangles is a concept common to many schools of family therapy but developed most fully by Murray Bowen, who defines the triangle as the most stable unit of relationship. Dyads become unstable as stress rises in the relationship, so one or both members of a dyad will triangle in a third person to reduce the relational stress, with the third person functioning either as a mutual focus of concern (as when enemies cease hostilities to deal with a mutual threat, or parents put aside differences to deal with a symptomatic child) or as a new alliance for one member of the dyad (as when A gossips to C about his problems with B, creating a sense of pseudocloseness with C based on their mutual dislike of B, and fostering increased distance between B and C).

Relational triangles are ubiquitous and can even be useful, as when a couple presents for marital therapy. Triangles become problematic if they enable avoidance of responsibility or rigidly keep the conflict on one side of the triangle (e.g., the scapegoat) rather than distributing it around the system. The various triangles in a system interlock so that change in any one of them is made more difficult by how others in the system are thrown off balance by, and resist, any change.

Bowen and one of his disciples, Ed Friedman, developed a number of principles of emotional triangles, including the following: (1) a person cannot fix how two people relate to

each other. (2) Attempts to do so will likely have the opposite effect. (3) If anyone attempts to take responsibility for how two other people relate, that person will end up carrying the stress for the relationship. For example, if a mother takes responsibility for ending the fighting between her children, she enables the combatants to avoid the responsibility for dealing with their conflict, thereby encouraging continued fighting and increasing her stress. If a father seeks to end the relationship between his daughter and her irresponsible boyfriend, he is likely to only make the boyfriend seem more alluring, enable the daughter to avoid awareness of her own dissatisfaction with her boyfriend, and push the two closer together. (4) One can only change a relationship of which one is a member. (5) The way to positively affect how two people relate to each other is to try to maintain a well-defined relationship with each, and to avoid the responsibility for their relationship with one another. ALANON illustrates this principle in their recommendations for how a spouse of an alcoholic might step out of the triangle of 'alcoholic-bottle-spouse.' They tell spouses 'you didn't cause it, you can't control it, you can't cure it.' Spouses must stop taking responsibility for, or trying to influence, what the alcoholic does and focus instead on taking responsibility for their own relationship with alcohol and for their relationship with their alcoholic spouse – for example, "I love you and want you in my life. I do not like alcohol's impact and do not want alcohol in my life. You are free to choose what to do with alcohol. However, I will no longer stay in your presence when you have been drinking. I will not cover for you with work when you are hung over, nor will I lie to our parents if they ask."

Enduring Techniques of Family Systems Therapies

Joining

Joining refers to the process of establishing a therapeutic relationship with the family; making the family comfortable in one's presence; forming a safe context, and allowing oneself to be sufficiently subject to the emotional dynamics of the family group that one can appreciate and spot the relevant emotional exchanges that reflect the family structure.

Strength orientation

An attunement to that which is genuinely positive, resilient, admirable, impressive, pleasantly surprising, or delightfully unexpected and a readiness to notice and celebrate strengths and solutions as much as to ferret out hidden problems, impasses, and failures are hallmarks of a strength orientation in therapy. It is the opposite of pathologizing, problem-dominated descriptions. Having listed their problems and concerns, the family may be asked to delineate what they admire or appreciate about other family members, especially the identified patient, for it is out of such resources that solutions will be built. Stories of success are elicited and amplified. If necessary, a drift back to problem talk is interrupted and redirected. Setting treatment in such a context of explicit appreciation and affirmation is like providing anesthesia before surgery; it makes an otherwise anxiety-provoking process much more bearable. A strength orientation is not naïve optimism, and is not incompatible with recognizing pathology, injury, dysfunction, or pain, but resists letting those be the whole story, insisting

instead on the importance of both sides of the coin, with neither obscuring the other.

A strength orientation is reflected in an ability to appreciate how the abusive mother is doing a far better job parenting than her sadistic father did; to see the love and commitment of the black sheep of the family when he is the only one of the siblings to step up when mother is terminally ill; knowing to interrupt the story of yesterday's conflict to have the family amplify on their passing comment that it had been a very good week until yesterday. What made it a good week? When was the last time they had had such a good week? How did they pull that off this week in light of all the challenges? Narrative therapists talk about strengths in terms of 'unique outcomes,' – occurrences that could not have been predicted by the dominant story (e.g., of failure) and that reflect other truths that, if included in a rewritten narrative, would change the outcome of the story.

Solution-focused interventions

Solution-focused therapy is a school of family therapy in its own right, developed by students of strategic therapy and the Mental Research Institute. Solution-focused interventions are based on the presumption that solutions to complex problems can be fairly simple, and that knowing where one wants to go in the future is more important than knowing how one got to the present predicament. The presenting problem was not always present in the client's life, and typically is not invariably present in the here-and-now either, but varies and sometimes is absent altogether. Solution-oriented approaches ask about what has worked in the past, or what makes the problem absent at times in the present, or keeps it from getting even worse, and about what would represent improvement or success. "If you woke up tomorrow and a miracle had occurred overnight and this problem was solved, how would you know the problem was gone? What would be different?" This question encourages people to define what they want most rather than what they do not want. This deeply felt desire is often bigger or different than mere elimination of the problem, and may be readily achievable even if the problem itself is never fully resolved.

Reframing

Reframing is the process of providing an alternate definition or perspective of the symptom (or of the system dynamic), one that often suggests a radically different response. "Jimmy's demands that you stay off his back are actually a plea for you to take control, which is why giving in to them isn't working," or, "Jessica appears to have taken it into her head that you are depressed and unable to function without her and therefore is refusing to attend school," or, "Your husband's silence may mean he feels too much rather than that he is unfeeling. Like the person who has to wear sunglasses because of sensitivity to even mild sunlight, his distance helps him keep his feelings from overwhelming him." An artful reframe is not arbitrary but has an inherent plausibility or emotional resonance that fits with the feedback loops and dynamics of the system.

Positive connotation

Describing a 'negative' behavior or attitude in terms of its positive, adaptive, or helpful aspects – "I can see the deep

love and commitment you have for your daughter in how much you fight with her when you think she is doing something harmful to herself." "Your son's provocative behavior may be his way of helping you face your difficulty expressing anger and setting limits effectively."

Paradoxical intervention

1. Paradoxical interventions are designed to alter the self-sustaining nature of a symptom by interrupting the reinforcing feedback loops that maintain it through engaging in opposite behavior. The 'paradox' derives from the counter-intuitive nature of the intervention in which the route toward a destination appears to lie in going away from it. A therapist working with a young man paralyzed by fear of failure and unable to finish his dissertation directs him to intentionally make a minor, embarrassing mistake in public in the coming week in order to practice recovery from failure. The focus is 'reframed' from avoiding failure to recovering from failure, and from loss of control (unintentional error) to gaining control (intentional error). Avoidance of failure keeps him from discovering that failure is manageable. The intervention is repeated over several weeks, changing client's experience of failure, and the paralysis dissipates. Sex therapists rely on a similar dynamic when prohibiting couples with performance anxiety from having intercourse, directing them to focus instead on giving and receiving pleasure, replacing a vicious cycle of mounting anxiety with a virtuous circle of mounting arousal.
2. An additional form of paradoxical intervention, also known as a therapeutic double bind or counterparadox, is one in which the client is 'blessed if she does, blessed if she doesn't.' Such interventions are a way to respond to the double bind presented by the family: 'we have a problem, help us change – we are afraid to change, don't make us change' (either way, the therapist loses). A group therapist asks a client who sees herself as unable to set limits to look intently at each group member in turn and firmly say 'No.' Appalled, she refuses. The therapist increases the pressure, she refuses more forcefully, setting a firm limit, which the therapist then highlights, celebrates, and explores. Whether she complies with or resists the directive, she succeeds in setting a limit.

The 'go-slow' prescription is a commonly used (though far from the only version of) paradoxical intervention. When encountering a treatment-resistant family, a therapist may direct them to make no improvements, suggesting they are not yet ready for the turmoil change will bring. The family will either comply with this recommendation, thereby becoming more cooperative with the therapist, or they will resist the therapist and become less symptomatic. Either way they win.

Reframing and positive connotation are commonly used when delivering paradoxical interventions in order to sidestep the family's defenses. It is difficult to resist a comment from the therapist that contains a compliment. In this sense, positive connotation represents a therapeutic double bind: If you reject this definition, you reject my positive assessment of you. Case example: A teenage girl was brought to me for therapy by her mother who was concerned about the girl's reaction to the parents' divorce, including restrictive eating and weight loss.

The girl was very worried about her father, who she described as quite lonely, withdrawn, and refusing to adequately care for himself since the divorce. It came out that the daughter's symptomatic behavior had the effect of prompting the worried parents to speak with each other quite frequently. I complimented the girl (positively connoting) for being willing to sacrifice her normal adolescent freedoms, including the freedom to eat when hungry, in order to ensure that her desperately lonely father had an ongoing connection with mother. This was delivered as a statement; the girl was not asked for a response to this idea. Not only was no change suggested, the implication hung in the air that she should continue to do so lest her father have a miserable life. On the way home, the daughter asked her mother to stop at Burger King so she could order a Whopper. The restrictive behavior ceased immediately, though a number of other issues remained for us to resolve in ongoing sessions.

A variation of the go-slow prescription is a paradoxical technique known as 'prescribing the symptom.' The therapist asks the patient or family to make the symptom worse rather than better, perhaps because they need to better understand the dynamics giving rise to the symptom, or because a relapse will allow the family to see if there is anything from that experience they wish to carry forward with them into the future.

Successful use of paradoxical interventions requires a skillful, sensitive hand and a nuanced understanding of the systemic feedback loops maintaining the symptom as well as those connecting therapist and family. Like any powerful tool, paradoxical interventions, if misapplied, have the potential to do significant damage.

Taking a 1-down position

This is the opposite of trying to get '1-up' on the other person; being willing to lose the battle to win the war. Originally associated with strategic and brief approaches to family therapy, 'going 1-down' means giving ground to the other, elevating them in importance, letting them save face – the bumbling TV detective Columbo being a classic example of this maneuver. Taking a 1-down position can serve (1) to disarm the other and sidestep a symmetrical battle for dominance with those threatened by loss of dominance – for example, taking an interest in the concerns of the dismissive, hostile individual therapist of a family member by asking how the family therapy might help with what that therapist feels is the central issue, or how the therapy should be structured to avoid injury to their client, or (2) to avoid stepping into an ambush when invited into a battle for control – for example, when difficult in-laws seek to demonstrate the inadequacy of the young couple by constantly offering unsolicited advice, the couple gives up trying to prove themselves, which never succeeds anyway, and instead go 1-down by asking the parents for advice in excruciatingly long phone conversations until the parents protest that it is time for the young couple to figure things out on their own, ending their advice-giving, or (3) in the case of those taking a submissive position of asking to be told what to do, to show oneself to be even more inadequate than the other in order to provoke the other to take more control, responsibility, and authority for their situation – for example, when a 'help-rejecting complainer' asks repeatedly what he should do and repeatedly

ignores the advice, the therapist 'goes 1-down' by professing (or, as Carl Whitaker would have it, simply admitting) impotence and strategically giving up, yet continuing the therapy, letting the patient or family retain ownership of their anxiety.

Enactment

With enactment, the problem is brought into the room behaviorally rather than via description. For example, a couple is asked to actually have a typical argument in session, or to show how they are unable to communicate. Enactment permits clarification of aspects of the problem that are outside the awareness of the participants, and hence are not reflected in their descriptions of the difficulty.

Circular questioning

Circular questioning is a technique developed by Boscolo and Cecchin of the Milan group to encourage family members to develop a systemic perspective regarding the cycles (or circles) of interaction giving rise to their problems, and to see their relationships from the perspective of others. There are a variety of types of circular questions, including (1) questions that ask family members what they can do to provoke undesirable behavior in another, usually asked of parties that are unaware of their own contribution to an interaction or outcome, for example, "What would you have to do to get your wife to criticize everything you did after you arrived home from work?" "If you wanted to really make your parents suspicious and intrusive, how might you do that?" "When your sister and brother fight, how could you make it worse?" (2) Questions that ask the family to rank order family members (or others) along some continuum of interest to the therapist, useful for eliciting relational connections, loyalties, and feelings, for example, "Who in the family was most interested in coming to today's meeting? Who least?" "Who would be most disappointed to see the fighting stop? Who after that?" "Who in the extended family is most involved in the conflict between dad and Sean?" "Who is the most interested in changing this problem?" (3) Questions that ask family members to describe or comment on a relationship to which they do not belong, useful for obtaining additional information about family dynamics – for example, "If your father could ever bring himself to speak openly, how would he explain your brother's persistent belief that your father never approved of him?"

Use of self

Many schools of family therapy (with the notable exception of strategic family therapy approaches) speak of the therapist's

use of self in therapy as central to the 'art' of therapy and as a corrective to a superficial overfocus on technique. Therapists' skillful use of self is often seen as accompanying and enhancing the development of self in family members. Murray Bowen speaks of the need for the therapist (and anyone who is working on self-differentiation) to develop an ability to observe self – to regard one's own reactions and behaviors with curiosity and interest rather than judgment, and to become a 'non-anxious presence' and, just by virtue of being nonanxious, automatically foster change in anxious systems. Carl Whitaker speaks of the need for the therapist to be an authentic self – open to and comfortable with one's own 'gut' (unconscious process), suspicious of life-draining 'head trips' (intellectualization) – and able to invite others to make friends with their own craziness. Salvador Minuchin speaks of the need for therapists to transcend technique and develop self-acceptance, spontaneity, creativity, openness, and finally, in deep appreciation of the interconnectedness of all things, wisdom.

Glossary

Civil (involuntary) commitments The process whereby the state commits an individual to a psychiatric facility.

Forensic psychology The interface of psychology and law.

Police psychology A specialty of forensic psychology in which psychologists work with police departments.

Psychological evaluations A process whereby psychologists administer special tests to clients (i.e., intelligence tests, personality tests, etc.).

Voluntary The process whereby a person voluntarily requests admission to a psychiatric facility.

Forensic Psychology: Background and Contributions

Forensic psychologists are uniquely qualified to contribute psychological expertise to the legal process. Typically trained at a postdoctoral level, including a Ph.D., Ed.D., or Psy.D., in Clinical Psychology, Counseling Psychology, School Psychology, or Forensic Psychology, and with a Postdoctoral Residency, forensic psychologists bring specialty training in applied psychology to a variety of legal situations. In fact, with the legal system confronted by a growing array of complex psychological issues, the forensic psychologist's specialized training can provide the legal system with in-depth psychological insights on matters ranging from the prediction of dangerousness to situations involving involuntary hospitalization and children's development, and help educate the courts on various psychological issues impacting behaviors interfacing with legal systems.

The expertise of the forensic psychologist's specialized knowledge can, ideally, enhance the wisdom of the legal community and provide judges, attorneys, juries, police departments, psychiatric forensic unit staff, and the public with information to make better-informed decisions. Certainly, the courts are faced by a challenging array of cases where psychological participation can be useful. At present, for example, more than 2000 youth have been committed to life without parole and more than 600 000 adults are reported as incarcerated in correctional programs. Equally distressing, there has been an increase in psychiatric admissions for adolescents. Particularly noteworthy about these groups, it has been estimated that approximately 80–90% of psychiatric and correctional populations have a history of physical, sexual, or psychological abuse. In all these cases, a forensic psychologist can help educate interested parties on key psychological issues impacting the behaviors that led to such placements and help to better understand the way behaviors can change from such a trajectory.

Selecting from a growing roster of problems facing children, approximately 270 000 children are reported in foster care in the United States. Removed from homes for such problems as abuse and neglect, the court system plays a critical role in the placement of such children, but court personnel are not typically trained in the mental health issues facing children or families. The forensic psychologist brings this expertise to these professionals and can help inform the system in ways which might change future behaviors and guide new intervention models.

These data, then, buttressed by information on such matters as violence in the home (reported to occur in 1 in 14 marriages) or sexual abuse (by the age of 18, 1 in 3 women have been reported to be a victim of sexual abuse), lead to the conclusion that for the legal system, the forensic psychologist can be a useful resource. That is, the forensic psychologist can answer questions and provide information helpful to judges, attorneys, juries, parole officers, and juvenile justice personnel. For example, a person who hears voices and who cannot tell what is real from what is not would not be expected to generally understand their rights if arrested. In such a case, a forensic psychologist can provide clarifying testimony about the client's reasoning and understanding. In another example, a forensic psychologist can provide testimony on the background of a defendant who was sexually abused and violently sodomized by a parent prior to murdering that parent.

Given the importance of the issues faced by the legal system, then, the forensic psychologist can serve an educative role in clarifying psychological dynamics and providing rich details and information through the use of psychological assessment instruments. In addition, the forensic psychologist can provide direct services through the completion of psychological evaluations, as example, and also serve as a consultant to multiple parties. Clearly, the courts face difficult cases in which psychological factors influence behavior. The forensic psychologist helps serve as a bridge in the interaction between psychology and the law.

Professional Training

The psychologist invited to provide the court with psychological expertise must be appropriately trained and credentialed to provide such services. In view of the importance of psychological testimony in the judicial system, alone, it is important to understand the depth and extent of training required of psychologists for licensure/certification: psychologists providing services to the public are required to hold licensure/certification by their respective states.

To be eligible for licensure or certification (a designation that varies by individual state statutes), psychologists must have typically completed an undergraduate baccalaureate degree of approximately 4 years duration followed by graduate

training leading to a doctoral degree in applied psychology which would include practicum and internship training. Appropriately, forensic psychologists must earn their doctoral degrees in a designated area of professional psychology (e.g., clinical psychology, school psychology, counseling psychology, or possibly, forensic psychology) and may hold the Ph.D. (Doctor of Philosophy), Ed.D. (Doctor of Education), or Psy.D. (Doctor of Psychology). Doctoral training must involve a balanced program of training as outlined by the licensing boards for psychologists of each state.

Following receipt of the doctorate, candidates for licensure typically complete 1–2 years of postdoctoral experience under the supervision of a licensed psychologist and prior to conducting independent practice complete the requisite state and national examinations for practice. This leads to credentialing as a licensed psychologist.

Forensic psychology, as a unique area of practice of psychology, involves specific areas of expertise separate from that typically learned during graduate school. Therefore, just as physicians complete specialty training following medical school, so too, forensic psychologists typically (with the exception of those who complete programs offering integrated training with a law school) acquire specialty training following receipt of their doctorate.

Through postdoctoral specialty training, often augmented by participation in workshops and symposia involving specific areas of forensic practice, psychologists acquire the necessary training for forensic work. For clients, attorneys, and the public, as in selecting a physician, it is worthwhile to make specific inquiry about each psychologist's background, training, and professional credentials. Ultimately, the best fit between client's needs and psychologist's background requires careful attention. Of growing interest, a number of licensed psychologists acquire Board Certification through the American Board of Professional Psychology and acquire the designation of Diplomate in Professional Psychology [A.B.P.P.].

The Role of the Forensic Psychologist

Forensic psychologists typically use their knowledge of human behavior and various psychological assessment instruments to provide the legal system with an assessment, diagnosis, and recommendations for a range of clients. As examples, forensic psychologists may be asked to provide a psychological assessment to aid in the disposition of a case for a convicted child molester, rapist, or murderer, or they may be asked to conduct a comprehensive psychological evaluation to aid in the determination of placement for a child in a custody hearing.

A forensic psychologist may also be involved in a subsection of forensic psychology called police psychology which can involve such areas as police selection, hostage negotiation, or stress reduction. The demands of involvement in screening police candidates versus intervention as a psychotherapist for a police officer who shot a criminal in the line of duty can represent two extremes for the forensic psychologist.

Forensic psychologists, then, are often asked to offer testimony, expertise, and guidance in a wide array of cases. Today, a sampling of cases that the forensic psychologist might be involved with might include arson, murder, rape, foster care, drug addiction, sexual abuse, child welfare, or a psychiatric

commitment. Indeed, the legal system can present a wide array of cases to the forensic psychologist. Still, while the actual cases vary, in a general way the role of forensic psychologists can be construed to involve the general areas of practice which characterize professional psychology: assessment, intervention, consultation, and research. Each is discussed briefly in the following paragraphs.

Assessment

The unique role of psychological testing (i.e., psychological assessment) has remained an important area of practice for forensic psychologists. Psychological testing provides the court with both quantitative and qualitative data which can encompass intellectual abilities, cognitive reasoning, personality strengths and weaknesses, competency data, mental status information, and data pertaining to neuropsychological functioning. Although specific tests chosen for forensic practice vary greatly, selected psychological tests often used include the Minnesota Multiphasic Personality Inventory, Wechsler Intelligence Scales, California Psychological Inventory, 16 Personality Factor Questionnaire, Myers–Brigg Type Indicator, Rorschach, Thematic Apperception Test, Bender–Gestalt, and Projective Drawings. Certainly, though, there are literally hundreds of assessment instruments commonly used by forensic psychologists in order to systematically evaluate, diagnose, and gather material on clients.

For many professionals in the court system, psychological testing is truly an integral aspect of the testimony of the forensic psychologist. The expectation, generally, is that psychological test results provide objective, impartial, psychological information which can inform the testimony of the forensic psychologist. However, psychological tests provide data only about current functioning and do not accurately predict future behavior. Nonetheless, psychological testing can provide comparisons with the normative sample on which the test was developed and provide indications of psychological and psychiatric disorders which can be invaluable for court systems.

Of no surprise, the questions often asked of the forensic psychologist in a court situation, or in a referral, often relate directly to the results of the psychological evaluation. What is the intellectual level of the defendant? Is the client suicidal? Is the client dangerous? Will the client benefit from counseling and/or psychotherapy? Indeed, all the data compiled from the psychological testing ideally must be integrated into a comprehensive picture which can be presented to the court. Ultimately, in providing testimony, the forensic psychologist may be presented with additional questions, and the psychologist must present findings which can help the court system render a decision.

Intervention

Forensic psychologists are confronted by a wide range of challenges since the services to be provided can vary widely from client to client. A police officer referred for counseling because of depression or stress will require a different treatment, for instance, than a psychiatric patient committed to a forensic psychiatric hospital unit to restore competency for trial. As such, forensic psychologists must be knowledgeable about the advantages and disadvantages of different interventions and treatments and may utilize individual, group, or family treatment as deemed appropriate.

Certainly, not all clients seen by the forensic psychologist are willing participants in the treatment process. In fact, the court may require treatment for clients when the client is not interested in such a path. One client, for example, may be ordered to receive treatment to restore competency while another may be ordered to receive treatment as a condition of parole. Thus, the contours of psychological treatment are often governed by the court rather than by either the psychologist or the defendant, and the treatment atmosphere for a client, who may or may not believe they need intervention, but must participate because of a court mandate, can dramatically affect the process of treatment as well as the outcomes.

In a basic way, the inherent problems of designing an effective treatment program for a police officer ordered by a department to participate in counseling, a client mandated by the court to receive treatment because of violent episodes, or a patient committed to a forensic psychiatric hospital for treatment can vary markedly. In effect, a treatment plan may vary in design if designed for a police officer seeking to voluntarily address some issue or if designed for a parolee, for instance, who involuntarily is ordered to participate in psychotherapy as a condition of that parole. In short, one especially challenging aspect to forensic psychology is the fact that while there *are* clients who will voluntarily desire psychological services, the forensic psychologist will also encounter many clients who participate in treatment only because of the court.

The forensic psychologist, then, draws from a wide array of treatment modalities and models, and may select and recommend intervention including but not necessarily limited to individual, group, or family approaches which can each blend and mix a wide array of therapeutic theories. Fundamentally, counseling and psychotherapy interventions can be challenging when embedded within this forensic framework. In addition, it is not uncommon that client reports may, legally or administratively, be required for review by various individuals. As such, a forensic psychologist may actually provide treatment to an individual while not able to maintain confidentiality. In addition, because of such court-ordered disclosure issues, a forensic psychologist might conceivably view a prison or court system, for instance, as the client rather than the patient.

Consultation

Consultation is the area of practice for forensic psychology in which psychologists provide information to many different agencies. Consultation with courts, police departments, judges, attorneys, court personnel, and staff in correctional and forensic psychiatric settings illustrates agencies and individuals with whom forensic psychologists may work.

The forensic psychologist must possess strong communication skills, both written and oral, and be able to explain psychological terminology to many individuals not familiar with the language of psychological practice. The forensic psychologist who is asked to provide an evaluation of a client as to whether they are competent to stand trial must be able to explain relevant findings to the judge, trial attorneys, and the jury. Because of the need to effectively communicate psychological data to so many different individuals, consultation skills are critical for the forensic psychologist.

Certainly, the forensic psychologist working with a police department to construct a psychological battery of tests to aid in police selection procedures will present different information and utilize different consultation strategies than the forensic psychologist asked to provide a psychological consultation in a child custody case. As consultants, then, forensic psychologists must effectively choose the techniques most germane to each case and strive to present psychological expertise in a fashion that can most effectively meet the needs of each client. For the forensic psychologist, consultation skills are often a routine part of daily practice.

Research

Psychological research may ultimately provide definitive answers for questions which cannot at present be fully understood. What intervention is most effective with sexual offenders? What are the implications of long-standing sexual and/or physical abuse? What are the effects of witnessing repeated acts of violence in the home versus living in a neighborhood characterized by street violence? What differences exist between individuals who commit different crimes, including arson, rape, or murder? What factors affect juries? What behavioral characteristics affect court deliberations?

Clearly, there is a large area of research where the forensic psychologist may ultimately help the court. Research involving eyewitness testimony is one area which has already begun to yield important information. Other areas include advances in the understanding of neuropsychological deficits of adolescents who commit violent crimes ranging from murder to arson.

The utility of psychological research is undeniable. Even so, there remains a great dearth of knowledge. In general, greater research attention is needed on the predictors of dangerousness, on the developmental characteristics of different types of offenders, and on the effectiveness of different treatment interventions with children, adolescents, and adults. In short, psychological research conducted by forensic psychologists can be of tremendous value to the courts and society by offering greater scientific precision and understanding about the most effective ways the courts can intervene in cases involving psychological dynamics. Of course, the full range of knowledge and information which can potentially be learned through psychological research endeavors involving forensic psychology has yet to be fully ascertained.

Predictions of Dangerousness

Testimony surrounding the prediction of dangerousness remains one of the more frequently asked questions of the forensic psychologist. Whether involved in the civil (involuntary) commitment of the mentally ill to psychiatric hospitals or providing a psychological evaluation involving the possible confinement of a defendant to a correctional facility, the concern for potential for dangerous behavior endures as one of the more problematic issues for the forensic psychologist.

You might ask, then, *can* forensic psychologists predict dangerousness?

Regardless of theoretical position or quality of training, from a psychometric standpoint, any psychological prediction

involves a degree of error. In psychological terms, the forensic psychologist can err in two ways. The first way is to suggest that a person will be dangerous when they will not (false positive). Basically, this involves overpredictions of dangerousness. The second way is to suggest that the person is not likely to be dangerous when they will (false negative). This involves under predictions of dangerousness.

More false positive errors are made than false negative errors. This means that forensic psychologists overpredict dangerous behavior and suggest imprisonment or involuntary psychiatric hospitalization when it is not necessary. However, even with the fact that psychologists predict dangerous behavior more times than actually occurs, this does not reduce the fact that there still exists a group who are seen as not dangerous and who are. That means that while the error is reduced, it is not eliminated.

Over the past 25 years, research involving predictions of dangerousness leads to the unavoidable conclusion that there is a high incidence of error involving the prediction of dangerousness. Some studies report that more than 80% of individuals were *inaccurately* predicted to be violent! In other words, these individuals did not display the violent behavior which was predicted.

Empirically, it is important to remember that the science of human behavior is not sufficiently well developed to allow reliable predictions to be made about future behavior. Thus, while courts are pressing for determinations and predictions surrounding the possibility of future violence, forensic psychologists know that such predictions cannot be made without error. At present, this means that psychological determinations risk either the release of clients who may act violently or confining clients who will not be violent.

Over the long run, we have yet to know whether forensic psychologists will someday be able to make such predictions with ideal accuracy. This may indeed, come to pass. It is not, however, a reality at this point in time. Mostly, we can expect that the forensic psychologist can provide considerable psychological information about how a client is functioning during the examination itself. And a psychological evaluation can be helpful in clarifying whether the client understands their behavior. This type of information can be quite helpful and can help the judge, attorneys, and jury in rendering a decision.

In short, while the prediction of dangerousness remains a commonly asked question for the forensic psychologist, the ability to predict future behavior remains a murky issue at best. Still, the forensic psychologist can be helpful in clarifying present behavior. However, the available research indicates that the prediction of future dangerousness, while potentially invaluable to the court system, cannot be reliably predicted.

Commitment

Commitment to psychiatric hospitals can be either voluntary or involuntary. In the United States, civil (involuntary) psychiatric hospitalization – civil commitment – has loomed as one of the critical areas where forensic psychologists must effectively interface with the courts. The ability to hospitalize a patient, whether the patient wishes it or not, is the basis for involuntary commitments. Historically, the basis of civil

commitment has rested in the concept of the ‘*parens patriae*’ power of the state to act as a guardian on behalf of those in need. Thus, commitment was not viewed as punishment. Rather, it was viewed as a way to protect the welfare of the individual.

Unquestionably, our history is filled with instances where commitment has been inappropriate, including instances where a parent sought hospitalization for children and husbands sought psychiatric commitments for wives because of disagreements far removed from the need for psychiatric care. Fortunately, civil commitment laws have been altered and rewritten in order to more effectively protect patient rights. However, for forensic psychologists, involuntary commitment remains a critical area of practice. In fact, most psychologists employed in psychiatric hospitals today routinely complete psychological evaluations used, at least partially, to determine whether certain patients require commitment.

As previously stated, psychiatric commitments are of two types: (1) voluntary commitments and (2) involuntary commitments. Each is described in brief subsequently.

Voluntary Commitments

Voluntary commitments involve the willing, ‘voluntary’ agreement by a patient to undergo psychiatric treatment. The fact that an individual voluntarily is admitted for psychiatric treatment, though, does not necessarily indicate that the patient will necessarily be released on request. Voluntarily committed patients must request their release in writing. When this discharge request is received, the hospital is obligated to subsequently either release the patient or file for involuntary commitment.

Generally, then, even if a patient voluntarily requests psychiatric treatment initially, there is no guarantee that the patient will subsequently be released on their request. When appropriate – when the treatment team believes that a patient is in need of further treatment – the hospital may petition the court for a civil commitment. If the court agrees with the hospital that the patient meets the statutory requirements for a civil (involuntary) commitment, the patient may subsequently be ordered to remain hospitalized. On the other hand, if the court rules that the patient does not meet the criteria for an involuntary period of hospitalization, the hospital will be ordered to release the patient. What is striking about this, then, is the fact that not all ‘voluntary’ patients remain voluntary and not all patients voluntarily admitted for psychiatric treatment will necessarily be discharged simply by virtue of their requesting such a release.

Involuntary Commitments

Involuntary commitments are characterized by the ability to hospitalize a patient, whether the ‘*patriae*’ power of the state, which is to act as guardian of those in need.

From a historical standpoint, the Supreme Court addressed the status of civil commitments in the 1975 case of *O'Connor v. Donaldson*. This case involved a patient, Donaldson, who spent approximately 14 years hospitalized. The Supreme Court ruled that civil commitment was unconstitutional based solely on mental illness and that the patient must be dangerous to either self or others: Donaldson was not dangerous and was ordered released.

Addressing standards and guidelines for commitment, it is noteworthy that the commitment guidelines that follow are general inasmuch as civil commitment laws vary from state to state. As a result, the interested reader will want to refer to individual state laws for specific details. Generally, the criteria which follow are provided to serve as an introduction to the area of civil commitment. Those confined for forensic evaluation or for reasons involving criminal justice may be confined under different standards.

Patients who meet the commitment criteria generally: (a) demonstrate a mental disorder, (b) are considered dangerous to either themselves or others, (c) are committed consonant with the principle of the least restrictive placement, and (d) lack the ability to make an informed decision involving treatment.

Procedurally, an individual can be committed for up to 6 months duration, with renewals. State statutes vary from state to state, with varying lengths of time allowed relative to placement and the lapses of time after which hearings must be held. The latter is noteworthy as admissions can come from a variety of referral sources. For instance, if a patient is admitted from an emergency room, hearings must be scheduled within certain time parameters – generally 48 hours. On the other hand, court-ordered commitments may possess a longer time parameter.

It is during the initial examination and admission period that the patient undergoes an assortment of examinations, one of which is often a psychological evaluation (i.e., psychological testing) completed by the forensic psychologist. The forensic psychologist is not the sole person completing examinations, but lawyers and judges often place great weight on the opinion of the forensic psychologist and on the results of the psychological examination.

Today, the psychiatric commitment of individuals to psychiatric facilities remains an area of considerable discussion, despite changes and refinements in the various laws governing the process of commitment. For forensic psychologists, the ability to make contributions involving civil commitment is of considerable importance as psychological evaluations offer an important vehicle for interviewing and examining patients. Indeed, although exact predictions about the need for psychiatric commitments can appear as much art as science, the use of a psychological evaluation serves as a useful adjunct to the clinical interviewing typically completed by the psychiatric (M.D.) and psychiatric social worker (M.S.W.).

Conclusion

How many clients interacting with the legal system display psychological issues of sufficient magnitude to warrant the involvement and expertise of a psychologist? How many court decisions are made without the necessary input of experts in mental health? Because of the divergent number of cases confronting the judicial system, it is unknown how many individual cases are adjudicated without the expertise of the forensic psychologist.

As a general rule, the courts are faced with difficult if not seemingly impossible questions. Because many cases involve psychological dynamics – cases ranging from child custody disputes to cases involving the necessity for psychiatric

hospitalization – forensic psychologists who blend specialized knowledge of psychology and the law provide valuable inputs for attorneys, judges, juries, and families. In addition, forensic psychologists are actively working with staff, administrators, and families in the correctional system, in psychiatric settings, in police departments, and are providing valuable inputs in legal matters involving many differing cases involving the interaction of psychology and the law.

Unfortunately, the compendium of questions facing both psychologists and the courts remains too voluminous and complex to yet be completely unraveled. Should an adolescent murderer with severe neuropsychological disorders be put to death? What are the best predictors of dangerousness? What differences exist between someone who murders a stranger versus a family member? Clearly, the questions are many. Fortunately, forensic psychologists are working to provide society with responsible information in which to better understand these and related issues. For although the judicial decisions are rendered by the court, the psychological input of the forensic psychologist can be an invaluable aid to the court system. As has been noted in this article, the forensic psychologist brings to the court specialized knowledge about psychology and the law. And it is this expertise which can help the court face a wide array of challenging cases.

In general, forensic psychology is still a young science, which has yet to completely unravel many of the questions posed by the courts and society. At the same time, forensic psychologists are active contributors to the court system and are providing expertise in highly specialized matters. It is safe to say that some day we may yet unravel mental illness and criminal behavior. In the meantime, the challenge for the forensic psychologist, the courts, and society, is tremendous.

Free Will

H Rachlin, Stony Brook University, Stony Brook, NY, USA

Glossary

Compatibilism The view that even though all behavior of organisms originates in principle in genes and environment, the concept of free will (the distinction between voluntary and involuntary behavior) is nevertheless meaningful.

Determinism The view that because all behavior of organisms is in principle predictable as the outcome of prior

causes originating in genes and environment, there is no room in psychology for the concept of free will.

Libertarianism The view that at least some important actions by some organisms are not predictable on the basis of genes and environment. These actions are held to be due to free will, an autonomous internal cause.

Philosophers have bequeathed to psychologists three fundamental positions on the question of free will: libertarianism, determinism, and compatibilism. Libertarianism (not necessarily the same as political libertarianism) says that at least some interesting or important actions of people and maybe even some actions of nonhuman animals are truly free. These actions are vitally important for the organisms in which they originate but they are unpredictable on the basis of innate structure, experience, past behavior, or anything else. Such actions, libertarianism implies, are outside the realm of scientific study. According to libertarians, psychology can at best vaguely predict free behavior perhaps through empathy or some other undefined process. But a psychology of purely voluntary behavior can never be scientific.

Determinism says that all interesting or important behavior – of humans, of organisms in general, and that of inorganic objects – is in principle predictable on the basis of prior states and events. Therefore, say the determinists, there is no such thing as free will. Determinism implies that the concept of free will is useless in psychology or, worse than useless, a cloak for ignorance of the true causes of behavior.

Libertarians and determinists agree that if one is right, the other must be wrong.

Compatibilism, on the other hand, says that some acts may be both determined and free at the same time – depending on how you look at those acts. Compatibilism implies that the distinction between voluntary and involuntary behavior is a useful and meaningful distinction even while a scientific psychology is possible.

Libertarianism

Humanistic, phenomenological, existential, and hermeneutical branches of psychology take the position that, although psychology can never be scientific, a nonscientific psychology is nevertheless possible within a libertarian framework. Existential psychology, for instance, holds that the fundamental psychological reality ('being') consists of immediate phenomenal appearances. Our perception of objects in the world, as well as our mental representations of those objects, contains more or less 'nothingness' (like jigsaw puzzles with more or fewer pieces missing). The essential function of our wills is to

construct: (a) our physical and (b) our mental worlds ('essence') from appearances ('existence'). Thus, the concept of free will plays a very important part in existential psychology. It is the basic process by which an abstraction (a chair, for instance) arises from particulars (appearances of chairs). This primary function of the will determines in turn the distinctly secondary function of controlling overt behavior. Behavior is uncontrollable and unpredictable according to existential psychology because (absent physical constraint) individuals might always have behaved otherwise than they did. Two individuals with identical genes and experiences may nevertheless see the world differently, see themselves differently, and behave differently because of different innate, and free, wills. Psychologists today are mostly determinists or compatibilists because to be a libertarian is to confess that much of what is usually considered the domain of psychology (the areas of motivation, choice, rational thought, and so forth) is crucially important in human existence and at the same time beyond systematic understanding.

Determinism

Those modern psychologists who are determinists are usually reductionists of one sort or another. They say that while the mind (and the will) is crucially important it is nothing but ... (and here they specify some deterministic system). The most common sort of reductionism is physiological reductionism. In modern philosophical psychology, physiological reductionists are also called 'materialists.' Modern materialists hold that the mind is nothing but the workings of the brain (or the wider central and peripheral nervous systems combined). The creed of modern physiological reductionists was perhaps nowhere better argued than by the Russian reflexologist Ivan Michailovich Sechenov, in 1863. Sechenov said:

All the endless diversity of the external manifestations of the activity of the brain can be finally regarded as one phenomenon – that of muscular movement. Be it a child laughing at the sight of toys, or Garibaldi smiling when he is persecuted for his excessive love for his fatherland; a girl trembling at the first thought of love, or Newton enunciating universal laws and writing them on paper – everywhere the final manifestation is muscular movement. In order to help the reader to reconcile himself with this thought more readily, I will

remind him of the frame-work created by the mind of humanity to include all manifestations of brain activity; this frame-work is *word and deed*. Under *deed*, the popular mind conceives, without question, every external mechanical activity of man based exclusively on the use of muscles. And under *word*, as the educated reader will realize, is understood a certain combination of sounds produced in the larynx and the cavity of the mouth, again by means of muscular movements.

From the strict materialistic point of view, animals including humans are machines explicable by physical and chemical principles; it is the job of the psychological determinist to uncover the workings of these machines. What seems like voluntary behavior is just involuntary behavior of a more complex kind. For Sechenov, Newton enunciating universal laws is just a more complex version of Newton kicking his leg when his knee is struck by a hammer. From this viewpoint, physiological psychology is the only truly scientific psychology. Other forms of psychology would be mere holding actions, rough classifications with which we make do until our knowledge of the physiological basis of behavior catches up. The recent development of magnetic resonance imagery (MRI) machinery has tended to support the materialistic view. Complex psychological states have been shown to be accompanied by corresponding activity in specific brain locations.

But not all modern determinists are materialists of this physiological sort. The deterministic system inserted in the blank space of 'The mind is nothing but ...' need not be a strictly physiological system. B. F. Skinner, a modern radical behaviorist, believed that an animal's apparently voluntary actions are caused by what he called its 'history of reinforcement,' the pattern of prior rewards and punishments for classes of acts (called operants) defined by common consequences. For Skinner, an operant's consequences determine its subsequent occurrences. It is this characteristic of operants that, according to Skinner, makes them seem (but not really be) voluntary. For example, a rat may press a lever with its left paw, its right paw, its nose, etc. All constitute the same operant, the rate of which is predicted by the theory. Since operants are what Skinner's theory predicts, the rat is within the theory 'free' to press the bar as it may – with any particular movement. But according to Skinner this sort of freedom is unimportant. Therefore Skinner was right to declare himself a determinist. In *Beyond Freedom and Dignity*, Skinner claimed that free will is a myth and that people's desire for freedom is nothing but a desire to replace control of operants by aversive consequences with, equally deterministic and ultimately more precise, control by reward.

A similar kind of determinism is claimed by modern cognitive scientists. The sort of behavior these scientists are interested in predicting is largely verbal or informational – the sort that could go into or come out of a computer. A successful theory, according to cognitive science, is one that can be translated into a program that passes the 'Turing test.' A computer program held to embody a theory of the mind may be tested by human observers who feed questions into the computer and receive answers from it. To the extent that the machine's answers are indistinguishable from those given by a real human being, the computer's program is an adequate model of the mind. Any program that passes this test will necessarily be highly complex, perhaps involving probabilistic neural

networks, perhaps not. It is that complexity of our actual minds, a complexity not generally available to our conscious introspection, which according to the cognitivist creates in us the illusion that our behavior is free. When the true program by which our minds are governed is uncovered we will see, says the cognitivist, that our behavior was never really free.

The cognitive scientist's theory of the mind is nothing but the program itself. But a given program may be instantiated in many ways – by transistors, vacuum tubes, relays, analog circuits, a number of connected abacuses, and so forth. For the cognitive scientist, however, the particular mechanism by which the program is instantiated, while 'free' to vary within the system, is held to be unimportant, not the aspect of behavior that makes it seem voluntary. Thus, modern cognitive science, like modern neuroscience, is generally deterministic. In cognitive neuroscience, cognitive psychology and neuroscience collaborate in abstracting from the behavior of humans and nonhuman animals the part that is computer-like – cognitive psychology studying the software and neuroscience the hardware of the computer.

Compatibilism

If there are several conceivable kinds of determinism there is an even greater conceivable multiplicity of kinds of compatibilism. Compatibilism implies a dualistic approach to scientific activity (if not to existence in general). To understand the compatibilist point of view, it might be easiest to go all the way back to the founder of philosophical dualism, the ancient Greek philosopher, Plato. In the famous Allegory of The Cave in his dialog, *The Republic*, Plato asked us to conceive a group of prisoners in a cave, chained so that they can see only shadows on the wall. The shadows are two-dimensional projections of a three-dimensional world consisting of objects, other people and even themselves; the prisoners cannot even perceive themselves in three dimensions. Then one prisoner is freed and exposed to the three-dimensional world, first the world in the cave behind the prisoners (where a fire projects the shadows), then the real world outside the cave in the sunlight. The main difference between the free man and the prisoners is that the free man has gained knowledge of the three-dimensional world while the prisoners remain ignorant. When in the allegory the free man is returned to the cave the prisoners do not believe his stories of the three-dimensional world and either laugh at him or, worse still, persecute him (a reference to the behavior of the Athenians to Plato's teacher Socrates). In the allegory, the prisoners' chains correspond to our own ignorance of reality. Plato sees us as being bound by our own ignorance.

The prisoners' two-dimensional world is analogous to our three-dimensional world, the world of our perceptions, our pleasures, and our pains. This world, a world of illusions, is contrasted with a multidimensional real world of what Plato called 'Forms.' The sun, in the allegory, is compared to The Good; what is seen in the full light of the sun is the real world of Forms. The benefit of behaving in accordance with our pleasures and pains (seeking pleasure) is illusory and temporary as contrasted with the benefit of behaving in accordance with the Forms (seeking goodness) which is true and

permanent. A person whose behavior is guided by mere pleasure and pain is supposed by Plato to be like the prisoners in the cave while a person whose behavior is guided by the Forms is said to be free. According to Plato, everyone wants to behave in accordance with the Forms; none of us would willingly trade a better for a worse alternative given that we could accurately weigh worse and better alternatives. The problem is that we are blinded by our pleasures; only the most intelligent of us are capable of accurately weighing all our alternatives; therefore, only the most intelligent of us are capable of true freedom of behavior.

Plato thus packed freedom, knowledge, and goodness into one package. We would necessarily have all three of these virtues if our behavior were determined by the Forms. What are the Forms? Where are they located relative to us? How can we bring our behavior into line with them? How can we know if we are succeeding or not? All these questions were discussed at length in Plato's philosophy and taken up in interpretations and extensions of Plato from Aristotle to present-day philosophers and psychologists. Let us consider three interpretations: strict dualism, internal/external dualism, and molar/molecular dualism.

Strict Dualism

The Forms are to be found not in this world but in another world located somewhere else, perhaps in heaven. We have access to this other world only by revelation from God. This sort of mystical dualism has had little effect on modern psychology. We will therefore not discuss it further.

Internal/External Dualism

The Forms are to be found not in the outer world but inside of us. We have access to the inner world of Forms only through deliberate insight exercised by our free wills. This view was formalized in the neoplatonic philosophy of St. Augustine (fourth century AD). It separates what he considered to be an illusory external freedom of the sort Skinner referred to as freedom from aversive contingencies from true internal freedom (freedom of the will). According to Augustine, our souls are naturally directed outward to the chaotic world with its random pleasures and pains; our behavior naturally follows this chaotic pattern; when our souls face outward we are like leaves in the wind. However, by an effort of the will (aided by the Christian religion), we can turn from the outer world to an inner world where we can find direction of another kind – from God (equivalent to the world of the Forms). Obeying God is thus a consequence of turning inward, away from the world, an action we do of our own free will. Even if every move we make is strictly determined by God, our wills are said to be free because by an internal effort of will we freely chose this form of control rather than control by essentially random pleasures and pains.

Leaving aside the question of God's foreknowledge of our behavior, Augustine's distinction between behavior controlled by rewards and punishments in the external world (living in 'The City of Man') and behavior controlled from the internal world (living in 'The City of God') is a kind of compatibilism: looked at one way, behavior is controlled – either by rewards

and punishments or by God. Looked at another way, we are free to determine the source of control – from without or within. For Augustine, this internal freedom is God's greatest gift to human beings and is also the reason why evil exists in the world. If there were no evil, we could only do what was good; we would never have to choose; God, not us, would be responsible for our good behavior. But, because we may do evil, we are responsible for our own good behavior (at the cost of also being responsible for our own evil behavior). Augustine's compatibilism, like those of Plato and Aristotle, ties free will to responsibility – a link that persists to this day in compatibilist thought.

The difference between Augustine and Plato is that for Plato the effort a person has to make to be guided by the Forms is (in modern terms) a cognitive effort. For the Forms to guide our behavior, we have to calculate, said Plato. Plato's true Forms are thus accessible only to an intelligent elite. For Augustine, the City of God is available not to a cognitive elite but to a motivational elite – those who have the spiritual strength (foreknown by God) to turn inward for direction. Once we do turn inward, we will automatically do the right thing (our souls will be at peace).

Ironically, while Augustine's conception of an inner world has had a very strong influence on modern psychology, his compatibilism has not. Augustine viewed everyone's inner world as one world; for Augustine, when two individuals both turn inward for direction, they both turn to a common God, common principles, common social rules such as the Ten Commandments. Their behavior in such a case would be in synchrony due to this common control. For Augustine, we all inwardly see the same thing although if we turn outward we see different things – our individual versions of a chaotic world.

More than 1000 years later, during the Renaissance, the French philosopher and mathematician, René Descartes, was to turn Augustine's conception inside out. For Descartes, the outer world was the source of common control; renaissance physics had just begun to find remarkable regularity in that world. The human commonality of Augustine's inner world, on the other hand, was replaced by the concept of an isolated (and 'free') individual inner soul, identical with the individual mind, with which we are familiar today. Descartes believed that the individual human soul is absolutely free. Although he conceived of people's bodies as just machines and all non-human behavior and some human behavior (like the knee jerk and pupillary dilation) as controlled by machinelike reflexes, hence strictly determined, Descartes claimed that the most important human actions are controlled by the free, individual mind working through the body (the 'ghost in the machine'). Descartes thus abandoned Augustine's compatibilism for libertarianism.

As indicated previously, libertarianism denies the validity of scientific psychology, because it exempts the most important human actions from scientific understanding. Descartes' philosophy has therefore been modified by modern psychologists via two routes, both of them deterministic. One route, that of Sechenov and his modern followers in neuropsychology, expands the territory of the bodily machine from simple reflexes to more and more complex ones – from Newton's knee jerk to 'Newton enunciating universal laws.' This form

of determinism simply banishes the ghost from the machine – or threatens to do so once physiology has developed to the point where it can explain complex human behavior.

The other route to a scientific psychology, psychic determinism, retains the ghost alongside the machine but claims that the ghost itself is not free; the ghost's operations, like the machine's, are said to be lawful. This second route led from Descartes to the beginnings of experimental psychology. The initial impetus of experimental psychology was to discover the 'laws of the mind' and to give them causal status equivalent to that of physical laws. Once the 'laws of the mind' were discovered it would be seen that all behavior of all organisms is as involuntary as the behavior of a leaf in the wind. The German philosopher Gottfried Wilhelm Leibnitz (late seventeenth century) compared the individual mind and the physical world to two clocks (originally set by God) running in parallel, both reading the same time. The workings of the mind were no less clocklike (no less lawful) than the workings of the body – different but corresponding in form.

A common characteristic of this branch of determinism from Gustave Fechner, the founder of psychophysics, to Wilhelm Wundt, the founder of the first psychology laboratory (at Leipzig, Germany, mid-nineteenth century), through Wundt's student, Edward Bradford Titchener, the founder of the first American Psychology Laboratory (at Cornell University, at the turn of the twentieth century), to modern-day cognitive psychology, is the desire to get past 'mere' overt behavior to understand the inner laws of the mind. For Wundt and Titchener, these laws were structural and associationistic: elementary sensations combined in more complex perceptions combined in turn in still more complex cognitions – all strictly determined, none free in any way.

The antistructuralists of the early twentieth century, the Gestalt psychologists, differed from the structuralists on the nature of the mental laws. Gestalt psychologists believed that the laws of the mind worked more like electrical fields than like discrete circuits. But for them, the laws of the mind were just as deterministic as the laws of those electrical fields. The deterministic computer model of modern cognitive psychology discussed previously is a continuation of early experimental psychology's search for the laws of the mind.

All psychologies of inner dualism have in common the hope of eventually coordinating the laws of the mind with the laws of the body (coordinating one of Leibnitz's clocks with the other). The eighteenth century British associationist philosopher and physician, David Hartley, divided his book, *Observations on Man, His Frame, His Duty, and His Expectations*, into alternate chapters on physical and mental explanation of all human behavior, including moral behavior. Modern cognitive neuroscience is a much more sophisticated, more rigorous, and more experimentally based endeavor than was Hartley's but it rests upon a corresponding parallelistic determinism – a functional organization of the nervous system running parallel to a functional organization of the mind.

A common feature of parallelistic determinism from Wundt to the present day is its focus on internal causal systems – interactions between one part of the body and another or one part of the mind and another. If the body and the mind are each machines then psychology must be fundamentally

directed at discovering the workings of those machines. What are the units of the mind? How are they connected? How do they operate? These are the questions that parallelistic determinism substitutes for Plato's questions about the Forms. The cognitive mechanism is seen as a mechanism for transforming the particulars of everyday experience into abstract conceptions. Trying to understand human behavior (the sort of understanding sought by Plato's wise man who journeyed out of the cave) is for cognitive determinists like trying to understand the program of a computer by analyzing its inputs and outputs. According to some modern cognitivists, understanding of the human mind will be obtained when we can build a computer that successfully simulates it.

Thus, while strict dualism leads to libertarianism, internal dualism has led to the sort of determinism characterized by modern cognitive psychology. We now turn to a third interpretation of Plato's distinction between particulars and abstract Forms – molar dualism. This form of dualism leads, as we will see, to modern compatibilism.

Molar/Molecular Dualism

The interpretation of Plato's Forms that has led to modern compatibilism is that of his immediate follower and the other great ancient Greek philosopher, Aristotle. For Aristotle (and perhaps for Plato himself), the Forms, as abstract conceptions of objects in the world (objects including other people and ourselves), exist not in another world (as strict dualism says) and not inside us (as internal/external dualism says) but in the world itself. Aristotle saw the dimension of particular-versus-abstract as a dimension of functional interaction with one natural world. Thus, although Aristotle was a monist in the sense that he believed in the existence of a single world, he was a pluralist as regards our understanding of the world. Consider a modern example. When we watch a movie, we see only one thing – the movie. Our understanding of the movie is usually at the level of character and plot. But in some sense, the movie is nothing but colored shadows on a screen. In the usual case, we see through the many particular shadows, the many particular 'projections' that represent a character in the movie so that we recognize the character immediately each time he or she appears on the screen. In that sense, the lights and shadows on the screen may be said to be 'perceptually transparent.' But we understand this phrasing as a metaphor. The characters do not exist in a room behind the screen – they exist on the screen. It would be wrong (Aristotle would have said) to think that only the particular shadows exist on the screen but the characters exist in our heads. Shadows and characters are just two ways of looking at the screen (and of course both exist in our eyes and brains as well as on the screen but, as Aristotle insisted, we see the world, we do not see our eyes. Nor do we see our brains).

With some effort, we can look at a movie as pure shadow and light – that is, we can see the movie in terms of particulars, and with some effort (plus some considerable experience), we can see the movie at a still more abstract level than characters and plot; a critic, for instance, might see the movie in terms of the director's style or might even be able to discern the school where the director was trained.

Understanding the Forms, Aristotle said, is just an abstract way of perceiving the world. Aristotle agreed with Plato that the more abstract our vision of the world is, the better we will be able to deal with it. Why? For the same reason Plato gave – because abstract conceptions of the world are relatively permanent while particular conceptions are relatively temporary. Since Aristotle lived and died 300 years prior to the birth of Christianity and more than 600 years prior to St. Augustine, he did not conceive freedom as an internal attempt to turn away from the particulars in the world but rather as an external attempt to see through them and to conceive the world abstractly.

A person who does this is, according to Aristotle, free from particular influences in the same sense that an ocean liner is free from the influence of small waves. A modern concept of self-control (inherited from St. Augustine) would view a person on a diet who eats an extra hot dog as externally controlled by the smell and taste of the hot dog; the same person refusing the hot dog would be viewed as internally controlled, as self-controlled (hence as free). Aristotle, on the other hand, would have seen the eating of the hot dog as caused by the particular qualities of the hot dog, its particular taste, its particular smell, while the refusal of the hot dog is caused by its abstract qualities: the hot dog as part of an unhealthy diet. Both goals (good taste, good health) are what Aristotle called final causes, rather than efficient causes in the sense that they are consequences rather than antecedents of acts. But the good taste is a final cause of the particular act of eating the hot dog while the good health comes from no particular act but rather an extended pattern of acts over time. Looked at one way, eaters who respond to the most abstract features of their diets, like viewers who respond to the most abstract features of a movie, are free: free from (in some sense normal or typical) influence by particulars, by immediate forces, and by temporary pleasures and pains. Looked at another way their behavior is controlled: controlled by abstractions.

The more complex an organism's behavior is, the more abstract are the principles that explain it. The life of the philosopher, Aristotle said, is the most abstract, and therefore the best and freest life. For Aristotle, even though all of a person's actions are caused (by both efficient and final causes) it is still meaningful to talk of better and worse acts; it is still meaningful to talk of free acts and unfree acts: final causes of free acts are consequences that are beneficial in the long run (to society as well as the individual) while final causes of unfree acts are consequences that may be beneficial only in the short run and possibly harmful in the long run. Thus, Aristotle was a compatibilist.

The influence of this point of view on modern psychology has come through studies of self-control or delay of gratification discussed elsewhere in this volume. Nevertheless, it will be instructive to briefly summarize one procedure that epitomizes the conflict between particular and abstract. The procedure is a game originally designed for a single player but extended also to groups. In its group form, it is a version of the famous prisoners' dilemma of game theory and is easiest to understand in that form.

The instructions to a group (of 10 members, for example) are as follows:

Each of you is asked to choose alternative A or alternative B. If you choose alternative A you will get $\$N$. If you choose alternative B you will get $\$(N + 4)$. N will equal the number of members of the group who choose A. (No other member of the group will know what you chose.)

In this game, if all 10 members choose A, each gets \$10. If all 10 members choose B, each gets \$4 ($N = 0$). However, any individual will get almost \$4 more (actually \$3.90 more in a group of 10 members) by choosing B than by choosing A, regardless of what the rest choose.

With this game some people choose A and some choose B depending on a host of factors. But the central question the game asks is how do people perceive themselves in relation to the group? Choice of A benefits the group as a whole but hurts the particular individual (relative to choice of B) while choice of B does the reverse.

In its original, within individual, form the game treats the individual from time to time (or trial to trial) as analogous to a group of individuals. Thus, an individual chooses repeatedly between A and B, and is rewarded with N points for choosing A and $N + 4$ points for choosing B. But N is equal to the number of A-choices made by the individual over the past 10 trials. As trials go on, N for the present trial is determined by a running count of the subject's choice on the previous 10 trials (while the 11th-trial ago is dropped out). Clearly it is better for the individual over time to always choose A, since the person will then average 10 points per trial, than to always choose B (averaging 4 points). Even a single choice of B will lose points on the average.

Again, the degree to which people choose A or B is a measure of the degree to which they see their choices as particular events or as abstract patterns over time because in this game those two perceptions are made to conflict with each other (much like the figure-ground conflicts constructed by Gestalt psychologists).

The only conception of free will that remains meaningful in modern scientific psychology is this originally Platonic conception: when people act for the long-term good of themselves and their society, in cases where such acts conflict with their immediate and individual pleasures, they may meaningfully be said to be acting freely; they are not constrained by pleasures and pains. This freedom is compatible with a determinism that sees even their choice of abstract good over particular pleasure as in principle predictable. The reason for making this distinction between free and unfree behavior is not Platonic but pragmatic; such a distinction has proved to be useful in developing a science of behavior.

Friendship

B Fehr, University of Winnipeg, Winnipeg, MB, Canada

Friendship has been described as the neglected, 'understudied' relationship. However, when people are asked what gives their lives happiness, joy, and meaning, friendships appear at the top, or near the top, of the list. In a study that tracked the day-to-day interactions of teenagers and adults, it was found that the greatest enjoyment and excitement was reported when in the presence of friends – more so than when alone or in the presence of spouse or family. Thus, although other kinds of relationships (e.g., dating, marriage) have received much more research attention, there is evidence that friendships are of great importance in people's lives.

The purpose of this article is to chart the life cycle of friendship, beginning with the initiation and formation stage, followed by the maintenance stage. Some friendships are not maintained, but rather enter into the deterioration stage. Deterioration can lead to dissolution, which is the final, terminal stage of friendship, unless efforts are taken to restore the relationship. Given that the vast majority of people's friendships are same-sex, the focus will be on same-sex friendships.

Friendship Formation

Friendship formation is a complex process in which a number of factors must converge. Four major factors have been identified in the literature: environmental, situational, individual, and dyadic.

Environmental Factors

Day-to-day contact is conducive to the formation of friendships. A classic study revealed that friendships develop when individuals come into contact with one another through residential proximity. The researchers asked residents of a married students' housing complex to name the three people in the complex with whom they socialized most. The person who lived next door was named most frequently, followed by the person who lived two doors down, and so on. It was also found that residents were more likely to develop friendships with those who lived on the same floor, rather than on different floors – even when the physical distance between the living units was the same. The additional effort required to walk up and down stairs was a deterrent to friendship formation. These findings have been replicated in studies of students living in dormitory residences, residents of a condominium complex, residents of a public housing complex, and new recruits on naval bases.

The workplace is another avenue through which potential friends are brought into contact with one another. A survey of nearly 1000 men found that the workplace was the most common source of friendships, followed by the neighborhood. Within the workplace, physical proximity enhances the probability of friendship formation. For example, a study of state

police trainees who had been assigned to dorm rooms and classroom seats alphabetically by surnames found that friendships were most likely to form between those whose surnames began with the same, or nearby, letter of the alphabet. In research along the same lines, university students were randomly assigned seats during their first class. Friendships were most likely to form between students who were seated next to each other, followed by those who sat in neighboring seats and so on.

The role of the workplace in the formation of women's friendships is less clear. For women who have family responsibilities, the demands of combining paid work with domestic work may leave little room for the cultivation of friendships in the workplace. For women who are not employed outside of the home, there is some evidence that the neighborhood may play the same role in friendship formation as the workplace does for men.

Finally, other friends and relatives are an important source of new friendships. For example, in one study, high school and university students were asked to name a same-sex friend and to list the friend's 12 closest social network members. The respondents were then asked to indicate how many of these network members they had met prior to meeting their friend. Approximately two-thirds of the participants had been acquainted with at least one person in their friend's social network before meeting their friend. Thus, people's existing network of family and friends can provide links to new friendships.

In summary, the seeds of friendship are sown when people are in physical proximity. Although proximity was once regarded as a necessary precondition for friendship formation, computer-mediated communication (electronic mail, computer networks) is enabling people to form friendships in the absence of face-to-face contact. So far it is unclear whether online friendships are replacing 'real-world' friendships or whether online friendships develop into offline friendships. What can be said is that computer-mediated communication has opened another avenue for friendship formation. However, the people with whom one crosses paths in daily life continue to be an important source of potential friendships.

Situational Factors

A number of situational factors determine whether or not friendships develop. These include the frequency of interactions and how available each person is for a new friendship.

Frequency of interaction

Hundreds of studies have shown that the greater the frequency of exposure to another person (or even photographs of him or her), the greater the attraction, even if no actual interaction ever occurs. (If a person is initially disliked, however, repeated exposure may lead to decreased, rather than increased, liking).

This phenomenon is known as the *mere exposure effect*. One reason why it occurs is that the more familiar people become with someone, the more likely they are to assume that they are similar to him or her. (As is discussed in the section on Dyadic Factors, similarity is a major determinant of attraction).

Availability

Even if two people have pleasant, frequent contact, they have to weigh whether they have sufficient time, energy, and other resources to devote to a new friendship. Commitments to family, a spouse or romantic partner, existing friendships, and work or studies may limit each person's availability for a new friendship. For example, one study found that the middle-aged women they interviewed perceived practical limitations on the number of friendships they could develop. A respondent's 'friendship budget' depended on the number of friends she wanted, as well as the number of friends she felt could be maintained, given her existing relationships and other commitments such as work.

Thus, the situations in which people find themselves can either hinder or facilitate the development of friendships. If two people come into frequent contact with each other, the probability of friendship formation is increased. This probability is further increased if each person's 'friendship budget' can accommodate another friend.

Individual Factors

External factors such as physical proximity are important in bringing potential friends into contact with one another. However, in order for a friendship to develop, each person must be attracted to certain qualities in the other. Research has shown that physical attractiveness, social skills, responsiveness, and shyness are among the individual characteristics that influence friendship formation.

Physical attractiveness

Although physical attractiveness receives greater emphasis in romantic relationships than in friendships, beauty, nevertheless, plays a role in friendship formation. Studies using photographs, laboratory interactions between people varying in attractiveness, and actual face-to-face interactions confirm that people express greater liking and are more likely to pursue friendships with those who are physically attractive than those who are not.

Social skills

There is considerable evidence that people with well-developed social skills are more likely to successfully initiate friendships than those with poor social skills. For example, in one study, it was found that socially skilled university students had a greater number of acquaintances and close friends than did less skilled students. In a follow-up laboratory study, participants engaged in a brief conversation with two confederates. The confederates reported the greatest liking for the most socially skilled participants. Other research has shown that social skills are a particularly valuable asset in the early stages of friendship formation. Once a friendship has been established, the link between social skills and friendship satisfaction becomes weaker – "instead, competence in providing warmth and support becomes important" (Buhrmester et al., 1988: 1006).

Responsiveness

People who are responsive (e.g., show interest and concern during interactions) also are more likely to develop friendships. Researchers conducted a series of studies in which participants interacted with confederates who had been trained to behave responsively (answering questions, giving replies that were on topic) or unresponsively (refusing to answer questions, giving unrelated replies). In all studies, participants reported greater liking for the responsive confederates. In addition, participants thought that they were liked by responsive confederates and believed that they could become close friends.

Shyness

People who are shy tend to experience greater difficulty with forming friendships than those who are less shy. Shy people tend to initiate fewer conversations, make less eye contact, smile less, are slower to reply to their interaction partner's statements, and generally behave less responsively than people who are not shy. These behaviors have the effect of communicating that a friendship is not desired. Not surprisingly, shy people form fewer friendships than those who are less shy. For example, in one study, the researchers assessed the social relationships of university students during their first week of classes and again 2 months later. Shyness was correlated with having fewer friends, overall, and with having developed fewer new friendships on campus.

In summary, people are most likely to cultivate friendships with those who are physically attractive, socially skilled, responsive, and not shy. However, even if a potential friend possesses all of these qualities, this does not ensure that a friendship will develop. The situational influences that are operating on each person must be considered as well.

Dyadic Factors

Another important class of variables concerns the nature of the relationship between prospective friends. Research suggests that a friendship will be formed if two people are similar, like one another, and if self-disclosures become more personal and intimate over time.

Similarity

The bulk of the research on friendship formation has focused on the role of similarity. Byrne (1971; Byrne and Clore, 1970) developed an experimental paradigm to test his similarity-attraction model. Specifically, participants were led to believe that their interaction partner held attitudes that were either similar or dissimilar to their own and then reported on their degree of attraction. This research revealed that the greater the proportion of similar attitudes, the greater the attraction to another person. (Conversely, the greater the proportion of dissimilar attitudes, the greater the dislike.) Subsequently, researchers examined similarity in many other domains. By now there is considerable evidence that people become friends with those who are similar to them in terms of demographic variables (e.g., age, physical health, education, religion, race, ethnicity, income). People are also attracted to, and form friendships with, those who hold similar leisure or activity preferences and who are similar in terms of social skills and

communication skills. In research conducted with students, friends are found to be similar in terms of academic interests, academic achievement, and attitudes toward school.

Interestingly, there is little evidence that friends are more similar overall in terms of personality than nonfriends, even though friends believe that their personalities are similar. However, research on personal construct similarity shows that people who view the world in a similar way are more likely to become friends. Similarity effects also have been found for the construct of value similarity.

It has been suggested that superficial kinds of similarity (e.g., demographic characteristics) may be used as a criterion for selecting (or rejecting) friends. However, in order for a friendship to become close, two people must be similar in deeper and more meaningful ways (e.g., similarity in important values, similarity in how the world is construed).

In conclusion, there is substantial evidence that similarity in many domains leads to the formation of friendships. The most common explanation is that when people interact with similar others, their opinions and views are validated. According to the rewards-of-interaction explanation, another reason is that interactions are smoother and more enjoyable when people are matched, rather than mismatched, in terms of their attitudes and interests. It should also be noted that not only do two people form a friendship because they are similar, but they also become more similar as the friendship develops. This increase in similarity may serve to further solidify the relationship. Finally, given that people find similarity so rewarding, it is perhaps not surprising that friends tend to perceive greater similarity between them than actually exists.

Reciprocity of liking

Simply put, we like people who like us. In a classic experiment, groups of same-sex strangers participated in weekly discussion groups over a 6-week period. Before the first meeting, each person was told which group members the researchers expected would like him or her, based on information gathered earlier. (The experimenters actually randomly selected names.) Participants reported the greatest liking for the group members they believed liked them. Interestingly, when people believe that they are liked by another person, they may behave in ways that confirm that expectation. For example, in one study, participants were led to believe that they were either liked or disliked by their interaction partner. Those who thought that they were liked showed fewer distancing behaviors, were more pleasant, and engaged in more intimate self-disclosure than those who thought that they were disliked. These behaviors had the effect of inducing liking in their interaction partners.

Self-disclosure

According to social penetration theory, when two people first meet, they generally disclose nonpersonal, superficial information. If that level of interaction is enjoyable, disclosures gradually will increase in breadth (the number of topics discussed) and depth (the information that is disclosed becomes more personal and intimate). Research has confirmed that people are more attracted to someone who begins with relatively nonpersonal disclosure and progresses to more intimate disclosure later in the interaction. In studies specifically on

friendships, it has been found that friends disclose more intimate, personal information than do acquaintances.

Before leaving this topic, it should be noted that in the early stages of a relationship, it is important that disclosures are reciprocated. The reason is that disclosing personal information engenders feelings of vulnerability. If each person is taking similar risks, feelings of vulnerability are reduced and a sense of trust can be established. Once this occurs, strict tit-for-tat reciprocity is no longer necessary.

In conclusion, the formation of a friendship is a complex process in which a number of factors – both external and internal to the relationship – must converge. External factors such as physical proximity (an environmental factor) and frequency of exposure (a situational factor) serve to bring potential friends into contact with one another. Internal factors such as a person's social competence (an individual factor) and whether the two people are similar in important ways (a dyadic factor) determine whether a friendship actually will be formed.

Maintaining Friendships

There are two paths to relationship maintenance: One is deliberate, strategic planning for the continuation of the relationship; the other is “the breezy allowance of the relationship to continue by means of the routine everyday interactions and conversations that make the relationship what it is” (Duck, 1994: 46). Put another way, people use both explicit and implicit strategies to maintain friendships.

Explicit Maintenance Strategies

In one study, the researchers asked a large sample of undergraduates to list strategies (behavioral examples) that they used to maintain romantic, friendship, and familial relationships. The most frequent strategy reported was “direct discussions and listening to one another” (p. 9). This strategy was labeled *openness* and was exemplified by self-disclosure. The second most frequent strategy, termed *assurance*, involved communicating that the relationship was important. The most common behavioral manifestation of this strategy was supportiveness. The third strategy listed was spending time together (labeled *joint activities*). Other strategies included *positivity* (trying to make interactions pleasant), *cards/letters/calls*, and *avoidance* (of relationship issues or the partner). Most of these strategies were more likely to be used in romantic or familial relationships than in friendships.

Research that has focused exclusively on the maintenance of friendships underscores the importance of the three most frequent responses in this earlier research, namely self-disclosure, provision of support, and spending time together. With regard to the former, several studies have found that friends use self-disclosure as a maintenance strategy. According to Rosenfeld and Kendrick (1984), “the primary motivation to engage in self-disclosure with a friend is to help the relationship solidify and grow” (p. 337). Similarly, in another study, “attempt to strengthen and improve the relationship” was one of the reasons given by women and men for having self-disclosed to their best friend. Other research has found that women are particularly likely to endorse self-disclosure as a strategy for maintaining same-sex friendships.

Canary et al. also found that the provision of assurance and support was important in maintaining relationship. This finding, too, has emerged in other friendship maintenance studies. It should be noted that the form that social support takes tends to differ by gender. Women are more likely to provide emotional support (a listening ear; a shoulder to cry on) to their same-sex friends; men are more likely to provide practical support (e.g., help repairing a vehicle or building a deck).

Finally, the original study on explicit maintenance pointed to the importance of making the effort to stay in contact and spend time together. This strategy also has been confirmed in other research on friendship maintenance. Based on extensive interviews with middle-aged adults, Rawlins (1994) concluded that "the primary culprit cited for problems with friends was a lack of time. Consequently, keeping friendships alive... involved 'taking,' 'making,' or 'finding the time'" (p. 290).

Implicit Maintenance Strategies

Friendships are maintained by the everyday interactions that people naturally have with friends, even though these interactions may not be motivated by the explicit goal of relationship maintenance. The literature on implicit friendship maintenance again underscores the importance of self-disclosure (especially for women), the provision of support, and the importance of simply spending time together. Implicit friendship maintenance tends to take a different form for women and men. It is well documented that when women interact with same-sex friends, the focus is on talking, whereas men prefer to engage in activities, such as participating in sports. For example, when undergraduates were asked whether they would prefer to do an activity or 'just talk' with a same-sex friend, more than three times as many women as men chose talking; nearly twice as many men as women chose the activity. Topics of conversation also vary by gender. Women tend to talk about personal and relationship matters, whereas men tend to talk about the activities they engage in (e.g., sports, vehicles, work, computers). Regardless of the form that activities and conversation take for each gender, these kinds of everyday interactions serve to maintain and sustain friendship for both women and men. Hare (1977), for example, discussed friendship maintenance in terms of shared mundane activities such as socializing over food and drink, giving rides, and so on. Similarly, Duck (1994) argued that everyday talk is the essence of relationship maintenance. In his view, the mere occurrence of talk, regardless of its content, signifies that the relationship exists and is important. In support of this view, Duck and colleagues (1991) found that for both men and women, having a conversation with a friend was considered more important than the actual topics discussed.

Social support also can be conceptualized as an implicit maintenance strategy. It has been noted that close friends are the primary source of social support for most young adults, which has implications for the maintenance of friendships: "To maintain a close friendship, partners are thus obligated to provide comfort, help solve problems... celebrate victories, offer encouragement... and so on" (Burleson and Samter, 1994: 74). The authors suggest that such support is frequently given without deliberate maintenance in mind. Rather, there is

a tacit understanding that the provision of support is simply 'what friends do.' As discussed earlier, sometimes friends will provide support out of an explicit motivation to maintain the friendship (e.g., someone who dislikes dogs might nevertheless agree to take care of a friend's dog while she is away for the sake of maintaining the friendship). However, much of the time support is given automatically, without a lot of conscious deliberation about friendship maintenance.

In summary, the literature on the maintenance of friendships points to a number of strategies – both explicit and implicit – that facilitate the maintenance of friendships. Of these, three seem particularly important: self-disclosure, supportiveness, and spending time together. Thus, people self-disclose to friends, support their friends, and make the effort to spend time with friends with the deliberate goal of maintaining and strengthening the relationship. It is also the case that relationship maintenance is a by-product of the kinds of conversations and activities that naturally occur in friendships. In conclusion, in order for a friendship to thrive, it is important for friends to engage in personal self-disclosure, provide social support to one another, and simply spend time together.

Deterioration and Dissolution of Friendships

In the section on formation of friendships, the central theme was that four categories of variables must converge in order for a friendship to develop: environmental, individual, situational, and dyadic. As shall be seen, each of these factors also plays a role in the deterioration and possible dissolution of friendships.

Environmental Factors

In order for a friendship to develop, the individuals must have frequent contact with one another. Conversely, the loss of proximity is associated with friendship dissolution. Loss of proximity occurs when people attend different schools, change jobs, retire, or move away. According to one researcher, the majority of friendships do not survive significant changes such as geographic mobility. In one study of college students, more than half of the participants (57.4%) reported the dissolution of a close friendship within the last year. For the majority, the loss had occurred during the transition to college. Thus, an environmental factor such as reduced proximity can contribute to the termination of friendships. It is possible that technological developments such as electronic mail now mitigate these effects. However, so far the benefits of computer-mediated communication for friendship maintenance have not been examined empirically.

Situational Factors

The situational factors that play a role in friendship formation, namely, frequency of exposure and availability, also have been implicated in the deterioration and dissolution of friendships. For example, when researchers asked participants to report on reasons for the decline of relationships, the most common response was a reduction of interaction or involvement (e.g., spending less time together, sharing fewer activities). Friendships also may dissolve when one or both people become less

available for this kind of relationship. Availability may be reduced by many different changes in life circumstances, such as the transition to parenthood, increased work demands for one or both friends, or the formation of new relationships. The development of new friendships is frequently accompanied by casualties in established friendships, as people discover they lack the resources (e.g., time, energy) to maintain a roster of preexisting and new friendships. Romantic relationships pose an even greater threat to friendships. It is well established that the greater the involvement with a romantic partner, the lesser the involvement with friends. For example, in one study, it was found that the number of friends decreased from an average of 4.13 for occasional daters to 1.06 for married respondents. Moreover, romantic involvement was associated with a reduction in the quality and quantity of interactions with the few friends who were retained.

In short, situational factors that result in decreased interactions between friends are likely to put the relationship in peril. This point is underscored in an interview study with middle-aged adults. A striking finding was that “the interviews were riddled with accounts of how vulnerable friendships were to altered circumstances . . . shifting schedules, changing jobs, moving away, developing new interests. It felt like valued friendships were continually slipping away from these adults, in most cases due to events that transcended the friendships” (Rawlins, 1994: 287).

Individual Factors

Earlier, research was presented showing that friendships are more likely to develop when potential friends possess positive qualities (e.g., social skills, responsiveness). Unfortunately, negative characteristics such as being demanding, moody, possessive, or boring may only become apparent once a friendship is established. The discovery of such characteristics can jeopardize a friendship. Based on her study of serious problems in friendships, Wiseman (1986) concluded that, “the discovery of just one undesirable trait can cause the recasting of the character of a friend” (p. 199). Similarly, in a program of research on adolescents’ friendships, the most frequent reason given for the dissolution of a friendship was disloyalty/lack of commitment, followed by the discovery of character flaws that undermined admiration for the friend. In a study of women’s friendships, participants reported that some of their friendships had ended because the friend behaved in ways that triggered a complete reassessment of his or her character. Betrayal of trust was especially likely to result in a friend receiving a negative evaluation. Indeed, other research has confirmed that friendships are likely to deteriorate and dissolve when betrayal of trust occurs. In conclusion, as Duck (1982) observed, “new, surprising, and significantly negatively charged information about the other can hasten the relationship’s death” (p. 7).

Dyadic Factors

The dyadic factors that lead to friendship formation (i.e., similarity, reciprocity of liking, self-disclosure) also play a role in the deterioration of friendships. In addition, once friendships are formed, conflicts may arise. When friends fail to engage in constructive conflict resolution, the relationship becomes vulnerable to dissolution.

Similarity

One of the best predictors of friendship formation and maintenance is similarity. It follows that if friends change in ways that create dissimilarities between them, the relationship may be threatened. Indeed, when asked why a friendship ended, a typical response is that the two people followed different life paths and no longer had anything in common. One study compared the amount and type of similarity between college roommates who remained friends versus those who did not. Those whose friendship ended were less similar in terms of psychological, intimate constructs than those whose friendship remained intact.

Reciprocity of liking

Reciprocity of liking was another factor identified as important in the formation of friendships. Conversely, decreased liking is associated with the dissolution of friendships.

Self-disclosure

Self-disclosure was identified as a key strategy for forming, as well as maintaining, friendships. Perhaps not surprisingly, when a friendship begins to deteriorate, the decline is reflected in the friends’ self-disclosure. According to one program of research, friends tend to avoid personal, intimate self-disclosure when their relationship is deteriorating. For example, in one of study, participants recorded their interactions with a friend over a 2-week period. Disengaging friendships were characterized by less effective and less personal communication than growing friendships. It is unclear whether the avoidance of intimate self-disclosure is a cause of friendship decline or whether friendship deterioration causes people to restrict the intimacy of their disclosures. This is an issue that can only be addressed by longitudinal data in which patterns of self-disclosure and reports of deterioration are tracked over time.

Conflict

As a friendship develops and becomes more intimate, there is an increase in the reported benefits of the relationship. However, reports of anger, conflict, and hurt feelings also increase. Unfortunately, when conflict does arise, the research suggests that the most common response is passive avoidance, as opposed to strategies that involve explicit discussion of problematic issues. For example, in one research program on conflict in friendships, integrative strategies (explicit, constructive discussions) were least likely to be used, even though they were most likely to produce a satisfactory resolution. Moreover, the use of integrative tactics was negatively correlated with both the frequency and duration of conflicts. Thus, when faced with conflict issues in friendships, people generally respond with avoidance, even though this response is least likely to lead to a satisfactory resolution.

To summarize, in the same way that environmental, individual, situational, and dyadic factors must converge in order for friendships to develop, friendships are likely to dissolve when these factors conspire against them. The importance of these four factors in friendship dissolution is underscored in Rose’s (1984; Rose and Serafica, 1986) program of research. When college students were asked to describe the decline of a closest, same-sex friendship, nearly half (47%) mentioned an

environmental factor, namely physical separation (e.g., moving to another city, attending different schools; Rose, 1984). The situational factor of reduced availability also was apparent in these responses: 18% of participants reported that old friends had been replaced by new friends; 12% attributed friendship dissolution to one or both friends' romantic involvement (i.e., dating or marriage). The individual-level factor of dislike also emerged; 22% of the respondents named attitudes and behaviors that undermined liking for the friend. Rose and Serafica (1986) subsequently conducted a finger-grained analysis by soliciting dissolution accounts for different kinds of friendship: best, close, and casual. Participants' responses were coded using a five-category scheme: less proximity (e.g., friend moved), less affection (decrease in liking, commitment, acceptance), less interaction (decrease in quantity or quality of time spent together), and interference (romantic involvement). Interestingly, different causes were identified for the dissolution of the different kinds of friendships. For example, casual friendships were more likely to end because of reduced proximity, whereas close and best friendships were more likely to end because of interference or decreased interaction. These findings raise the intriguing possibility that environmental, individual, situational, and dyadic factors may have a differential impact on friendship dissolution, depending on the stage of the relationship. The bottom line is that numerous factors conspire against the continuation of friendships.

Restoring Friendships

It has been argued that no other social relationship is as fragile as friendship. Unlike institutionalized relationships such as marriage, when a friendship deteriorates, there are no societal supports in place to assist in reconciliation and repair. Instead, people are left to their own devices. Are people able to resuscitate ailing friendships? Researchers asked respondents to describe the decline of a relationship (friendship, romantic, marital, or familial) and the turning points that resulted in its rejuvenation. For friendships, the most common rejuvenation event (reported by 33% of participants) was a change in the behavior of one or both friends, including giving the other more 'space,' spending more time together, being more independent, talking more, and so on. The second most frequent rejuvenation event (31%) was labeled 'have big relationship talk.' These talks entailed apologies, arguments, acknowledging the importance of the relationship, setting ground rules, and the like. They differed from other conversations in that they served the explicit function of restoring the relationship. The third rejuvenation event (19%) included gestures of reconciliation (e.g., initiating a joint activity, directly expressing a desire to reconcile). This was followed by reassessment of the importance of the relationship (8%) and accepting or forgiving the other (8%). Finally, a mere 2% of respondents reported that they had restored a friendship by seeking third-party help (e.g., seeing a counselor, talking to other social network members; Wilmot and Stevens (1994)). (Note these numbers add up to more than 100% because participants tended to report more than one rejuvenation strategy.)

When the researchers compared the different types of relationships, they found that the rejuvenation events were endorsed much less frequently for friendships than for other

kinds of relationships. This suggests that when friendships deteriorate, people may not take active steps to restore it. As discussed earlier, research on conflict has shown that in friendships, people are most likely to respond with passive avoidance, as opposed to open, explicit discussion of problem issues. Passivity is also the *modus operandi* when people terminate friendships. In one study, 72% of the termination strategies that participants had used to end a friendship were classified as indirect. This passivity is also reflected in the language that people use to describe the dissolution of their friendships – 'drifting apart' or 'fading away,' rather than 'breaking up.'

Although the passive approach to conflict management has deleterious effects, ironically, this same approach to friendship termination may have beneficial consequences for friendship restoration. Research has found that faded friendships are seen as relationships that could be revived. Reconciliation is perceived as much more difficult if a friendship has been explicitly terminated.

Conclusion

In conclusion, despite its status as the 'neglected' relationship, there is sufficient research on friendship to paint a portrait of the life cycle of this kind of relationship. Friendships are formed when environmental factors bring people together, when the situation permits for ongoing, frequent interaction, when the individuals involved possess qualities that facilitate the formation of relationships (e.g., social skills), and when the interactions between the two people flow smoothly. Friendships are maintained and strengthened when friends engage in personal self-disclosure, support one another, and make the effort to spend time together. Not all friendships survive. Friendships deteriorate and dissolve when the factors that facilitated the formation of the relationship are negated (e.g., reduced proximity, the discovery of disliked qualities in the other). Given the benefits of this kind of relationship in terms of physical and emotional well-being, it is encouraging that people have knowledge of the kinds of strategies that can result in the rejuvenation of lapsed friendships.

Published by Elsevier Inc.

Glossary

Avoidance theory of worry Another cognitive model that focuses on how individuals with generalized anxiety disorder cognitively avoid facing anxiety-laden fears by verbal-linguistic thought, rather than imagery in the form of worry.

Cognitive-behavioral therapy A form of 'talk therapy,' based on the principle that our thoughts mediate feelings and behaviors. The approach is commonly used, effectively, in the treatment of generalized anxiety disorder.

Experiential avoidance A type of avoidance common in generalized anxiety disorder, where anxious individuals attempt to circumvent experiencing and facing their anxiety and rely on worry as a coping technique. A psychological approach called acceptance-based behavior therapy has been developed that addresses this concept of experiential avoidance and its treatment.

Intolerance of uncertainty It is both a generic term for chronically anxious/worried patients' difficulty in

facing the uncertainties of daily living and a psychological approach aimed at helping them address this fear of uncertainty.

Looming vulnerability A cognitive model that defines the concept of threat in dynamic terms, where images and thoughts are rapidly rising in risk, thereby increasingly intensifying appraisals of threat and danger.

Generalized anxiety disorder An anxiety disorder characterized by excessive anxiety and worry across multiple content domains that is experienced as uncontrollable by the person. The anxiety and worry interfere with functioning in important roles and areas of daily living.

Metacognitive model A cognitive model that focuses on the nonadaptive beliefs anxious individuals have about the uncontrollability and danger of worry.

Worry A type of cognitive activity marked by negative affect and chains of apprehensive thought processes aimed at the problem solving of issues where the outcomes are often uncertain.

Generalized Anxiety Disorder: An Overview

Diagnostic Definition of Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is a condition characterized by chronic, persistent, and excessive anxiety or uncontrollable worry associated with three or more accompanying symptoms such as restlessness, difficulty in concentrating, fatigue, muscle tension, disturbed sleep, and irritability. The worry that occurs is often focused on multiple content areas (e.g., job performance, finances, health, and safety of self, children, or family members). It is frequently about 'minor' and remote things. The anxiety and worry contribute to occupational impairment and barriers in other important areas of function. The symptoms of anxiety and worry in GAD are not the result of any medical conditions such as hyperthyroidism, or because of medication, substance abuse, or any other disorder such as a mood disturbance.

Clinical Picture

Unlike a phobia, which is cued by a specific object or situation, GAD has a far more diffuse, unrelenting quality to its presentation. Many GAD sufferers report being in poor health and medical concerns bring them to primary care providers complaining of somatic symptoms. Patients often have a long history of physical complaints before health professionals identify that chronic and unrelenting worry/anxiety may be the underlying cause of their symptoms.

There is no fixed clinical picture for GAD and it presents with considerable heterogeneity. Many GAD sufferers experience

gastrointestinal distress, acid reflux disease, hypertension, and autonomic hyperarousal. As compared to nonpathological worry, the anxiety and worry are more pervasive, pronounced, distressing and protracted in duration. The excessive worry often arises from minor concerns and may appear to surface with little apparent overt reason for its onset. It is perceived as difficult to stop and uncontrollable. Some research suggests that there is a 'generalized tension subtype' and a 'generalized worry subtype.' Some view GAD as a 'dysphoric disorder' more similar to depressive illnesses, while others feel that GAD and depression share a trait called, 'negative affectivity.' These hypotheses about the various clinical presentations of GAD may lead to changes in the much anticipated DSM-V and other classification systems.

Case Example

Carol is a 38-year-old, Caucasian, married mother of three children. She has been 'happily' married for 10 years and her husband and three children (ages 9, 8, and 6) are in good health and doing well. She is a registered nurse and works for her husband – an accomplished radiologist – and his practice. She reports no conflict in her personal and professional relationships and that she and her husband are financially secure and have many friends.

When 18 years old, she reported to her physician that she was troubled by childhood worries that seemed to worsen as she got older. Although unable to verbalize all worries, she reported frequent headaches, stomach aches, difficulty in

sleeping, and feelings of tension in her back and neck. She reported fears of going to college, worries that something horrible might happen to her parents while she was away, and could not decide what she wanted to study in college. She did well academically but was worried about her grades, whether her parents could afford her tuition, and the welfare of her parents and siblings. She developed a frequent need to use the bathroom that would flare up for hours at a time and believed that she had irritable bowel syndrome. She also suffered from depression and began missing classes. After several months, her parents visited and found her 15 pounds thinner, looking strained and fatigued. She began to see a psychologist who diagnosed her with comorbid GAD and depression and recommended that she be evaluated by a psychiatrist who prescribed an antidepressant and benzodiazepine. Although she noticed improvement, her worry and somatic symptoms did not fully leave her even after a year of medication and therapy.

She reported that she saw herself as living a 'picture perfect' life after her marriage and attainment of a nursing degree – but her symptoms never fully abated. She continued to worry and be somatically preoccupied, and was bothered by back and neck tension. Her husband noticed her seeming irritability, restlessness, 'worry about everything,' and spending an unusual amount of time in the bathroom and worrying about 'everything.' She resumed treatment with medication – not having perceived benefit from her supportive psychotherapy. A combination of antidepressants and benzodiazepine helped her to achieve symptomatic relief. However, with each new stressor, responsibility, and developmental challenge – for example, birth of children, the children starting school, aging parents, etc. – her worry and somatic anxiety intensified. She resisted suggestions that she should try a more evidence-based psychosocial approach than the supportive treatments received in the past. However, she has resisted further psychotherapy – arguing that her schedule is too hectic and therapy too costly and will take forever. Although medication compliant, she still suffers from debilitating symptoms when facing stressful events or transitions.

Carol exemplifies a case of comorbid GAD with dysthymia (low-grade and persistent depression) where the person has had GAD, most likely since late adolescence, combined with depression (low self-esteem, depressed mood, poor appetite, decreased libido, and some loss of pleasure in things). She appears to undergo exacerbations of her lower level and chronic anxiety around increased internal/external demands (called 'double anxiety' – anxiety episodes superimposed on a lower level of severity, but persistent course of GAD). Her preference is pharmacotherapy, but she has now pursued a course of evidence-based therapy where she saw that it might help her to maintain her recovery. As with some people who have GAD, others do not fully appreciate the level of her distress. She maintains a reasonably intimate relationship, raises children, and works part-time. However, she often feels disconnected from others, is preoccupied with fluctuating domains of worry, and is fixated on her health, the welfare of others, and finances. She has no close friends, little time for leisure, and minimal peace of mind. This is true despite the lack of any evident reasons for her GAD symptoms – no history of loss/abuse, solid relationships with family growing up, current financial stability, and good health.

Phenomenology of GAD

Prevalence

GAD is one of the most common and debilitating anxiety disorders, but often symptoms are at a subthreshold level and do not always result in sufficient distress or impairment to warrant a diagnosis. It is frequently seen in primary care settings without being properly diagnosed. Lifetime prevalence rates for GAD range from approximately 3% to 7% in adults, and 12-month rates are in the 1–4% range. The prevalence rates are higher in anxiety disorder clinics, where up to a quarter of the individuals have GAD as a presenting or comorbid diagnosis.

Once considered rare among children, GAD occurs in this population at around 2–4% and at even higher rates in specialty child psychiatry clinics and in adolescents. Anxieties and worries in children often center on performance in sports, school, or on social and environmental catastrophes. GAD may be most common in middle age (45–55 years old), while in older adults, subclinical GAD (not meeting full diagnostic criteria) is typical.

Age of Onset

GAD can develop at any age, but most commonly develops in the late teens and early twenties. Although earlier onset (which can occur in childhood) is marked by the absence of a specific precipitating event, crisis, or challenge, later onset GAD is often characterized by precipitating life stressors.

Gender Differences

Women have GAD in a ratio of 2 or 3:1 compared to men. Explanations for the greater prevalence in women have been proposed in terms of hormonal factors, greater openness about feelings and treatment seeking, and societal/cultural pressures associated with raising children and responsibility for their safety (a frequent focus of worry in GAD), and having to work full time. Gender divergence begins in adolescence and women in their forties are particularly vulnerable and overrepresented in clinical settings.

Course and Prognosis

GAD is typically chronic and an unremitting lifetime condition, but can also exhibit a more episodic-like course with periods of relative latency. The course is particularly poor when GAD is comorbid with another disorder such as major depressive disorder (MDD), another anxiety disorder, or a personality disorder. Comorbidity for GAD is approximately 85–90% with another disorder – the most common being MDD and then social anxiety disorder. Co-occurring personality disorders happen in around 60% of GAD cases. Pure GAD is rare. The course of GAD involves frequent use of medical services and contributes to approximately 6.3 missed days of work per month and broad impairments in social, marital, vocational, and academic life.

Conceptual Models of GAD

Psychodynamic Model

According to contemporary psychodynamic models, GAD develops as a result of unresolved 'core conflictual relational

themes' (CCRTs) that are associated with the particular symptoms expressed by the individual sufferer of GAD. For example, modern day psychodynamic thinkers have proposed that by focusing on the therapeutic alliance, therapists are able to use this relationship as a 'corrective experience' to offset the hypothesized damage done by insecure attachments and traumatic experiences that have occurred during earlier periods in life. Some individuals develop GAD because of these earlier interpersonal conflicts and traumas with significant others. Psychodynamic therapists help individuals with chronic anxiety face similar feared situations and people – similar to the idea of facing a phobic object. If an individual is unable to approach those things he or she fears, the anxiety associated with these unresolved relational/interpersonal conflicts persists and can become chronic, as in GAD. Anxiety is then manifest psychologically and behaviorally.

Beck's Cognitive Theory

Beck's cognitive formulation of anxiety disorders has been one of the most influential and supported contemporary models. According to Beck, GAD is related to the continuous activation of maladaptive danger schemas that guide information processing (e.g., attention, interpretation, and memory for threat stimuli). Such danger schemas – internal frameworks developed from past experience – contain distorted beliefs in individuals who have GAD and lead them to overestimate the magnitude and severity of threat and underestimate the extent of their coping resources in even neutral or mundane situations. For example, individuals with GAD exhibit overactive threat processing and cognitive biases that serve to maintain the disorder. For instance, they overestimate the probability of threat and consequences of harm, scan the environment for potential threats, and interpret ambiguous situations as likely leading to catastrophic worst-case scenarios. Individuals who suffer from GAD are seen as suffering from a continual stream of threatening 'automatic' thoughts and disturbing threat-related visual images across multiple content areas that elicit anxiety, worry, and tension. A great deal of evidence has supported Beck's cognitive model of anxiety and GAD in particular. However, one criticism of the model is that it does not take metacognitive factors – beliefs about worry – the cognitive activity in worry, and emotional experience sufficiently into account.

Barlow's Model of Anxious Apprehension

In contrast to Beck's model, Barlow's model focuses more on emotion and behavior than cognition in the concept of anxious apprehension (negative affect). Barlow assumes that GAD is the basic anxiety disorder and so it shares anxious apprehension with all other anxiety disorders. That is, anxious apprehension is a broad-based phenomenon common in anxiety. However, in spite of its universal presence in anxiety, the presence of this negative affect is both distinct and unique to GAD, just like fear is more central to panic disorder. Barlow goes on to propose that the synergy between biological (genetics) and psychological vulnerability (decreased loss of control) combined with environmental factors (early adverse developmental experiences) leads to attempts to cope with anxious apprehension via behavioral avoidance and worry. These early developmental experiences are critical factors, in this

model, as to whether a young person will bring a sense of control over his or her life with him or her into adulthood or a low sense of control that contributes to heightened arousal, lack of predictability over events, and increased somatic output. This latter perception of decreased control interacts with the other mentioned factors becoming a precursor for the emergence of an anxiety disorder, such as GAD.

Avoidance Model of Worry

Borkovec's cognitive avoidance model of pathological worry has stimulated one of the most effective of current treatment interventions. His model proposes that pathological worry – a central process in GAD – is a maladaptive cognitive response to threat stimuli that consists primarily of abstract lexical activity. Such lexical activity functions to help the worrier to avoid painful affect in response to the threat. In this view, worry has a short-term benefit for the worrier in facilitating escape from disturbing mental imagery, negative emotions, and bodily sensations. Evidence confirms that worry is primarily lexical and that verbal thoughts elicit far less cardiovascular arousal than images of the same emotional stimuli. The short-term benefit of worry, however, is thought to come with a long-term cost. In specific, it reinforces and thus maintains a pathological worrisome thought activity in GAD – and lack of extinction of these fear-based cues and aversive imagery. Evidence confirms that worry is associated not only with a dampening of somatic activity, but also with the decreasing of emotional processing and increasing of anxious meanings. Evidence suggests that pathological worry activity in GAD can serve the unhealthy purpose for sufferers to not confront more painful issues and interpersonal issues. Borkovec's model has been highly influential on recent approaches to cognitive, emotional, and acceptance-based perspectives of avoidance in GAD.

Looming Vulnerability Model

The looming vulnerability model of Riskind and his collaborators holds that individuals worry, experience anxiety, fear, and engage in self-protective strategies to the extent that they appraise danger as dynamically developing and approaching in relation to the self. What sets this model apart from others is its emphasis on threats as dynamic unfolding events – such as deadlines, oncoming injuries, or failures. Thus, threatening stimuli are not static but rapidly rise in risk as they approach and expand in space and time. Thus, the threatening stimuli that initiate anxiety, worry, and cognitive avoidance are defined by the perceived dynamic aspects of threat and not just defined in terms of the probability and severity of aversive events. Evidence supports that looming vulnerability is elevated in GAD, that it predicts vulnerability to anxiety, worry, and emotional avoidance, and that it influences information processing biases. However, it has received less research than some of the other models on GAD and has only recently been explored as a source of intervention strategies.

Intolerance of Uncertainty Model

According to Dugas, intolerance for uncertainty is a key mechanism that is implicated in GAD. It is defined as a cognitive

bias that is reflected in an excessive tendency to find uncertain situations stressful and upsetting, to believe that unexpected events are negative and should be avoided, and to think that being uncertain about the future is unfair. Furthermore, intolerance of uncertainty leads to the inability to act when faced with an uncertain situation. According to the intolerance of uncertain model of Dugas and collaborators, GAD sufferers, when confronted with ambiguity and uncertain events/situations, become highly distressed and upset. In this model, intolerance of uncertainty precedes and produces the onset of worry. Worry then serves as a way to cope with uncertainty about an unpredictable future. The model suggests that GAD sufferers have dysfunctional beliefs about worry (e.g., worry is motivating, worry assists in problem solving, and worry means that they care), poor problem orientation (e.g., problems cannot be solved, problems are a threat), and cognitive avoidance (e.g., not wanting to think about distressing thoughts and images). There is substantial support for this model and treatment trials have examined and found evidence of associations between intolerance of uncertainty and GAD and the usefulness of targeting this in treatment.

Metacognitive Model

Wells has proposed a metacognitive theory of GAD that distinguishes two categories of worry – Type 1 and Type 2. Type 1 worries are what people ordinarily think of when they refer to worry, and concern events and physical problems they may face in everyday life. Type 2 worry, in contrast, concerns the phenomenon of ‘worry about worry.’ Metacognitive beliefs and appraisals lead to metaworry which is a key feature of pathological worry that distinguishes people with GAD from others. People with GAD may simultaneously have positive beliefs about worry and its usefulness in helping them to solve problems and negative beliefs about its harmful effects. In particular, GAD is associated with beliefs and appraisals of the uncontrollability and dangerousness of worry. For example, people with GAD may believe that their worry is damaging their health. The beliefs in Type 2 worries are about both the uncontrollability of worry and its danger to survival. Positive metacognitions are generally adaptive and use worry to actually cope, while negative metacognitions focus on lack of control and threat which lead to deleterious effects and the development and maintenance of GAD. At this point, a host of ineffective strategies such as checking behaviors, reassurance seeking, avoidance, and suppression come into play, further reinforcing negative metacognitions. Some aspects of the model seem better supported than others, but overall it has proven to be an important conceptual contribution on GAD.

Emotion Dysregulation Model

The emotion dysregulation model of Mennin and colleagues draws heavily on emotion theory and the regulation of emotional states, rather than just increased cognitive control and mastery. This model focuses on four main components that are central in GAD. GAD sufferers share the following: (1) they experience emotions more intensely than others (positive and negative), (2) there is a poorer understanding of emotions, (3) attitudes about emotions are viewed as more aversive and

threatening, and (4) emotion regulation strategies are largely ineffective. For example, raw emotional experiences often go unprocessed, according to this model, and in many cases are viewed in GAD as aversive in nature. This in turn creates a challenge in learning new skills, in order to solve problems that are now impaired in GAD. Worry and cognitive control strategies are once again used to confront this dysregulation, as is the suppression of emotions and emotional reactivity. Initial evidence for the model is well supported with most of its premises. Although this approach is promising, some findings suggest that GAD sufferers are in reality well equipped to identify their emotions and are not nearly as fearful of their emotions as once thought compared to others with certain psychiatric disorders.

Acceptance-Based Behavior Model

Roemer and Orsillo’s acceptance-based model contends that experiential avoidance (e.g., aversive affect, avoidance of internal experiences) is the most prominent feature of GAD. Experiential avoidance refers to GAD sufferers avoiding unpleasant internal experiences. In other words, to diminish internal distress and somatization, they suggest, like Borkovec, that worrying is one way to accomplish this goal. However, they further postulate that worrying reinforces more problems than it solves, ultimately leading to a repetitive cycle of more worrying and behavioral restriction. For example, in the long run, individuals with GAD end up not pursuing valued goals, are too future oriented, lack a mindful, present-oriented focus, and become even more behaviorally rigid over time. Thus, experiential avoidance impedes effective problem solving and the broadening of more adaptive and flexible solutions to reduce internal distress and decrease somatic activity. Ultimately, this leads to increased distress and more unpleasant internal experiences.

The Biological Model

There is no one biological model on GAD, but a number of theories that offer insights about how biology and genetics play a role in this disorder. These theories run the gamut from neurotransmitter deficits and surplus, to hypersensitivity/overactivation in the amygdala, anterior cingulate, and dorsal medial prefrontal cortex regions of the brain. New technologies such as functional magnetic resonance imaging (fMRI) have made it possible to look closely at these areas and make predictions about how neural correlates of worry compare in GAD subjects versus controls.

Genetics seem to suggest a moderate degree of heritability in GAD with best estimates ranging around 30%. These rates are almost exactly the same for MDD and lower than in panic disorder. GAD and MDD have been viewed as sharing similar genetic, but different environmental, influences. Individuals with GAD are more likely to have first degree relatives with GAD compared to controls, and twin studies have found higher rates of GAD in monozygotic twins, than in dizygotic twins. In the end, it may still prove to be an interaction of factors that range along the spectrum of heritable traits such as neuroticism, negative affectivity, plus environmental correlates that influence the emergence of anxiety disorders more broadly and GAD in particular.

Treatment of GAD

Cognitive–Behavioral Approaches

Cognitive–behavioral therapy (CBT) has proven itself in multiple controlled trials to be an effective first-line treatment for GAD. Borkovec's approach is particularly supported. There is no single CBT approach, yet they all share the assumption that distortions in thinking and their modification bring about change – that is, the particular cognitions and beliefs needing to be targeted – has become more precise and better delineated in the newer approaches, than earlier, more traditional and generalized treatments that address more globally dangerous threats and anxious apprehension. In Beck's cognitive therapy, the focus is on helping patients with GAD to recognize, refute, and cope with the continual stream of threatening automatic thoughts and images, while at the same time, modify or change dysfunctional attitudes that compose underlying maladaptive danger schemas. This in turn leads to increased self-mastery and general coping skills. In Borkovec's approach, worry exposure is critical.

Metacognitive therapy, in contrast to the more traditional model of Beck, does not focus on the contents of worry *per se*, but rather negative beliefs about worry (metaworry). Interventions in this approach are aimed at challenging Type 2 worries concerning the uncontrollability and dangerous effects of worry. Various interventions such as worry postponement, decreasing reassurance and thought suppression are employed to change these negative beliefs about worry. Positive beliefs about worry that are erroneous, such as an overreliance on worry as beneficial, are also challenged. An open trial and recent randomized-controlled study has provided support for the metacognitive approach.

The intolerance of uncertainty approach aims to help GAD sufferers better tolerate uncertainty, and not decrease its intensity. Psychoeducation, worry awareness training, uncertainty recognition, behavior exposure, reevaluation of the usefulness of worry, problem solving training, imaginal exposure, and relapse prevention are distinct modules in the treatment process. The processing of core fears also helps to soften cognitive avoidance which maintains worry. A series of randomized-controlled trials (RCT) have largely validated the efficacy of this approach in the treatment of GAD.

Emotion-Focused Approaches

Two recent approaches focus on dysregulation of emotional states and experiential avoidance of them in the treatment of GAD. Emotion regulation therapy attempts to help individuals with GAD better self-regulate their emotions to decrease their worrying using elements to increase emotional awareness and decrease emotional avoidance.

Acceptance-based behavior therapy focuses on experiential avoidance which is common in GAD. The goal of treatment is to enhance confronting internal experiences to help decrease worrying and avoidance as viable coping techniques. Key treatment strategies in this approach include techniques that enhance present-focus living, a nonjudgmental acceptance of internal/external sensations, and decrease behaviorally restricted and restless unfocused activities by enhancing mindful action of

desired values. Acceptance-based behavior therapy has conducted an open trial and recent RCT with promising results in improving worry, depression, and anxiety. A future RCT with a control group is in process.

Psychodynamic Approaches

Crits-Christoph and colleagues have developed a supportive-expressive psychodynamic approach that is a brief interpersonally oriented therapy for GAD. It focuses on worry and interpersonal problems within the context of a relational psychodynamic model. Their main premise is that worry is a defense mechanism and the effects of trauma lead to interpersonal/relational challenges. The goal of the treatment is to alter 'CCRT' via the creation of a strong therapeutic alliance. The approach has produced mixed results with it being helpful in reducing rates of symptoms of anxiety leading to improvements in remission in GAD patients, but not being of benefit in decreasing interpersonal issues (the main goal of the treatment). However, newer research lends support for this type of short-term dynamic treatment. This has been demonstrated in a similar, but modified version of Crits-Christoph's approach in a recent RCT comparing supportive-expressive psychodynamic therapy versus CBT. Results showed that both therapies were effective in the treatment of anxiety and depression in GAD. Yet, CBT was more efficacious in reducing worry. Interpersonal challenges improved with both treatments.

Integrative Approaches

Integrative approaches have become popular in the treatment of GAD and other psychiatric disorders. Borkovec and colleagues have developed an approach that combines a cognitive-behavioral treatment package with interpersonal/experiential processing. The treatment incorporates CBT components (self-monitoring, relaxation training, cognitive therapy, rehearsal of coping responses, scheduling of pleasant activities, stimulus control techniques, establishing worry periods, and decreasing intolerance of uncertainty). In addition, targeting nonadaptive relationships, building the therapeutic alliance, and helping GAD sufferers experience a deepening of their emotions by expressing them, rather than avoiding them, are key strategies in this treatment. The results have shown that the additive piece of interpersonal/emotional processing to CBT showed some early promise, but other recent research produced more modest outcomes and the added benefits of integrative approach are still being determined.

Pharmacological Approaches

Multiple agents have been tried and tested in the pharmacotherapy of GAD. First-line agents are still the selective serotonin reuptake inhibitors (SSRIs) such as paroxetine, sertraline, and escitalopram and the selective serotonin norepinephrine reuptake inhibitors which include venlafaxine and duloxetine. Benzodiazepines can be used for short-term control of somatic symptoms selectively as monotherapy and in long-term use because of intolerance to other classes of medications. Other medications that are more second line are buspirone, hydroxyzine, and imipramine. Pregabalin, a novel anxiolytic, may

prove to be a first-line given its efficacy, but has not achieved FDA approval in America. Tiagabine has not proven to be effective in GAD. Beta blockers also have limited use and should ideally be avoided as they may contribute to emergent depression. The same can be said about herbal/alternative compounds where empirical support is lacking. Other medications requiring more research that may have a future in the pharmacological treatment of GAD are bupropion, gepidone, opipramol, agomelatine, abecernail, and riluzole. Many RCTs have been conducted on the first-line treatments, as have been effective relapse treatment studies to support their maintenance use (long-term treatment). Pharmacotherapy is a mainstay in the therapy of GAD and has proven to be of equal efficacy to the psychosocial approaches mentioned throughout this article.

Treatment Refractory GAD

There is no consensus among the experts on how best to manage those GAD sufferers who remain symptomatic after receiving full courses of evidence-based protocols. Given the modest clinical outcomes for therapeutic and pharmacologic treatment of GAD (40–60% response range), novel interventions in both areas need to be used to help those sufferers who are often refractory to first-line approaches such as CBT and SSRIs/SNRIs. There has been some growing research suggesting that if a tried and tested approach does not work, it is well advised to try another empirically validated approach (Beck, personal communication, 2009). The plethora of psychosocial and pharmacological modalities leaves the clinician with many more options than in the past. Identifying the core worry domains and associated symptoms (psychic vs. somatic) can assist in this process. The mechanisms of change inherent in the various therapies such as intolerance of uncertainty, cognitive/experiential avoidance, negative metacognitions about worry, emotional regulation, interpersonal conflict, and looming vulnerability, for example, can be assessed in the early stages of treatment making it possible to match the treatment to the varied clinical presentations and target-specific areas in need of change with GAD patients.

In regard to pharmacotherapy, different pharmaceuticals will work for some patients rather than others in spite of FDA approval. Optimization of doses, switching from one class to another, and polypharmacy in the form of augmenting antidepressants with atypical antipsychotics such as risperidone, olanzapine, and quetiapine have proven in some research to be effective in the GAD refractory patient. Mood stabilizers such as depakote may also be of benefit. For some patients with somatic impairment, monotherapy with benzodiazepines, perhaps with antidepressants, may prove to be a viable option, despite dependency and withdrawal concerns. Finally combining CBT with medication or trying one when the other fails is also a possibility to enhance response rates. In the end, clinical

acumen, patient preference, building the therapeutic alliance, and just plain trial and error, in some cases, until something takes hold may be the missing ingredients.

Conclusion and Future Directions

GAD is a common anxiety disorder characterized by pervasive anxiety and worry that is excessive and experienced as uncontrollable. A variety of theoretical models have been developed to account for the onset and maintenance of GAD, including those that emphasize overactive processing of threat information, worrying, emotion dysregulation, and genetics. CBT and pharmacotherapy are currently considered the most effective approaches. GAD is considered a treatable disorder but many treatment refractory cases exist and efforts continue to enhance treatment for this condition.

Glossary

Convergent thinking The ability to think analytically in one direction in order to converge on a single answer to a problem.

Creative productive giftedness The ability to develop innovative products, solutions, or ideas that become valued by their targeted audiences.

Divergent thinking The ability to think flexibly in a variety of different directions in order to generate multiple solutions or strategies for solving a problem.

Eminence Distinction within a domain, society, or historical time period, typically for one or more outstanding achievements.

Genius Exceptional intellectual ability; original and exemplary achievement that significantly alters a domain or creates a new one.

Giftedness Outstanding performance or capability in comparison with others of the same age, environment, or experience. Areas of high performance or potential include general intelligence, specific academic disciplines, leadership, creative, and/or artistic.

Historiometrics The statistical analysis of historical and biographical information.

Intelligence An internal, fairly stable ability that accounts for individual differences on mental ability tests; the ability to comprehend and adapt.

Intelligence quotient (IQ) A score derived from a standardized intelligence test where the average is set at 100.

Psychometrics The design and use of psychological tests and measurement.

Schoolhouse giftedness High IQ or aptitude scores and rapid adaptation to the academic environment.

Genius, eminence, and giftedness are highly related in that each involves extraordinary abilities valued by members of a society. Where they differ is in the average age of their identification and their degree of impact on a particular discipline. Giftedness typically is recognized in an individual's childhood achievements, while genius and eminence tend to be adult phenomena requiring major creative breakthroughs or distinction in one's field of endeavor. Although these intangible constructs are difficult to define and explain, the aim is a worthy one. Understanding giftedness, genius, and eminence means that a culture can benefit from their identification and development; scientific knowledge about the workings of the human mind is also advanced. After presenting the historical context that continues to affect current practices, this article describes the characteristics, theories, and cultivation of giftedness, genius, and eminence. The connections and disparities between these three constructs are highlighted.

Historical Legacies

A society's values largely determine which of its members are recognized as geniuses, eminent, or gifted. As values and beliefs change, so do the definitions of these three constructs. In Ancient Rome, for example, genius was a divine spirit commonly bestowed upon people and places to protect them. In the eighteenth century, the term adopted a more secular and exclusive meaning when it began to signify the innate and exceptional creative abilities of relatively few individuals. Interestingly, in Western cultures, genius became associated with insanity because of the belief that the 'creative force' could drive one mad.

During the mid-nineteenth century, the British aristocrat Sir Francis Galton conducted some of the first scientific

measurements of genius. Galton defined genius in terms of eminence (i.e., reputation achieved through widely acclaimed accomplishments), domain-specific passion, and hard work. Results from his historiometric analyses of family lineages, physical tests of intelligence (e.g., auditory acuity), and twin studies confirmed his belief that genius is an innate ability that runs in families (including his own of course). Although his physical measurements of 'natural' ability were eventually deemed inadequate, Galton successfully focused scientific attention on the connection between eminence and genius. He also laid the groundwork for later historiometric and psychometric measurement of genius and giftedness.

Lewis Terman, a twentieth century pioneer of intelligence testing in the United States, adopted Galton's view of genius as genetically inherited, stable throughout one's lifespan, and psychometrically measurable. However, unlike Galton, Terman simply defined a genius as any person with an intelligence quotient (IQ) of at least 140. Moreover, he believed that eminence in adulthood could be predicted from a child's high IQ. To test this belief and to learn more about the nature of giftedness, Terman initiated an extensive longitudinal study of 1528 intellectually gifted children in California. These participants, affectionately nicknamed the 'Termites,' were selected on the basis of teacher nominations and high IQ scores. Contrary to the popular belief that gifted children have poor physical and mental health, Terman's results showed that they were superior to their peers in motor coordination, physical condition, social adjustment, and school achievement.

Results from Terman's ongoing longitudinal research have been published in multiple volumes titled *Genetic Studies of Genius*. Did the Termites actually become adult geniuses? Overall, they were certainly successful experts in their disciplines. For example, the male participants received more college degrees, higher salaries, and more awards than the national

average. Many of them were also highly represented in honorary societies and *Who's Who in America*. The 672 female participants showed a similar pattern of midlife success except that, like most women of this era, they were less likely than the men to have advanced degrees and professional careers. However, despite their high levels of expertise, none of the male or female participants had groundbreaking discoveries, extraordinary artistic achievements, or other signs of creative greatness. (Ironically, even though none of the Termites won a Nobel Prize, two children who reportedly failed the study's psychometric screening did grow up to become genius-level Nobel Laureates.) Terman eventually acknowledged that childhood IQ scores of 140 or above did not accurately predict genius in adulthood. Furthermore, IQ did not even distinguish participants with the most successful professional careers from those who had been the least successful. Instead, factors related to their parents' education and child rearing involvement appeared to play an important role in the degree of career success these gifted children obtained as adults.

Galton and Terman left behind a powerful legacy. Their work helped pave the way for the psychometric measurement of creativity and personality. In addition, their views and methodologies are visible in current approaches to giftedness, genius, and eminence. For example, IQ tests have dominated the measurement of giftedness; childhood giftedness is no longer equated with adult genius; and genius is viewed as intertwined with eminence. Similarly, Galton's and Terman's groundbreaking research methods – historiometrics, psychometrics, twin studies, and longitudinal research – are commonly used today to examine giftedness, genius, and eminence.

Childhood Giftedness

Common Characteristics of Giftedness

Giftedness is democratic, in that it appears in all ethnicities, all socioeconomic statuses, and in equal proportions for females and males. In addition, it is typically identified in childhood and takes a variety of forms. Some children are schoolhouse or globally gifted, which means they excel in a wide range of academic disciplines. This category represents the type of giftedness studied by Terman. More common are children who display extraordinary performance in one specific domain, while showing average or below average ability in others. According to the US Department of Education, children can be gifted or talented in any academic discipline, leadership capacity, or the visual or performing arts. A subset of this population is known as 'twice exceptional' because they demonstrate extraordinary achievement in one area and are diagnosed with a learning disability in another. For example, gifted children can have extraordinary artistic or mathematical abilities and also dyslexia.

Despite the heterogeneity of giftedness, numerous studies indicate that gifted children typically differ from their same-age peers in several respects. First, these children are often precocious and tend to acquire information in certain domains earlier and at a more rapid rate than others their age. Giftedness is frequently demonstrated in the preschool years through such behaviors as precocious reading, advanced use of language, mastery of complex tasks, and extraordinary memory.

In general, precocity usually occurs in domains with a limited and well-defined body of knowledge that can be acquired through methodical study. For example, a young gifted child is more likely to excel at musical performance or mathematics than at musical composition or creative writing.

In addition, gifted children tend to process information in ways that differ qualitatively from other children's processing. For instance, the gifted are more likely than their same-age peers to use divergent, flexible strategies to combine materials and solve problems. They also tend to learn independently and create novel methods for acquiring relevant information. These qualitative differences in information processing are usually obvious by early adolescence.

Perhaps the most striking characteristic of extremely gifted children is that they are intensely and intrinsically motivated to master their domains of interest. Often beginning in the early years of their lives, they become obsessed with certain activities and types of information. They can spend endless hours immersed in drawing or reading books about reptiles. Sometimes their obsession is triggered by a crystallizing experience that exposes them to features of a domain related to their latent abilities. For example, hearing the harmonies in Wagner's music ignited Claude Debussy's interest in composing.

However, children who are gifted are more likely than other children to develop unevenly. In other words, their intellectual, socioemotional, and physical development typically occur at different rates. Their emotional maturity, in particular, often lags behind their advanced cognitive abilities and interests. For example, a 10-year-old gifted child might read at the college level, have age-appropriate physical abilities, and the emotional skills of a 9-year-old child. This means that it is not uncommon for extremely gifted children to have difficulty making friends and regulating their feelings. Furthermore, they recognize that they differ from their peers and are not treated the same. Although this sense of being atypical can lead to pride, popularity, and high self-esteem, it often results in low self-concept, depression, and feelings of isolation. Some gifted students, particularly girls, purposely underachieve in an attempt to be socially accepted by their peers. Level of exceptionality can be a contributing factor to a gifted child's poor social adjustment. For example, from her study of a small sample of children with extremely high IQs (i.e., above 180), Leta Stetter Hollingworth concluded that profoundly gifted children do not relate well to their peers as a result of dissimilar abilities, interests, and intensity of emotions.

Common attributes of gifted children's families are also worthy of mention, although these attributes do not necessarily cause giftedness. Parents of the gifted, for the most part, are highly responsive to their children's need to be intellectually challenged and absorbed. These parents tend to allow their progeny higher than normal amounts of independence, while providing them with strong support, relevant opportunities, and discipline. In short, they are child centered and have high expectations for themselves and their offspring. They are also likely to have moderate to high levels of education and socioeconomic status.

These characteristics illustrate the qualitative and quantitative differences between children who are gifted and those who are not. Many of these differences appear early in life and continue throughout adolescence.

Theories of Giftedness

Theories of giftedness are valuable because they guide both research and practice. However, they have an exceedingly difficult task, which is to describe, explain, and predict the various characteristics and forms of giftedness. With this mission in mind, current theories were developed in response to the evolving recognition within science and society that giftedness is more than what standardized intelligence tests measure. More specifically, these views propose that creativity, domain-specific strengths, and personal characteristics interact with high cognitive ability and motivation to produce giftedness.

Creativity plays a central role in most contemporary models of giftedness. However, these models differ in whether creativity is viewed as a necessary or an optional component. For example, Joseph Renzulli, director of the National Research Center on the Gifted and Talented at the University of Connecticut, developed his 'three-ring' conception of giftedness with creative, productive giftedness in mind. According to this theory, the three main interactive components (or rings) of giftedness are high levels of creativity, higher than average general or domain-specific abilities, and strong commitment to a specific area of interest. Other models propose that creativity is an option rather than a requirement. For example, the Munich model of giftedness (MMG) portrays creativity as one of many potential and independent competencies that predict later performance in language, the arts, and other domains. Personality characteristics and environmental factors play a role in determining which of a child's competencies actually develop and result in gifted performance.

As the above examples indicate, most current theories define giftedness as largely domain-specific. For example, some views propose that giftedness is neither more nor less than expertise in a particular domain. Exceptional performance is simply the result of extended training, deliberate practice, and commitment. Another example of domain specificity is Howard Gardner's theory of multiple intelligences, which proposes that individuals can be gifted in one or more of eight independent intelligences. These intelligences differ in their developmental courses and the areas of the brain they employ. Three of them – linguistic, logical–mathematical, and spatial – are related to abilities typically assessed by intelligence tests. The remaining five – bodily kinesthetic, musical, intrapersonal, interpersonal, and naturalistic – are not measured by intelligence tests but are valued in most cultures. In short, theories no longer view giftedness simply as a global trait or a general ability.

Not surprisingly, theories of giftedness reflect behaviors and potentials that a society values and hopes to foster. One recent societal concern involves a perceived decrease in social capital or civic actions. Therefore, some contemporary frameworks include characteristics that allow individuals to use their gifts to advance the greater good of others. More specifically, one's personal qualities, such as optimism, courage, passion for a particular topic, and wisdom, interact with his or her above average cognitive ability and creativity. This interaction increases the likelihood that the gifted individual will effectively address collective needs in one or more domains.

Finally, theories of giftedness need to explain how the construct originates. The expertise explanation mentioned earlier proposes that exceptional behavior stems primarily from

environmental factors, such as practice and training. According to this view, labeling some individuals as gifted is misleading because the term incorrectly implies genetic endowment. In contrast, most theories of giftedness propose that giftedness is dependent on both genetic make-up (nature) and appropriate opportunities in the environment (nurture). For example, Gardner claims that individuals become gifted in one or more intelligences through genetic inheritance, environmental opportunities, and socialization of cultural values.

Overall, theories of giftedness present a multidimensional conception that captures its variety and complexity. In addition, they explain how potential evolves into exceptional achievement. Many of the theories also provide practical guidance for how to identify and cultivate giftedness in ways that can benefit society.

Cultivating Giftedness

In order to reach their full potential, children need a stimulating and challenging educational environment. The characteristics of childhood giftedness described earlier imply that conventional methods of instruction are unlikely to promote the gifts of children who learn more independently, quickly, and differently than their age-related peers. Unfortunately, given the multidimensionality of giftedness, it is not entirely obvious how these children should be selected for educational programs that meet their needs. Identification of gifted students currently depends, in large part, on how a school district defines giftedness.

Some schools in the United States apply Terman's definition of exceptional general intelligence; therefore, they require children to have some combination of high scores on achievement or IQ tests (e.g., an IQ of 130 or above), strong teacher recommendations, and good grades. When creativity is included in a school's definition of giftedness, traditional psychometric measures of creativity are often administered, even though these measures do not predict significant creative productivity in adulthood. Similarly, aptitude tests are sometimes used to identify domain-specific giftedness. The Center for Talented Youth (CTY) at Johns Hopkins University conducts national and international talent searches, where math and verbal scores on the Scholastic Reasoning Test (SAT I) or the American College Test (ACT) are used to identify mathematically and verbally precocious seventh and eighth graders.

As views of giftedness become broader, less traditional forms of assessment are used more frequently. These methods of identification are derived from some of the theories of giftedness described earlier. For example, a number of schools select children according to Renzulli's three-ring conception of giftedness, while others use Gardner's theory of multiple intelligences. Nontraditional forms of selection include portfolios, auditions, behavioral checklists, performance-based assessment, and peer recommendations.

Once children are identified as gifted, a decision must be made about how best to educate them. The two most common options are enrichment and acceleration. With enrichment, gifted children remain at a grade level consistent with their chronological age and their curriculum is supplemented with advanced material and activities. Depending on a student's form of giftedness, more depth is provided either in all

academic disciplines or only in particular ones. Furthermore, this supplementation can occur within the regular classroom or as part of a 'pull-out' program where gifted children leave their regular classrooms at least 1 h per week to work with other gifted children on content specific projects and activities. School-based enrichment programs are usually not implemented until the third grade but they have been known to begin as early as the first grade. However, as noted earlier, schools are not the only source of enrichment. Parents typically provide their gifted children with responsive surroundings and stimulating opportunities.

In contrast, acceleration allows intellectually gifted children to enroll in advanced courses or enter grades that are consistent with their mental abilities. For example, the CTY and the Study of Mathematically Precocious Youth provide intensive summer programs that cover a 1-year curriculum in 3 weeks. These programs allow precocious youth to interact with each other, learn advanced material, and sometimes enroll in college early. Acceleration typically results in greater academic achievement than does nonacceleration; it has not been found to harm social competency skills. In general, current research indicates that acceleration is more effective than enrichment in promoting gifted development.

Adulthood Genius

Common Characteristics of Genius

As noted earlier, childhood giftedness does not guarantee, or even predict, adult genius. Although there is overlap between the two constructs in terms of intelligence, creativity, and intrinsic motivation, it is not surprising that most gifted children do not attain genius status in adulthood. Although individuals can have what is sometimes referred to as a genius-level IQ, true genius requires certain personal and environmental characteristics not needed for giftedness. Several of these distinguishing characteristics will be reviewed here.

Most importantly, geniuses must demonstrate creative greatness (or Big-C creativity) in order to transform a broadly valued domain or create a new one. Obviously, this high level of originality and usefulness is not required for childhood giftedness. Creative greatness is associated with reasonable risk taking or rebelliousness in order to change the status quo, the willingness to make considerable personal sacrifices for the sake of one's work, and above average intelligence. Interestingly, extremely high IQ scores (i.e., 180 or above) are not better predictors of Big-C creativity than are IQ scores of 130. The characteristics described below are related to creative greatness.

To become a genius, an individual must have sufficient drive and persistence to acquire domain-relevant knowledge, overcome obstacles, and persevere in the face of multiple impasses. As Leonardo da Vinci reportedly stated, "It had long since come to my attention that people of accomplishment rarely sat back and let things happen to them. They went out and happened to things." However, persistence is crucial because ~10 years of intense training in at least one discipline typically precedes a major breakthrough. Put simply, genius begins with expertise. For example, Picasso needed to master realism before moving beyond it. Furthermore, major insights

and innovations are more likely to occur when expertise is gained in more than one domain. Darwin assimilated knowledge from zoology, botany, anthropology, economics, and other disciplines. Persistence is also important because the right creative approaches are usually far from obvious, which means that many failed attempts occur before a successful breakthrough. Geniuses are extremely productive, with more failures and successes than the norm.

Closely related to persistence is the ability to maintain intense concentration while working on a major problem or project. Mihaly Csikszentmihalyi refers to this highly focused state of consciousness and undivided attention as flow. Individuals who experience flow often report losing track of time or forgetting to eat because they are wholly immersed in what they are doing. Flow happens most frequently when individuals are working in domains that match their abilities and passion. This state of effortless concentration increases the likelihood that material will be mastered and major insights will occur.

Finding significant problems often precedes noteworthy innovations. Whereas giftedness typically involves solving problems that other people have already identified, genius often entails discovering previously unknown ones. Put another way, forming relevant questions is at least as important as answering them. For example, Isaac Newton's curiosity about why an apple would fall perpendicularly to the ground resulted in his theory of universal gravitation. According to Csikszentmihalyi, finding significant problems and then solving them requires a relatively extended preparation or training period, immersion in a field that utilizes this training, the synthesis of information from different domains, and insight into a new configuration that helps solve the problem. This entire process usually takes longer than the one for solving already identified problems but the results are usually more revolutionary.

However, problem finding and significant discoveries are embedded within an important social context. Even though geniuses are frequently alone when they have their breakthroughs, the training, evaluation, and verification stages surrounding their insights depend on productive social interactions with colleagues. The link between collaboration and genius may seem counterintuitive because geniuses often spend a great deal of time working alone. However, they need to be extroverted at critical times. Working with others exposes them to unfamiliar concepts and viewpoints, thus making it more likely that they will eventually combine relevant information in unusual ways. During this collaborative process, colleagues contribute ideas and feedback. These ideas are then modified and creatively merged, resulting in a new context for problem solving. In addition, social interaction can foster group flow, which is comparable to an individual's intense periods of concentration described earlier. According to Keith Sawyer, group flow happens when dissimilar individuals work well together to accomplish a common goal. In general, collaborative improvisation improves each person's performance and increases the likelihood that problem finding insights will occur.

Perhaps the most intriguing characteristic associated with genius has to do with mental illness. Overall, geniuses show higher quantities and greater intensity of psychopathological symptoms than does the general population. Depression and bipolar disorder are the most common psychopathologies

found in geniuses; schizophrenia is relatively uncommon. However, these mental disorders are more likely to be found in geniuses working in some domains than in others. More specifically, affective disorders and alcoholism occur more frequently among geniuses who are creative writers and artists than those who are scientists. Furthermore, mental illness occurs more frequently in the family lineages of geniuses than it does in other families. In other words, geniuses both with and without psychopathologies are likely to have family members who do have them.

Similarly, studies of twentieth century artists and scientists have shown that geniuses were more likely than other individuals to have been raised in stress-filled family situations. Many had experienced death of a parent, poverty, abuse, or other childhood traumas. As with mental disorders, childhood trauma was more common for geniuses who were writers, musicians, artists, and actors than for those who became scientists or political leaders. One explanation is that childhood stress predisposes certain individuals to create as a form of therapy and the experience of suffering provides the subject for works of art, music, and literature. It has also been found that families of future geniuses often provide intellectual stimulation but little emotional support. One popular view is that this type of upbringing fosters rebelliousness and the willingness later in life to challenge conventional practices within one's domain of work.

The characteristics described here help explain why only a small minority of gifted children become adult geniuses. As Terman's participants illustrate, most gifted children accomplish the first step toward genius, which is to become adult experts in a well-established domain of interest. However, genius requires a crucial second step that involves transforming the practices and rules of one's domain. Each of these two steps utilizes a different form of thought. The first relies heavily on convergent thinking for mastering knowledge and techniques. The second predominately involves divergent thinking in order to overcome impasses and envision new groundbreaking approaches. In addition, genius is associated with certain personality traits that giftedness is not. For example, geniuses tend to be dissatisfied with the status quo, both introverted and extroverted depending on the stage of problem solving, extremely productive, and willing to take risks with their work and reputations.

Theories of Genius

Psychological theories of genius, compared with those of giftedness, are small in number, largely focused on creative greatness, and not aimed at providing guidance for practical applications. Instead, they concentrate primarily on the internal and external contexts in which genius occurs. Two widely cited examples will be described here.

Mihaly Csikszentmihalyi proposes a systems model that takes into account cognitive, social, and cultural factors related to significant discoveries or inventions. According to this view, creative greatness does not reside within the creator. Instead, it involves positive interactions between three systems: an individual, a domain, and a field. An individual's talents, motivation, knowledge, and interests must be a good match for the particular domain to which he or she contributes. The domain

plays the important cultural role of transmitting its rules, procedures, and practices to the individual. When a creator produces something innovative that potentially transforms the domain, knowledgeable judges (or gatekeepers) in the larger field evaluate the contribution and decide whether it should be accepted. If approved, the modification is incorporated into the domain and then transmitted from generation to generation. Put simply, creative greatness or genius has not occurred if relevant members of a society have not recognized, accepted, and dispersed it. Csikszentmihalyi's theory explains how individuals can become geniuses long after they have died. According to this intriguing view, it is not simply that their creative greatness went unrecognized during their lifetimes. Instead, genius literally did not occur until their contributions had an impact on society.

In contrast to the systems model, Dean Simonton takes an evolutionary approach to genius by elaborating on Darwinian theory. According to Simonton's view, genius-level creativity occurs through the process of blind variation and selective retention (BVSR). More specifically, creative individuals randomly generate variations on ideas in hopes of producing ones that are original and useful. Some of these blind variations involve combinations of separate ideas, while others are mutations of old ideas. After ideas are produced, they are subjected to cognitive and sociocultural selection, with the ones most likely to survive and reproduce being retained. Through this process of random generation and careful selection, geniuses are able to leave behind important work that will influence future generations. However, the degree of blindness (or randomness) in the variation of ideas tends to vary across domains of work. For example, the generation of ideas is often more blind in artistic domains, where remote associations and trial-and-error approaches are used, than it is in the natural sciences, where variations are typically based on logic, data, and algorithms. Domain-related differences in the blindness of ideas potentially explain the domain-related psychopathology and family characteristics described earlier. A higher than normal rate of mental illness and traumatic family backgrounds are not liabilities for geniuses working in artistic or literary domains where variations in ideas are fairly blind and unrestricted. Oddly enough, psychopathologies and childhood trauma can be assets. In contrast, low rates of mental illness and stable childhoods are conducive to the less blind, logical variations found in the natural sciences.

Simonton uses the BVSR theory and historiometric data to derive and test mathematical models that explain and predict various aspects of creative greatness. For example, one of his models predicts when creators in various domains will make their first, last, and best major contribution. Again, one's domain of genius makes a difference. For example, the length of time needed to learn a domain, generate ideas, and turn these ideas into significant products is typically shorter for poets than it is for geologists. Consequently, distinguished poets tend to do their best work at an earlier age than do scientists. For all domains, however, data indicate that productivity changes as a function of career age rather than chronological age. More specifically, output increases for approximately the first 20 years of one's career, reaches its peaks, and then declines. Although overall productivity is much higher for geniuses than for nongeniuses, this curvilinear course for output

is the same for both groups. Other mathematical models based on BSVR and historiometric data explain the characteristics, backgrounds, mental processes, and environmental circumstances of geniuses.

Cultivating Genius

Unlike giftedness, there are no official guidelines for identifying genius in individuals of above average intelligence or special programs devoted to its cultivation. However, geniuses are not randomly distributed across time and place, which implies that some historical periods and environments have been more favorable for creative greatness than others. More specifically, genius tends to form cultural configurations that are chronological. In other words, geniuses are clustered together for certain time periods within a culture, often followed by decades with relatively few geniuses. The political, economic, and social factors that appear to inhibit or foster these cultural configurations will briefly be described.

In general, a culture's politics influence the development and expression of genius. For example, aversive events that heighten emotional arousal tend to interfere with originality and creative greatness. This means that genius is less likely to be manifested during times of war, terrorism, or other conditions that threaten human survival. In contrast, cultures conducive to genius generally have the peaceful coexistence of heterogeneous ethnic groups and ideologies. Diverse perspectives and experiences increase the cross-fertilization of ideas and stimulate divergent thinking.

Economic growth also tends to foster genius. Some disciplines, such as architecture and science, require considerable monetary support. Yet even relatively inexpensive endeavors, such as literature and poetry, thrive in a rising economy. Prosperity typically precedes the social change and intellectual receptiveness required for genius to emerge. In contrast, economic depression and stagnation tend to result in rigidity and dogmatism, which are counterproductive for creative greatness.

In any given domain, the number of geniuses in the preceding generation positively influences how many are in the current one. These cultural configurations provide mentors, role models, and colleagues who transmit knowledge, guidance, and diverse perspectives. However, these configurations are meaningless to potential geniuses not given access to formal training, mentors, resources, and opportunities. Discrimination based on gender, ethnicity, socioeconomic status, or other factors limits the range of individuals who are able to become geniuses.

Furthermore, social systems need to value originality and change. As Csikszentmihalyi's systems theory indicates, genius manifests itself only when a field recognizes and legitimizes novel contributions. Journal editors, sources of funding, and other gatekeepers must be receptive to innovative change.

To summarize, certain environmental factors promote genius. Whereas cultivation of childhood giftedness typically occurs in families and schools, particular features of a domain, field, and surrounding culture foster adulthood genius. A society can cultivate genius by providing resources, diversity, and receptiveness to change.

Adulthood Eminence

Common Characteristics of Eminence

Eminence occurs when individuals become widely known for their sustained, outstanding achievements. This construct is frequently assessed through number of biographies, length of biographical entries in standard reference works, nominations or citations by experts, or other documented signs that someone has attained significant professional influence in a socially valued discipline. Although some researchers consider eminence to be synonymous with genius, the view taken here and elsewhere is that there are more eminent individuals in a society than there are geniuses. More specifically, eminence has degrees, with geniuses receiving greater and broader recognition than outstanding experts. For example, some of Terman's participants met the criteria for eminence based on expertise by being listed in *Who's Who in America* and other reputable sources, without reaching the elevated status of recognized genius. Consequently, the characteristics of eminence incorporate the ones of genius described earlier, which in turn build on those of expertise. These attributes include above average intelligence, deliberate practice, extended training, persistence, problem finding, and risk taking.

An additional characteristic of eminent individuals is that they typically start their productive careers much earlier than their peers. Beginning lifetime work at a relatively young chronological age is a reliable indicator of high overall productivity. In short, considerable output often leads to high impact on a domain, which results in eminence.

Achieving a strong sense of personal identity by early adulthood helps an individual start a career as early as possible. By their mid-twenties, for example, many of Terman's least successful participants had not explored their career options or formed a relatively firm vocational commitment. The most eminent participants had already achieved their occupational identities. Self-knowledge about one's strengths, weaknesses, interests, and values predicts later motivation, goal orientation, and vocational success.

Finally, eminence typically requires self-confidence and the ability to promote one's accomplishments. Some studies have identified the personality traits of eminent individuals as aggressive, competitive, independent, nonconforming, and domineering. In other words, one need not be agreeable or likeable to become eminent.

A Theory of Eminence

The two theories related to genius that were described earlier also apply to the type of eminence that is achieved through creative greatness. In addition, Robert Albert's developmental theory of eminence explains why some gifted children achieve distinction in adulthood, while many do not. Albert proposes a systems model where interactions between personal experiences, maturation, learning, and the people in a child's life result in particular developmental outcomes. The child's abilities, emergent sense of self, temperament, and other factors organize and shape these ongoing interactions. How well the various systems collaborate during sensitive developmental periods influences later eminence.

According to Albert's model, adolescence is the stage at which personal identity and the capacity for creative behavior develop simultaneously. For highly creative individuals, their identities and creative abilities merge together so that their career aspirations and innovative accomplishments define who they are. However, many gifted children are at risk of having their identities scripted for them by their families or other influential people. This foreclosure of identity means that during adolescence or early adulthood they are not in a position fully to explore and select options that best fit their strengths and interests. The end result is that they never reach their full potential or achieve eminence. However, some gifted children are given the opportunities and support to discover their strengths, weaknesses, passions, and real-life opportunities. This period of exploration allows them to make firm occupational, moral, and personal commitments. In turn, their achieved identities lead to the independence, intrinsic motivation, and self-assertiveness required for creative behavior and later eminence.

Cultivating Eminence

It is not clear that eminence needs to be cultivated. However, the programs that advance giftedness and the environmental factors that foster genius indirectly promote eminence. Mentors, resources, intellectual receptiveness, and opportunities to develop expertise and creative potential increase the chances that outstanding achievements will occur and be recognized.

Furthermore, helping, or at least permitting, gifted adolescents to achieve their personal identities makes it more likely that they will choose the best vocations for their talents. This also allows them to start their productive careers early, increasing the likelihood of eminence. In addition, acceleration can shorten time in school and improve the chances of increasing individuals' overall productivity in a career. In particular, young children who have a combination of schoolhouse and creative productive giftedness will be more likely to achieve eminence if they are given advanced overall instruction and ample opportunities to develop their expertise and creative talents.

Putting the Pieces Together

Current conceptions of giftedness and genius have moved beyond narrow, IQ-based definitions toward broader views. For example, many theories and practices now recognize that there are numerous ways to be gifted; high performance on intelligence tests is only one of these ways. Similarly, genius involves domain-transforming creativity in addition to above average intelligence. Despite their broader definitions, giftedness and genius are more different than alike. Although both

constructs involve superior abilities and intrinsic motivation, adulthood genius typically requires Big-C creativity, problem finding, high productivity, a desire to change the status quo, and recognition by members of one's field. In contrast, childhood giftedness usually entails precocity and proficiency in one or more domains. Although a small number of gifted children do become adult geniuses, the differences between these two constructs make it more likely that giftedness will result in expertise-related eminence rather than genius-related eminence. Both types of distinction reflect valuable contributions to a society.

Glossary

Aging in place The preference of growing numbers of older adults and new policy paradigm for long-term care. Involves provision of additional community-based services, assistive technology and home modification to maintain seniors in their homes rather than moving to age-segregated housing in 'active adult' communities, or accepting institution-based long-term care in the event of becoming frail or in need of assistance.

Biopsychosocial model The currently prevalent theoretical paradigm in gerontology that proposes a holistic, dialectic, or contextual understanding of the influence of biological, psychological, sociological, and history-graded variables in human development.

Convergence Trend in technology development whereby diverse technologies (e.g., telecommunication, computer/internet, sensors/controls, are integrated and coordinated. Convergence of the NBIC Fields (Nanotechnology, Biotechnology, Information technology, and the Cognitive sciences) holds significant long-term promise.

Ergonomics/human factors The scientific discipline concerned with understanding the interactions among humans and other elements of a system; the profession that applies theory, principles, data, and other methods to design in order to optimize human well-being and overall system performance.

Excess disability Behavioral, cognitive, or emotional inability or disability experienced by an individual that exceed those predicted by a disease process alone, and which are a direct result of contextual/environmental factors, such as flawed design, inappropriate expectations, etc.

Gerotechnology/gerontechnology A multidisciplinary field which considers the intersections of biopsychosocial aspects of aging with multiple forms of technology, primarily information/communication technology, assistive devices, home modification, and medical devices.

Information processing A useful conceptual model in psychology drawn from computer systems, which recognizes discrete steps involved when processing information from the environment. Some aspects of sensation, perception, cognition, attention, and other processing elements show predictable decline with age. Design of technologies must respond to these changes, and may be utilized to compensate for, slow, or reverse them.

Telehealth/telemedicine Use of computer/telecommunications technology to allow medical practitioners to provide health care information and services to patients at a distance, in their homes, etc. Also allows for telemetry and monitoring of patients' vital signs.

Ubiquitous computers/technology Comprehensive and often invisible and nonobtrusive integration of information technology into human environments, social systems, and labor (care provision, including self-care). For example, behavioral monitoring/tracking of automobile and pedestrian traffic in order to time traffic signals, or SmartHouse applications of monitors, sensors, or effectors in residential settings.

Universal design An approach to design of buildings and devices that encourages unimpeded usability for individuals with a wide variety of abilities and impairments. Similar to the concept of 'Barrier-Free Design.'

Introduction

Gerontology, the interdisciplinary study of older adulthood and aging, embraces a biopsychosocial model that encourages researchers, educators, providers, and policy-makers to consider jointly the complex, interconnected, and reciprocal influences involved in individual and population aging.

With advanced age, humans experience the natural process of 'senescence' – reduced viability and increased vulnerability – and are less able to respond effectively to a variety of environmental demands. Aging brings notable changes in biological, psychological, and social functioning. Predictable changes occur in bodily function (i.e., cardiovascular, nervous system, endocrine system, musculoskeletal system, etc.). Sensory, perceptual, and cognitive abilities also undergo inevitable changes (many, *but not all*, *negative*), which have significant behavioral ramifications for older adults. For example, an older adult with atrophied musculature, coupled with proprioceptive and balance difficulties may fall, or develop an exaggerated fear of

falling. Either may lead to reduced activity and mobility, further exacerbating the problem and leading to a precipitous deterioration in well-being and life-satisfaction. Many of these changes can be mitigated, reversed, or slowed with appropriate nutrition, exercise, and other interventions. Appropriate environmental design coupled with advanced technologies may also mitigate these declines and their ramifications.

Yet, scientific studies and anecdotal evidence demonstrate that many older adults maintain and enhance their various capabilities well into their very late years, most wish to continue to live full and meaningful lives, and many are becoming increasingly empowered to take necessary steps to make these goals a reality. This is particularly important because the life expectancy at age 65 is currently nearly 20 additional years. Steps are needed to assist older adults to maintain well-being mentally, physically, socially, and spiritually. Technologies can assist with this goal in a wide and expanding variety of ways.

Population aging is transforming global populations, primarily in Europe and North America. In the United States, for

example, those over 65 will comprise nearly 20% of the population by 2030 (they currently comprise 13%). Moreover, the aged population itself is aging, with significantly increased proportions and numbers over age 85. The number of centenarians in developed countries is expected to grow exponentially, doubling each decade in the near future. The United Nations estimated approximately 180 000 centenarians worldwide in 2000 and projects an 18-fold increase to 3.2 million by 2050.

We can expect both positive and negative consequences of population aging for societies and individuals; Dychtwald suggests it will transform many social institutions. Secular changes in employment, education, leisure, political, social, and spiritual engagements and other domains will occur, perhaps leaving older cohorts with obsolete knowledge and skills. Cohort membership is often a better predictor than age and this is certainly the case in the context of changing technologies.

The intersection of these 'megatrends' (population aging, technological innovations, and other secular trends) provides opportunities and perils for individuals and society. These intersections most interest those studying technology and aging. With increasingly deliberate actions, technologies are being applied to the needs and interests of older adults. Careful and deliberate use of technologies can enhance the likelihood of successful aging by providing fulfilling opportunities and mitigating many common age-related declines. Technologies may reduce costs and burdens associated with age-related maladies; however, careless and insensitive development, deployment, and use of technologies may do significant harm and increase costs.

Gerontechnology Defined

The study of technology and aging is referred to as gerontechnology (or gerontechnology). Jim Fozard (a longtime leader in psychology, human factors, and gerontology) suggests that "gerontechnology provides a systematic way to organize and understand research and education related to technology and aging." A major genesis of this study comes from within the field of human factors and ergonomics. Core concerns of this field include several *microlevel* interactions of individual persons (or their component systems – sensory, perceptual, cognitive, or motor) with specific technological interventions and interfaces that are part of the environment. For example, what screen resolutions and font sizes and types improve readability for the average older user? Which evolutions in graphic user interfaces create excess disability among users?

Gerontechnology also considers *many* macrolevel and social variables studied by various other disciplines. For example, a Spring 2010 special monograph issue of the *Sociology of Health and Illness* considered "how old people, healthcare professionals, and technology designers create, use, and modify science and technology to negotiate and define health and illness." Related questions might include what kinds of useful information can seniors find on the Internet and to what end.

By linking advances from the multidisciplinary study of gerontology with work in rehabilitation engineering, architectural design, human factors and ergonomics, and the

computer and telecommunications fields, there is currently a significant increase in the number and nature of successful interactions of aging humans with technology at the micro-, mesa-, and macrolevels. These interactions have begun to positively influence health, well-being, and life-satisfaction, and show promise to reduce costs associated with traditional delivery of long-term care.

Technologies are variously defined as 'tools' or 'artifacts,' which when properly designed and utilized, simplify daily living, enhance efficiencies, extend capacities, or lengthen life span. A culturally based sociohistorical understanding of technology considers how they are embedded in complex social and labor systems (e.g., in the provision of care, including self-care). Technologies are classified in several ways; for example, as high, medium, and low (e.g., embedded nanochips, broadband, POTS – plain old telephone service), or as hard versus soft (as in hardware or software). Technologies may have a positive impact on seniors, but negative impacts are as likely when technologies are poorly designed, if instruction/training is flawed, or if maintenance and adaptability are absent. What has emerged in recent years is a clear priority to promote positive outcomes. The current notion of 'aging-in-place' as an effective strategy of successful aging is well served by a growing array of technological innovations.

Selecting appropriate technologies of any kind involves important decisions regarding cost, usability, dependability, and consequences of product failure, safety, and adaptability to changing user needs. The common failure of technologies to produce improvements in the lives of elders is of great concern to gerontechnologists. In fact, numerous examples from distant and recent past show less than optimal attention to seniors' needs, wants, and capacities. In a 2000 Congressional Briefing on technology and aging sponsored by the American Psychological Society, Wendy Rogers reported that users of a commonly owned blood sugar testing kit made clinically significant errors more than 60% of the time.

At the microlevel, Rogers and associates (Czaja, Charness, Fisk, Mayhorn, and others) from the multicampus CREATE Centers (Center for Research and Education on Aging and Technology Enhancement) have conducted careful task analyses of many household technologies used by older adults and repeatedly found that failure of proper use results from either poor design, poor instructions, or a combination of both. Research at CREATE, Gerontech-The Israeli Center for Assistive Technology and Aging, SENTHA at the Technical University of Berlin, Age Place at MIT, and others, provides examples of best-practice for sustaining and accelerating groundbreaking applied research in technology and aging.

At the macrolevel, Lesnoff-Caravaglia and others have considered moral and ethical issues involved in the overuse of technology that may have negative consequences for individuals, societies, and planet Earth. Questions arise such as:

- How can we make the appropriate choice to forgo implantation of a cardiac pacemaker in an 85 years old and avoid the decade-long 'living nightmare' described in a recent *New York Times Magazine* article?
- When is the sacrifice of privacy worth the benefits of having one's house wired for remote behavioral monitoring systems? How can we insure that use of such technology does

not limit social contacts with family caregivers and providers?

- How is our overdependence on technology making it more difficult to adjust emotionally to 'normal' aging and to understand and accept the immutable fact of limited mortality?

The Time for Gerontechnology Has Arrived

The concept of gerontechnology has been discussed for about 30 years. Twenty-five years ago, the US GAO's now defunct Office of Technology Assessment published *Technology and Aging in America*, which delimited the issues quite effectively. In the ensuing quarter century, there has been slow but measurable progress. So, why now, is there a dramatic acceleration of interest and innovation in technology and aging? Why are products reaching the market as researchers, practitioners, designers, and marketers display previously unseen purposefulness in linking human aging to technological innovation? The most obvious answer is market forces related to the aging of the baby-boomers in first world countries. Seventy million strong in the United States alone, they have commanded our attention throughout their lives. Several other factors contribute to this reality:

- Research on aging has matured from early descriptive studies that were oversimplistic and pessimistic to prescriptive interventions and translational studies.
- The 'successful aging' paradigm has shifted attention from a focus on age-deficits to one of empowerment, enrichment, activity, and life satisfaction. Applied research has indicated that many capacities are amenable to intervention aimed at restoring function or slowing decline. Translational research has brought findings from lab to home and communities and provided new tools and applications for safety, well-being, and life satisfaction. Translational research has been stimulated by the US National Institute on Aging (NIA) through funding of 13 Edward R. Roybal Centers for Translational Research in the Behavioral and Social Sciences of Aging.
- The 'perfect storm' of population aging coupled with declining availability of caregivers has created a sense of urgency with respect to long-term care.
- Aging and technological advance are no longer viewed as independent, unrelated, or incompatible. There is a new optimism, previously unseen, that technology can be useful for a broad variety of older adults.
- Efforts to close the 'digital divide' such as AARP's 'Older, Wiser, Wired,' 'SeniorNet' and others have brought older adults into the twenty-first century and they now use the internet at rates comparable to other age groups.
- A belief in the power of interdisciplinary approaches has gained favor in academe, making gerontology and gerontechnology more valued and productive. Improved collaboration has emerged among basic researchers, product development, and marketing enterprises.
- University gerontechnology courses are becoming more common; recently Lorenzen-Huber and associates at Indiana University reported on an innovative course bringing

together faculty and students from multiple disciplines in a course entitled Health, Technology and Aging, which combined entrepreneurship, gerontechnology, and informatics. At CalState-Fullerton Echo Chang teaches a new interdisciplinary course to promote design and use of assistive technology by elders.

- Entrepreneurs, venture capitalists, and large corporations are joining the endeavor. While this began in the late 1990s, the 'com bust' of 1999 had slowed the progress. For example, in August 2010, GE Healthcare and Intel Corp. announced a joint venture to combine, enhance, and market their respective home health and independent living applications (Intel Health Guide, Intel Reader, and GE's QuietCare[®] products).

The Technology and Aging Imperative

Technology has been widely touted as a quick fix for the anticipated escalating costs associated with aging boomers. Effectively and efficiently deployed technologies may cut cost and reduce the burden of care. Recent examples of this enthusiasm include the December 2005 US White House Conference on Aging and the Obama Administration's support for enhanced use of electronic medical records. Similar efforts are underway in Europe, Asia, Australia, and elsewhere to optimize the use of information and assistive technologies to provide care for older adults. Indeed, technology is the centerpiece of many 'key systems change' initiatives for 'aging in place' currently promoted by the US Administration on Aging. Recently, the US Department of Health and Human Services funded the National Opinion Research Center at the University of Chicago, and the American Association of Homes and Services for the Aging (specifically its Center for Aging Services Technology (CAST) and Institute for the Future of Aging Services) to encourage technology development and adaptation.

Theoretical Contexts for Technology and Aging

The current proliferation of new technologies for older adults partly results from careful study in the lab and user-centered design. Unfortunately, this is not always true. Appropriate theoretical underpinnings can insure that gerontechnological innovations are more positive than negative, more useful than harmful. These theories provide a conceptual framework and significant heuristic value to guide careful research and perhaps encourage additional innovative uses of technologies for and by older adults.

All of the following are relevant and useful, some will be briefly describe here:

- Sociology's Modernization and Aging Theory (Cowgill & Holmes)
- Psychology's Field Theory (Lewin), and its extension to aging in Lawton and Nahimow's Ecological or Press-Competence Theory
- The Information Processing Paradigm's contributions to the understanding of sensory, perceptual, and cognitive processing

- Positive Psychology (Seligman, Csikszentmihalyi, and others) and Mindfulness & Conscious Aging (Ram Dass)
- Successful Aging (Rowe & Kahn, and others)

Modernization and Aging: Is Technology Good or Bad for Older Adults?

Modernization and aging theory, developed by Cowgill and Holmes in 1972, proposed that technological innovation during the industrial age caused older adults in western nations to experience dramatic losses in social status and income. Presumed mechanisms included increased competition for scarce jobs coupled with excess profits leading to mandatory retirement and social security, and consequential reduced income and marginalized status. Moreover, limited opportunities for retraining/retooling coupled with rapid technological innovations left mature adults with obsolete skills and an inability to compete in a changing work environment. Thus, the theory proposed that complex interactive mechanisms operating on major social institutions stripped elders of status and control, left them behind in deteriorating neighborhoods, with less material resources, obsolete skills and knowledge, and the anomie of a forced retirement from a meaningful job and into an undefined role of 'retired.'

Here we must ask, 'Why would we expect anything different now?' The answer is probably rooted in the acceptance of the 'successful aging' paradigm and concerns over the perils of population aging brought on by the aging baby-boom. Technological development during the industrial age was not intended to do harm to older adults. Today, they are increasingly intended to provide assistance and improve quality of life. A purposefulness to use technologies to improve the lives of elders is gaining momentum, and is readily apparent in research labs, Wall Street, and Madison Avenue. By understanding the harmful mechanisms during the industrial age, we can perhaps avoid such mistakes now and in the future.

Heidrun Mollenkopf of the German Centre for Research on Aging at the University of Heidelberg has been a leading scholar in this area. Doug McConatha's 'Theory of E-quality,' which systematically discusses the Internet's modern variants of the industrial age's institutions, shows how technologies can be used to assist the aged and transform the same institutions which previously had harmed elders. For example, accessible distributed education delivered via the internet is helping to make our educational system less child/youth-centered and to encourage lifelong learning.

Successful Aging Theories

Neither the psychological sciences, gerontology nor the other scholarly disciplines were unaffected by the pessimistic view of aging exacerbated by industrialization. Research as recently as the 1980s focused primarily on cataloguing age-related decline. Thankfully, and with important ramifications for gerontechnology, these disciplines have recently developed a more balanced view, and shifted focus to promoting healthy, successful aging.

Now a growing body of research and theory on aging from multiple perspectives (biological, psychological, and social) provides a more balanced view of aging. For example, research

in geropsychology discusses hold versus no-hold capacities in cognitive functioning (see below). Sociological theory is more optimistic (e.g., activity and reinvestment theories have replaced disengagement), and recent biological research on exercise, nutrition, and telomeres, for example, holds promise for slowing or reversing the aging process and compressing morbidity.

Successful aging is defined differently across the disciplines. Rowe and Kahn emphasized health, strength, and vitality. Successful aging depends on a wide variety of biopsychosocial processes, capacities, and opportunities. Rowe has noted that optimism is perhaps the most important variable. Fisher and Specht note the importance of social interactions and maintaining a sense of purpose, autonomy, and well-being. Paul and Margret Baltes described the need for selection, optimization, and compensation (SOC) as individuals adjust to aging and disease. Their notions are the foundation for Wong's approach (2000), which involves balanced adjustment to the natural decline of aging. SOC provides a very useful roadmap for applying technology to aging.

Field Theory and Ecological Theory

In the 1930s, Lewin proposed that understanding behavior means we must consider the characteristics of the person and their environment; behavior results from the interaction of the two ($B = f(P, E)$). In the 1950s, Reigel and others noted how complex, interdependent, and dialectic are the influences on human behavior and the formula was expanded to ($B = f(P, E, P \times E)$). This expanded model has significant heuristic value for gerontechnology. For example, technology can be added to the model as an intervening variable, viewed as part of the environment, or used to predict technology's impact.

Lawton and Nahimow's Ecological Theory of Aging extends field theory to gerontology and fills in several important details. By considering basic human *Competence* along a continuum, intersecting with basic environmental demands (known as *Press*) also on a continuum, the model helps to predict the outcomes of $P \times E$ transactions. Working on the microlevel, it brings us closer to understanding the core of gerontechnology: How can/should we design and provide technologies to enhance the lives of older adults?

Undesirable outcomes (*negative affect and maladaptive behavior*) occur whenever competence and press are significantly mismatched, when either greatly exceeds the other. Positive and desirable outcomes are obtained when press and competence are equivalent. Specifically, *maximum comfort* is likely when competence is marginally greater than environmental press; *maximum performance potential* is achieved when Press is marginally above Competence. Setting demands slightly above an individual's capabilities often yields improved competence or performance.

This Ecological Model did not explicitly consider the role of technology in aging; nevertheless, it has numerous implications. New or adapted technologies can stimulate and enrich older adults' lives and encourage them to stay active and involved. Innovations can also compensate for various age or illness-related incapacities. With declines, demands from the environment must be reduced to avoid precipitating negative affect or maladaptive behavior. However, we should also not

use technologies excessively and reduce stress too much, or negative outcomes such as laziness and 'excess disabilities' beyond that caused by aging or illness may result. In sum, the model encourages careful addition of AT-EI (assistive technology and environmental interventions) to seniors' lives to optimize the likelihood of positive outcomes.

Adding secular change to the ecological model

Fozard adds an important technology-related dimension to Lawton's model by discussing secular change, noting that cohorts experience technology somewhat differently, based primarily upon their age when each technology was introduced. Cohort rather than age may be a better predictor of affinity toward and comfort with specific technologies. Consequently, technology innovators must consider alterations to appropriate design, based upon the aging of successive cohorts.

The Human Information Processing Model and a Brief Review of Age-Related Changes

The Information Processing Model of cognitive processing developed during the 1960s through the 1980s led to significantly improved understanding of how humans acquire, interpret, and respond to environmental stimuli. Using this model, researchers conducted systematic task analysis of the sequential processes of sensation, perception, and cognition, and related areas of attention and depth of processing. Coupling parallel work in human factors engineering and ergonomics better allows innovators to match a variety of new technologies to the needs of elders. Knowledge of which human capacities decline, which hold up, and which are amenable to restoration or rehabilitation, helps gerontechnologists to assist with the selection, optimization, and compensation that Paul and Margaret Baltes proposed.

Age changes in information processing are predictable and often unavoidable. While there are some improvements (i.e., semantic memory), most changes involve eventual decline. Depending on the specific process and deficit, technological and/or environmental intervention can help slow, reverse, mitigate, or compensate. Some more common or problematic changes in sensory, perceptual, and cognitive function and their implication for the design of various technologies are briefly outlined below.

Sensation and Perception

Vision

Several changes in visual sensation and perception occur with normal aging (e.g., presbyopia & reduced UFOV (useful field of view)) and/or various age-related disease processes (e.g., cataracts, macular degeneration, diabetic retinopathy, and glaucoma). For example:

- *UFOV declines:* There are age-related decrements in information processing speed and efficiency. While normal peripheral vision spans up to 180° for simple stimulus detection, the ability to discriminate accurately among stimuli occurs in a much narrower field, referred to as the UFOV. UFOV decreases dramatically with age and this is exacerbated by situations requiring speeded performance

and divided attention. Age-related reductions in UFOV are believed to be responsible for a significant percentage of at-fault accidents involving older drivers. Recent evidence indicates that that UFOV may be restored and widened through training. Collision avoidance features and other technologies in new automobiles can also reduce accidents by compensating for age-related decrements.

- *Yellowing and hardening of crystalline lens:* Yellowing makes color discrimination less accurate particularly for short wavelength colors (e.g., violet, blue, and green). Hardening leaves the lens progressively less able to accommodate or change shape so to focus in a continuous range from proximal to distal objects (a condition called presbyopia). Web sites, computer programs, signage, and other visual displays should avoid requiring discrimination among these colors, provide high contrast between figure and ground, and allow user adjustment of fonts and text sizes. Careful prescribing of eyeglasses, contact lenses, or lens implants (in the case of cataract surgery) should consider the interaction of age, lens, distance to and resolution of computer, PDA, or in-vehicle informatics displays.
- *Susceptibility to glare and visual blur increase with age:* These changes have several implications for design of visual displays, signage, etc. Displays with dark background and light text are sometimes preferable.
- *Light and dark adaptation take significantly longer, are less complete with age:* The same scene appears darker to an older person compared to someone younger. Brighter ambient lighting, passage markings, and task lighting in homes, theatres, and restaurants should be provided. Screens on electronic devices such as cell phones that are carried into environments with dynamic changing ambient lighting should automatically adjust screen brightness to compensate for such changes but also allow user adjustments.

Leading advocates for the application of the above knowledge to technologies and environments for the aged include Steun and others at Lighthouse International, research sponsored by the SPRY Foundation, and conducted by Ball, Kline, Scheiber, Scialfa, Rebok, and others.

Computer hardware (screen size, resolution, brightness, contrast) and software allow users to tailor the screen display to their specific needs and preferences. Successive generations of MS Windows, MS Office, and other products, as well as the programs of several other vendors, have provided accessibility features and improved user options. MS Windows, for example, provides a variety of accessibility options and setup wizards for modifying screen characteristics, and input device function (keyboard, mouse, etc.), to meet individual needs. MS Office products include a lengthy tutorial on accessibility features.

Unfortunately, work in this area is incomplete and users sometimes encounter unanticipated barriers when various programs and program settings are incompatible. Legislation in the United States and elsewhere, such as the Twenty-first Century Communications and Video Accessibility Act of 2010 (S. 3304) passed by the US Senate on 5 August 2010 is being used to set appropriate standards for telecommunications and computer devices and signals/web sites to allow easier access to individuals with sensory/perceptual disabilities.

Changes in audition

Changes in auditory function can profoundly affect older adults' interaction with their environments and technological devices. Presbycusis, age-related diminished ability to discriminate among high-frequency sounds (e.g., consonants in the spoken language), is the most common age-related hearing loss, and it makes it difficult for seniors to comprehend speech, particularly when low sound intensities are coupled with noisy environments. Technologies that utilize auditory signals, or that transmit spoken information must be cognizant of this fact and be designed accordingly.

The signal quality provided by cell phones – dependent on transmitted signal quality, bandwidth, speaker, and microphone design – is often problematic for older users, particularly in noisy environments. Additionally, many cell phones are not compatible with hearing aids. The US Federal Communication Commission mandated that at least one-half of each manufacturer's digital wireless phones be hearing aid compatible (HAC) by February 2008.

Changes in other senses

Age-related changes in gustatory, olfactory, somesthetic (comprised of sensitivity to touch, pressure, cold, heat, and pain), vestibular, and kinesthetic senses have all been noted in the literature. As with vision and audition, 'normal' change can be accelerated by, or secondary to, various disease processes. In fact, health status and other variables often exert a greater impact than age alone. Some issues related to technology and environmental designs include:

- Weakened musculature and compromised vestibular and kinesthetic sensitivity (often coupled with the visual system problems noted above) dramatically increases the likelihood of falls among the very old and/or disabled. Issues with balance, posture, and gait are also involved. Successful environmental design helps to compensate – for example by providing adequate lighting, minimizing stairs, uneven surfaces, or deep pile/padded carpets, and providing handrails and clear visual cues for grade changes and edges. Various technologies have been utilized recently in the assessment and prevention of falls. PERS (personal emergency response systems) such as Lifeline Systems®, have been developed over the last 20 years to call for assistance when falls occur.
- Age-related decrements in sensitivity to heat and cold make the aged more susceptible to hypothermia and hyperthermia (heat stroke). Implications for design are clear with respect to appropriate signaling and thermostatic control devices.

Cognition

Cognition includes processes such as learning, memory, intelligence, attention, creativity, and wisdom. (These topics are covered in detail in several other articles in this Encyclopedia.) Age-related cognitive decline is not universal; for example, while crystallized intelligence is maintained into old age (absent disease processes), fluid abilities show general declines. Longitudinal research demonstrates that age-related declines occur later and are less severe than had been found in cross-sectional studies; many skills hold up quite well in the absence of chronic illness. Significant inter- and intra-individual

differences mean that the design of environments and technological interventions aimed at improving status or function of elders should accommodate variability and change.

Mayhorn and colleagues provide an excellent review of cognitive functions with implications for technological innovations (in Burdick and Kwon, 2004). They note that the promise of innovative technology will be unmet unless designers and manufacturers apply user-centered approaches, focusing on needs, capabilities, and limitations of the potential older users. Some important findings and issues include:

- Working memory and some spatial abilities decline with age and are exacerbated as task complexity increases and divided attention is required. For example, long or complex telephone menu systems put older adults at a disadvantage. Declines in spatial abilities including the ability to mentally manipulate objects may reduce older adults' ability to efficiently navigate complex web sites or utilize informatics and GPS displays in automobiles.
- The long-term memory storage of factual information and vocabulary (semantic memory), storage of familiar images (iconic memory), and storage of well-rehearsed procedural memory are maintained in healthy elders. Mayhorn and others note that gerontechnologies should capitalize on these common strengths.
- Other cognitive processes either hold or decline with advanced age, depending on specific task demands. Remembering to do something at a specific time tends to decline, but remembering specific events does not. Performance of time-based tasks can be improved by connecting to an event (or environmental cue).

Gerontechnology: Survey of Active Domains

This section provides diverse examples of currently active domains where technology and aging intersect with increasingly positive outcomes for older adults, their families, providers, and society. The section is organized using a helpful taxonomy developed by van Bronswijk, Bouma, and Fozard in 2002. They note that technologies have five general domains of influence: (1) health & self-esteem, (2) housing & daily living, (3) mobility & transport, (4) communication & governance, and (5) work & leisure. Further, they suggest the following types of impact: (a) prevention or delay of decline, (b) compensation for age-related loss of function, (c) care support and organization, and (d) enhancement and satisfaction with respect to quality of life. These impacts are indicated in parentheses after examples.

1. Health and Self-Esteem

- Improving Quality of Health Care Delivery
 - Health Information Technology (HIT), Telemedicine, Telehomecare, and Telecaregiving are all rather new terms, demonstrating how technology is transforming medical care away from hospitals and into communities. Because older adults have more chronic conditions, their management in home settings with the help of technology is a promising and flourishing new paradigm.
 - Telemedicine practice is expanding rapidly, allowing providers to monitor patients in their homes on a

wide variety of parameters, including body temperature, heart rate and blood pressure, blood oxygen levels, etc. PDAs, Smart-Phones, and other handheld devices are being repurposed as medication reminders and health/wellness coaches.

- Intel Health Guide is a touch-screen home monitoring device that links patients to caregivers. Patients regularly measure such vital signs as blood pressure, pulse, and weight, and respond to questions specific to their condition. Videoconferencing allows clinicians to further assess patients for signs and symptoms of illness.
- Recently, an informatics for consumer health (ICH) online portal and companion LinkedIn Group was developed by the US National Cancer Institute in a combined effort of seven federal agency partners (AHRQ, CDC, NIST, NLM, NSF, ONC, & NCI) to foster collaborations in behavioral research leading to evidence-based products that support increased health behavior among consumers.
- Well-Informed Consumers
 - *Health information* is increasingly available on the internet, helping older adults and caregivers (formal and informal) to become informed consumers, to communicate with providers, and to practice wellness and health promotion activities. The SPRY (Setting Priorities for Retirement Years) Foundation has sponsored research, conferences, and training on improving web design. They also promote health literacy projects so that consumers can assess the quality of online information. MedlinePlus, an online resource from the US National Institutes of Health provides information targeted at both professionals and the lay public on several health topics and conditions. Older adults are frequent users of this resource. Another US government web site, NIHSeniorHealth.gov is designed specifically for older adults. (Prevention or delay of decline; compensation for age-related loss of function, care support & organization, and enhancement/satisfaction & quality of life.)
 - Several other government web sites have become the gold standard for accessibility, comprehensiveness, and usefulness, with information for older adults and their caregivers. Examples include the US Administration on Aging's Eldercare Locator, First Gov for Seniors, information promoting healthy lifestyles, etc. (Prevention or delay of decline; Compensation, Care support & organization, and Enhancement/satisfaction & quality of life.)
- Encouraging Healthy Lifestyles
 - Cognitive abilities are exercised, stimulated, and perhaps improved by technology-driven enriched environments. In Japan, elders purchased over 3 million Nintendo Brain Training for Adults® games in its first year of sales. In the United States, the Practical Memory Institute's Memory Works® is designed to have a similar impact. Posit Science has created brain-training software resulting from translational research conducted at the leading research centers on neurosciences on aging. Recently McLaughlin and Allaire at

North Carolina State University and others received \$1.2 million from the US National Science Foundation to study whether playing video games may slow age-related cognitive decline. The Robert Wood Johnson Foundation in 2010 also pledged \$8.5 million to study the impact of video games on driving skills, Alzheimer's, and other age-related issues. Definitive evidence-based practice in these interventions is emerging, but additional research is needed. (Prevention, delay, or restoration; enhancement/satisfaction & quality of life.)

- Nintendo's Wii Sport has become a surprise hit with older adults in the United States and elsewhere. Several long-term care facilities and municipal senior centers have purchased Wii, including all of the Erikson Retirement Communities. The National Senior League organizes national Wii Golf and Wii Bowling Tournaments, recently featured on various media outlets. While not providing the same benefits as actually bowling and golfing, they promote social engagement, stretching, and hand-eye coordination. Scientific studies on effectiveness are preliminary; a recent study published in the *British Journal of Medicine* indicates that participation reduces subsyndromal depression.
 - *Enhancing self-esteem and promoting social engagement.* Examples above provide older adults with opportunities for greater self-esteem, self-efficacy, and choice in how and where they receive care. Technology also can enhance self-esteem in a variety of other ways. For example:
 - The Elder Wisdom Circle involves older volunteers from around the United States, including some nursing home residents, providing internet-based advice, often to younger people.
 - Older adults in Pittsburgh suburbs have assisted inner-city children with writing and math via computer networking applications.
 - Older adults are catching up with the young in the use of social networking sites such as the Facebook. Technologies such as Skype help them stay in touch with children and grandchildren when visits are not possible in-person. (Enhancement/satisfaction & quality of life.)
2. Housing and Daily Living
- Aging in Place is a growing paradigm, which coupled with new approaches to community/home-based health care is transforming house, home, and health care. Related concepts include Universal Design, Senior Friendly Design, and Smart House. Centers leading this work include the Center for Universal Design at North Carolina State University, SENTHA at the Technical University of Berlin, the CREATE Centers, SmartHome at Indiana University, Technology Centre at British Columbia Institute of Technology among others. The MetLife Mature Market Institute recently published an excellent report on aging in place. (Compensation, care support, & organization; enhancement/satisfaction & quality of life.)
 - Technologies designed to help individuals age in place include Personal Emergency Response Systems (such as Lifeline®), and automated behavioral monitoring

(ABM) systems such as GE's Quiet Care[®]. Quiet Care[®] utilizes infrared and mechanical motion sensors placed throughout an older adult's residence. (These are also known as lifestyle monitoring or remote personal monitoring systems.) By tracking behaviors, sending data to a base station, and analyzing activities and trends, the system alerts caregivers to potential problems. For example, deviation of normal meal preparation or sleep patterns may alert caregivers to check in and take appropriate action. (Compensation, care support, & organization; enhancement/satisfaction & quality of life.)

- Anti-wandering devices help keep dementia patients safe without restraining them or locking down an entire facility. GPS positioning devices can help locate others should they wander or get lost. (Compensation for age-related loss of function, care support and organization, and enhancement/satisfaction & quality of life.)
 - Assistive technology and environmental interventions (AT-EI) include a range of products, services, devices, home modifications, and so on, which for many years have been a mainstay of the fields of rehabilitation and occupational therapy. As these fields turn greater attention to the needs of frail older adults, there are additional positive outcomes. (Compensation, care support & organization, and enhancement/satisfaction & quality of life.)
3. Mobility and Transport
- At the University of South Dakota, Schieber and associates have noted that older drivers need significantly more time to reestablish situational awareness of road conditions after distractions by even short text messages provided by their vehicle. 'Texting' with hand-held devices is perhaps more perilous, yet according to recent reports, 80% of adults are 'texted' while driving. Cars of the future will need to better adapt to changing capacities of older drivers; in particular by drawing and focusing attention to (rather than away) from key road situations and conditions.
 - At the University of Calgary, Scialfa and associates are working on understanding the characteristics of on-board informatics systems (to assist with way finding, etc.) which are safest and most useful for older drivers (Compensation).
 - General Motors is developing an 'Augmented Reality Windshield,' the next generation of heads-up displays currently appearing in high-end automobiles. The expected availability date is around 2018 and the display will help to outline the road, alert drivers to objects in the road, and otherwise draw attention to important features of the road environment (MIT Technology Review, March 17, 2010) (Compensation.)
 - At Johns Hopkins University, Rebok and associates are combining simulator technology adapted from NASA and pilot training with neuroimaging technology (fMRIs) in order to develop a better understanding of age-related driver behavior. This work may result in effective means of deciding which older persons should cease driving and to train effective driver skills (Prevention, Compensation).
 - MIT's Age Lab, in collaboration with UMass-Boston, and the University of New England's Transportation Center are investigating claims by a wide variety of new 'Brain Fitness' software programs to reduce accident risk by older drivers; for example, through improved functional field of view. To date, most lab-based indications of success have not been replicated in real-world settings.
 - PositScience has made several evidence-based cognitive training products available, including one on improving driving skills (Compensation).
 - The US Department of Transportation has funded diverse research designed to adapt transportation to the needs of a maturing society, including how to make mass transit more user friendly. At the University of Akron, Ronnie and Harvey Sterns have studied ways to improve usability for bus and train timetables. (Compensation, enhancement/satisfaction, & quality of life.)
4. Communication and Governance
- Research leading to senior-friendly cell phones and other communication devices is being conducted in partnership with industry by Bill Mann and colleagues at the University of Florida Rehabilitation Engineering Research Center on technology for successful aging. New easier to use cell-phones that are also hearing aid compatible are available (e.g., Jitterbug[®] and others). (Compensation, enhancement/satisfaction, & quality of life.)
 - Modern hearing aids are significantly better than those of the previous generations. Instructions and training help users to adjust and reduces rejection rate. (Compensation, enhancement/satisfaction, & quality of life.)
 - Social networking sites such as Caregivers on Call and caregiver stress provide specific avenues of communication to support caregivers of the frail elderly, who are often spouses, offspring, or siblings. (Care support and organization.)
 - Connected Living[®], launched in 2009 provides easy interfaces and training to help connect older adults with each other and with their families. (Care support and organization.)
5. Work and Leisure
- Workplace accommodations and telecommuting: Progressive employers that recognize the value of older workers develop employment practices, retraining opportunities, and flexible benefits packages that meet the needs of this population. The Institute for Community Involvement at the National Center on Workforce and Disability at UMass-Boston has studied specific needs of older workers.
 - At the University of Miami CREATE center, Sara Czaja and associates are conducting comprehensive studies on telework and telecommuting. Utilizing the knowledge base regarding information processing, perceptions, and attitudes toward telecommuting, etc., the research is identifying barriers and producing training programs for telecommuting. (Enhancement/satisfaction & quality of life, prevention, or delay of decline; compensation.)
 - There is a wide and growing variety of local and national Online Learning Communities for older adults throughout the world (e.g., SeniorNet). (Enhancement/satisfaction & quality of life.)

- The AARP produces a monthly e-mailed Computers and Technology Newsletter. AARP also has an online web site for seniors on Social-Media. (Enhancement/satisfaction & quality of life.)
- Older adults seeking online intellectual stimulation can connect to Technology, Education, Design (TED) and listen to hundreds of lectures and performances on TedTalks.

Age related disabilities often reduce older adults' ability to participate actively in the labor force and in the myriad of leisure activities available in their earlier years. Technologies help older adults to stay engaged in a variety of ways.

Organizational Catalysts for Gerontechnology

Previous sections have demonstrated that gerontechnology research, design, and implementation are occurring at an accelerating pace and growing number of venues. This section briefly lists national and international professional organizations that have stimulated development in this field.

The Human Factors and Ergonomics Society has been a key player in the early development of gerontechnology. After initial emphasis on military applications, HFES gradually developed various technical interest groups (TIGs) in the 1970s and 1980s. The interest group on aging is currently quite active.

The Gerontological Society of America's Formal Interest Group on Technology and Aging was founded by Gari Lesnoff-Caravaglia in 1987. Today the group has over 100 active members, sponsors a listserv and several sessions at GSA's annual scientific meetings. GSA's Formal Interest Group on Physical Environments and Aging (PEA) and on assisted living often discuss technological issues.

The International Society for Gerontechnology, founded in 1997, publishes the scholarly journal *Gerontechnology* and has held several international conferences on gerontechnology.

The American Society on Aging's Network on Environments, Services, and Technology publishes a quarterly newsletter and has a growing presence in the field. Aging Today, the monthly newsletter of ASA regularly has gerontechnology articles. ASA's scholarly journal *Generations* has focused on gerontechnology several times in the last decade.

Division 20 (Adult Development and Aging) of the American Psychological Association has demonstrated significant interest in technology issues. (Three prominent gerontechnologists – Neil Charness, Jim Fozard, & Harvey Stearns have all served as presidents of the division.)

The Association for Gerontology in Higher Education (AGHE) has in recent years published a Brief Bibliography on Technology and Aging, a cover story in the AGHExchange on the importance of teaching gerontechnology in diverse courses on aging, and the results of a survey of gerontological educators on their coverage of gerontechnology issues across the curriculum.

The Center for Aging Services Technology (CAST), founded in 2003, has become a leading player in the effort to develop and deploy innovative technologies for older adults, particularly in long-term care. It now has over 400 members representing technology companies, government, universities, and service organizations.

Finally, large corporations such as 3-Com, Cisco Systems, Compaq, Honeywell, Intel, Microsoft, and Sony have become involved. Microsoft's Aging and Accessible Technology web site provides an excellent summary of the many ways that computers, assistive devices, and environmental modifications are improving the lives of older adults, enhancing the provision of services and health care, and reducing costs associated with population aging.

Summary

After years of preparation, speculation, theory building and basic research, gerontechnology has rapidly moved into a translational research and application phase, as university-based interdisciplinary research labs, large corporations and small start-up companies have developed and marketed technologies designed to enrich the lives of older adults. These efforts have been promoted through the efforts of a variety of professional organizations and societies. Gerontechnology is improving health and self-esteem, housing and daily living, mobility and transport, communication and governance, and work and leisure opportunities for older adults. Much research is still needed to test the effectiveness of various innovations and to develop a clear indication of the best evidence-based practices. Many developments are still needed to optimize gerontechnology's potential benefits.

For example, the promise of Health Information Technology will only be realized with an enormous expenditure of funds, adaptation of standardized systems, and training of primary care physicians and their staffs, and when questions of confidentiality of patient records are adequately addressed. Second, the wide and growing array of assistive technology and environmental interventions can be overwhelming and expensive to consumers. Efforts to integrate stand-alone AT-EI systems, robotics, telemedicine, and telehomecare are needed to simplify the systems and enhance their usability. Franchimon & Brink, and others have suggested the combination of these systems as add-on modules controlled by a single ICT (Information and Computer Technology) smart-network. Developments such as this and others will dramatically transform gerontechnology over the next half-century.

Gestalt Psychology and the Development of Perceptual Organization

P C Quinn, University of Delaware, Newark, DE, USA

R S Bhatt, University of Kentucky, Lexington, KY, USA

© 2012 Elsevier Inc. All rights reserved.

Glossary

Common region principle Elements are grouped if they are located in the same enclosed region.

Connectedness principle Elements are grouped if they are physically connected.

Gestalt principles of perceptual organization Principles by which small elements come to be grouped into larger perceptual units or wholes.

Good continuation principle Aligned elements are grouped to form perceptual units.

Novelty preference Established preference that infants display for novel over familiar stimulation, with some exceptions (e.g., preference for mother over stranger in the social domain).

Proximity principle Elements that are close together in physical space are grouped to form perceptual units.

Similarity principle Elements that are similar in one or more physical characteristics (e.g., lightness, color, form, size) are grouped to form perceptual units.

Grouping is considered to be a fundamental perceptual ability because it helps to establish coherence in complex visual scenes. It plays a critical role in generating the representations that form the basic processing units in the visual cognition system of adults. It also serves a cognitive simplification function in terms of reducing the number of things that need one's attention. For those wishing to understand the ontogenesis of this ability, the major issue is how during development human observers come to know which elements of a visual scene should be grouped together to form which objects.

Traditional Views on the Development of Perceptual Organization

As described by Donald Hebb in 1949, the perception of a whole object is founded in the perception of the individual features of the object and their integration. In other words, reality is constructed in the same way that homebuilders erect houses, piece by piece. Eye movements are used to generate an internal representation of a visual pattern. By the Hebb view, the emergence of perceptual organization takes considerable developmental time and is dependent on the progression of eye movements that yield more holistic perceptions as visual scanning becomes more systematic with experience. In contrast to Hebb, the original Gestaltists of the 1920s, such as Wolfgang Kohler, Kurt Koffka, and Max Wertheimer, adopted a nativist stance, contending that perceptual organization is automatic and present even in an initial encounter with a visual pattern. This is so because nervous systems are constrained to follow certain grouping principles that lead to the perception of one organization over other organizations that are equally physically possible.

Initial Empirical Efforts and Their Theoretical Implications

Eye Movement Recording

At the time that the Gestaltists were theorizing about the development of perceptual organization, empirical methodologies

were not yet available to investigate the perceptual abilities of infants. However, such methods did become available in the 1960s and 1970s, and one technique in particular provided some initial data on the debate that had been struck between Hebb and the Gestaltists. Specifically, Philip Salapatek devised photographic records of infant eye movements while infants were engaged in visual scanning of simple outline figures. Salapatek reported that there was a developmental trend that took place over the first months of life in which scanning was initially limited to single features and gradually expanded to include a set of features and eventually the whole pattern. These eye movement data, considered by themselves, are consistent with a Hebbian account of the development of perceptual organization, although one can question how direct a relation there is between fixation and the window of attention that surrounds the fixation point. That is, if attention is distributed broadly about the fixation point, then it is possible that an infant that fixates the lower right corner of an outline of a triangle form is actually processing information across the entire portion of the visual field that encompasses the whole pattern.

Looking Time Studies

Early behavioral investigations of the development of perceptual organization were able to capitalize on the finding that infants prefer to look at novel stimuli. This preference enabled researchers to develop a procedure whereby infants are familiarized with one stimulus and then presented with the familiar stimulus paired with a novel stimulus. A preference for the novel stimulus (that is not attributable to an a priori preference for that stimulus) implies both memory for the familiar stimulus and the ability to discriminate between it and the novel stimulus. In a classic study that followed this general procedure, one that can be viewed as ushering in the period of modern behavioral work on the development of perceptual organization in infants, Philip Kellman and Elizabeth Spelke in 1983 presented 4-month-old infants with a display consisting of a rod partly occluded by a block.

The question was whether infants represented the continuity of the rod behind the block based on the gestalt properties of the visible portions of the rod, including their good continuation and similarity of shape and color. To ask this question, after familiarization with the rod–box display, infants were presented with a complete rod and a broken rod. The rationale is that if infants represented the continuity of the rod (i.e., if they had grouped the bottom and top portions of the rod based on their gestalt qualities), then they would respond to the complete rod as familiar and the broken rod as novel. However, if the rod fragments were not grouped together, then the broken rod should be perceived as familiar and the complete rod as novel. The finding was that the infants looked equally to the complete and broken rod displays, a null result that was difficult to interpret. A follow-up experiment was conducted that was a replication of the initial experiment, except that the cue of common motion was added to the visible portions of the rod. In this instance, the infants preferred the broken rod test display, a result indicating that the complete rod had been perceived as familiar, implying that the infants had grouped together the bottom and top portions of the rod. Further research by Kellman and Spelke confirmed that it was common motion information alone rather than the combination of common motion, good continuation, and similarity that enabled infants to group the rod.

A similar methodology was used to determine that same-aged infants perceived the continuity of two adjacent objects as long as the object surfaces were contiguous and even when the surfaces were dissimilar in size, shape, and textural markings. The results of these studies led Spelke to propose an account of the development of object perception that was, in some sense, a hybrid model incorporating Gestalt notions of innate organizing principles as well as a role for Hebbian learning based on experience with a structured environment. Specifically, Spelke argued that infants at birth are constrained by two *core* organizational principles: common movement and connected surface. Adherence to these principles would essentially parse from a visual scene those surfaces that move together and maintain their coherence as they move and grant them the status of objects. The object ‘blobs’ that are the output resulting from observance in accord with the core principles can then be tracked over real time. This type of experience, according to Spelke, allows infants to discover that objects also exhibit other properties, including proximity of parts, similarity of surface, and good continuation of contour. In this way, what the Gestaltists had taken to be innate organizing principles are, by the Spelke account, learned through their natural correlation with the common motion and connected surface core principles.

A different take on the looking time findings, one that emphasizes biological determinants of development, was advanced by Kellman. This account includes two processes, including a ‘primitive’ edge insensitive process that is presumed to be operational from birth and that utilizes common motion information, and a maturationally determined ‘rich’ edge sensitive process that becomes available later beginning at around 7 months of age and that responds to good continuation information. Thus, according to Kellman, 4-month-olds failed to utilize continuity to organize the static rod–box display,

because infants that age lack the edge-sensitive organizing mechanism that is necessary to utilize continuity.

Progress on the Classic Grouping Principles

While the Kellman and Spelke rod-polygon studies revealed that common motion was a more potent determinant of grouping in infancy relative to similarity and good continuation in a perceptual display in which the different sources of information were pitted against one another, one can ask whether similarity and good continuation might be functional when not in competition with another principle. Moreover, although the principles of similarity and good continuation were not sufficiently strong to provide a basis for grouping when they were the sole sources for organization in the case of partial occlusion with the rod and box display, it is conceivable that the principles could be functional for displays in which all of the elements are completely visible. In addition, the study of infants responding to the rod–box display investigated only one type of similarity (form), thus leaving unresolved the issue of whether infants might be able to utilize other forms of similarity (e.g., lightness, color, size). Furthermore, one other of the classic Gestalt principles, proximity, was not investigated in the rod–box studies, thereby keeping open the question of its functionality.

To understand how young infants utilize classic Gestalt grouping principles for displays consisting of completely visible elements, investigations have been undertaken to examine how infants respond to arrays of elements that could be organized by one or another principle. An advantage to this approach is that a number of studies assessing use of grouping principles by adults have used such displays, thereby allowing for some level of informed comparison between the two age groups.

Lightness Similarity

An initial study investigated whether 3-month-olds utilize lightness similarity to organize visual pattern information. The familiarization stimuli were columns or rows of squares or diamonds that could be organized only on the basis of the lightness versus darkness of the elements, and the test stimuli were vertical versus horizontal bars (Figure 1). The rationale is that if the organization in the column and row arrays is

Figure 1 Familiarization and test stimuli used to investigate whether infants can organize visual pattern information in accord with luminance similarity.

apprehended, then infants familiarized with columns should prefer the novel horizontal bars during the test and infants familiarized with rows should prefer the novel vertical bars. The findings provided positive evidence for the use of lightness similarity: infants preferred the orientation of bars that was oppositely organized relative to the array of elements presented during familiarization, and a control group of infants presented with just the test stimuli and not the familiarization stimuli did not show a differential preference between the two orientations. An additional control experiment showed that infants could discriminate between arrays differing in the shape of the filled or unfilled elements (square vs. diamond). This latter finding mitigates explanations of the preference for the novel organization based on immature resolution acuity and indicates that the infants were able to perceive the individual elements of the displays and organize them into larger perceptual units (i.e., columns vs. rows) based on lightness similarity.

Good Continuation

A second classic principle investigated in the same line of studies was that of good continuation. Adapting a methodology that had been used to investigate good continuation grouping by adults, infants as young as 3 months of age were administered the experimental procedure depicted in Figure 2. The displays consisted of a line of distractor circular elements and a target element that was either a square or diamond. Infants were familiarized to one pattern and then tested for discrimination between that pattern and a novel one. In the top panel (a), the target element appeared in line (and thus in good continuation) with the distractor elements, whereas in the bottom panel (b), the target element was off line with the distractor elements. The expectation is that if infants perceive the patterns in accord with good continuation, then the change in the target element should be more difficult to detect when the target element is in a good continuation relation with the distractor elements. In other words, if good continuation is

Figure 2 Examples of the familiarization and test stimuli used to investigate whether infants can organize visual pattern information in accord with good continuation. The in-line condition is depicted in panel (a); the off-line condition is shown in panel (b). Experimental design was fully counterbalanced so that for half of the infants in each condition, the target element in the familiar stimulus was a square; for the other half, it was a diamond.

functional, then the target element would be grouped with the distractors, thus making it less likely that a change in its form would be registered. By contrast, in the off-line condition, the target element would not group with the distractors and would retain its status as an independently processed unit of information, thereby increasing the likelihood that a change in its form would be detected. The findings were that infants preferred the novel test stimulus in the off-line condition, but not in the in-line condition. This evidence suggests good continuation as a second organizational principle that is available to young infants for the grouping of visual elements.

Proximity

A third classic grouping principle investigated was that of proximity. Using the same column versus row methodology employed to investigate infant sensitivity to lightness similarity, 3- to 4-month-old infants were presented with arrays of elements that could be organized into columns or rows of elements on the basis of proximity and then tested with horizontal versus vertical bars (Figure 3). Infants preferred the test stimuli with the novel organization, and subsequent control experiments indicated that these preferences could not be attributed to an a priori preference between the test stimuli or to an inability to resolve the elements within the columns and rows. The findings indicate that proximity joins lightness similarity and good continuation as a grouping principle that can be used to organize visual pattern information by young infants.

One may ask at this point in the presentation whether the results of the studies investigating use of lightness similarity, good continuation, and proximity by infants are inconsistent with the findings from the earlier rod-box investigation. The answer is not necessarily, inasmuch as proximity was not studied in the earlier investigation and lightness similarity was the principle at issue in the column-row study, whereas form similarity was the principle examined with the rod-box display. In addition, in the lightness similarity, good continuation, and proximity studies, all of the elements were completely visible, whereas in the rod-box investigation, one object was partly occluded by the other. This last point of comparison is consistent with the possibility that principles such as similarity and good continuation are functional in young infants for displays of completely visible elements, but perhaps not yet operational in cases of partial occlusion. The latter cases are arguably more complex because they not only require infants to connect the

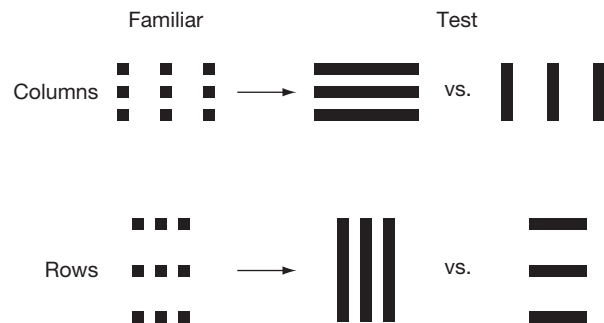

Figure 3 Familiarization and test stimuli used to determine whether infants adhere to proximity when organizing visual patterns.

visible parts of a partially occluded object, but also call upon infants to extract the depth placement of the occluder and the occluding surface. These observations are in turn suggestive of an ontogenetic trajectory in which infants initially deploy organizational principles in simple perceptual contexts and then with development come to utilize them more powerfully and flexibly so that they can be applied to increasingly more intricate perceptual displays of visual pattern information. A similar claim has been made about the ontogenesis of perceptual classification skills, namely, that with development, infants become more skilled at using inherent categorization abilities to represent less well-structured classes of information. A related conclusion has also been reached about how infants develop physical reasoning skills that are initially applied simply and narrowly, but become more sophisticated and more broadly utilized with development.

Progress on New Grouping Principles

While the classic grouping principles have been known to psychologists since the 1920s, the grouping principles that will be examined in this section, uniform connectedness and common region, were introduced by Stephen Palmer and Irvin Rock in the 1990s. Although there have been a number of investigations aimed at understanding how adults use the newer principles to group stimuli, to our knowledge, the studies to be reviewed in this section are the only ones to directly examine whether infants group visual elements in accord with these principles.

Uniform Connectedness

The principle of uniform connectedness (UC) refers to the visual system's tendency to group together elements that are connected and has been suggested to be the most fundamental principle of perceptual grouping. It has been argued that UC is needed to even determine that each local element in a configuration is itself a local entity. By this view, UC defines the 'entry level' units that are then grouped according to various organizing principles, such as proximity and similarity. To examine whether sensitivity to UC is functional in early infancy, as shown in Figure 4, infants as young as 3 months of age were habituated to the uniformly connected patterns shown in Panels A or B, and then administered a preference test pairing connected elements with disconnected elements. The rationale is that if the infants organized the habituation patterns on the basis of UC, then they should respond to the connected-element test stimulus as familiar and display a novelty preference for the disconnected-element test stimulus. This is the result that was observed, and a control condition showed that there was no a priori preference between the test stimuli. These findings indicate that infants by 3 months of age are sensitive to UC as an organizing principle. Notably, if the operation of UC allows for the delineation of entry-level units that can then be organized into holistic percepts according to other classic grouping principles such as proximity and similarity, then the infant results imply that 3-month-olds are able to use UC to identify the entry-level units that are then subject to further perceptual organization.

Habituation

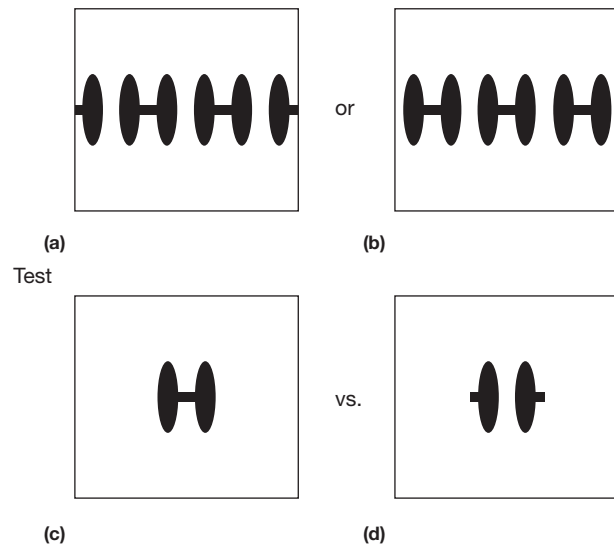

Figure 4 Stimuli used to test whether infants adhere to uniform connectedness when organizing visual patterns. Infants in the habituation conditions were habituated to the uniformly connected patterns in panel (a) or (b) and tested with the patterns in panels (c) and (d). Infants in the no-habituation condition were tested with the patterns in panels (c) and (d) without prior exposure to the patterns in panels (a) and (b).

Common Region

The second newer grouping principle investigated is that of common region. This principle proposes that elements within a region are grouped together and are separated from those in other regions. Grouping on the basis of common region is believed to help organize texture elements within a contour as going with each other and as belonging to the surface or object that is bounded by the contour. It has also been suggested that common region might be a different kind of organizational cue than classic Gestalt cues, because here the organization is driven by a characteristic that is external to the elements themselves. That is, the 'common region' quality that engenders grouping of the elements is not inherent in the elements. In contrast, other grouping principles such as similarity are based on the intrinsic characteristics of the to-be-grouped elements. One can thus differentiate between 'extrinsic' versus 'intrinsic' organizational cues, with common region conceptualized as an extrinsic cue. This distinction raises the possibility that common region could be a different kind of organizational cue than others, thereby adding to the importance of understanding its emergence in young infants to see if it is somehow unique.

To investigate whether young infants could use common region to organize visual pattern information, 3- to 4-month-olds were familiarized to images with two pairs of shapes, with one pair (say A and B) always located together in one region and the other pair (say C and D) located together in another region (see Figure 5). The actual location of the individual shapes changed from one trial to the next, but the shapes A and B always shared one region, while the shapes C and D shared another region. Infants were then tested for their preference between a *within-region* grouping (e.g., AB) versus a *between-region* grouping

Figure 5 Illustrations of the stimuli used to examine organization based on common region.

(e.g., BC; [Figure 5](#)). The stimulus patterns presented to the infants were such that the physical distance between A and B and between B and C was always the same. In other words, the only difference in the relationships between A and B versus B and C was that the former pair always shared the same region while the latter pair contained shapes from different regions. If the principle of common region is operational in infancy, then the infants should find the *within-region* grouping to be familiar and the *between-region* grouping to be novel, and discriminate between these patterns during the test.

It should be noted that the common region task is a demanding one in that it asks if grouping will carry over to novel regions, given that infants were habituated to vertical regions during habituation and tested with novel horizontal regions. That is, this experiment gets at the following question: When elements that were previously grouped based on a set of regions are subsequently encountered in novel regional configurations, does the visual system expect this grouping to be intact? If grouping and perceptual organization are to be functionally advantageous, they need to allow the world to be organized into meaningful entities that transcend particular situations. For instance, if a perceiver were to be exposed to two standing humans and associated the individual faces to the individual bodies, then, for this organization to be functional, the perceiver should expect the same grouping to prevail if the humans were now lying down.

The major result from the common region study was that the infants discriminated between the grouping of elements from different regions from the grouping of elements that had shared a common region during habituation. This result indicates that the infants organized information based on common region. The finding that infants are sensitive to

common region suggests that the extrinsic nature of this cue did not preclude its role as an organizing factor in infancy. In other words, infants, like adults, are not solely dependent upon the intrinsic nature of elements to organize them; they are able to use extrinsic factors such as common region to organize.

Progress on the Special Case of Form Similarity

Although the proposals of Spelke and Kellman suggested that important cues for grouping and perceptual unit formation were not available to young infants, the results reviewed have provided evidence that infants as young as 3 months of age can use a variety of static grouping principles, both classic and modern ones, to organize visual pattern information. In particular, the findings indicate that the principles of lightness similarity, proximity, good continuation, uniform connectedness, and common region are functional in at least some perceptual contexts. These data suggest that some level of revision is in order with regard to thinking about the sources of information available to younger infants for perceptual grouping. However, form information and its relative lack of availability as an organizing cue to younger infants were central to the proposals of Spelke and Kellman. It therefore becomes important to ask whether form similarity can serve as a perceptual grouping principle for young infants.

Development of Form Similarity: An Age Difference in Performance

The functionality of form similarity in young infants was examined in a study in which 3- to 4-month-olds were familiarized with columns or rows of Xs versus Os, and then tested with vertical versus horizontal bars ([Figure 6](#)). Infants failed to display a preference. A control experiment showed that infants were capable of discriminating between the familiar arrays shown in [Figure 6](#) and arrays that consisted entirely of Xs or Os. This latter result indicates that the failure of the infants to use form similarity was not due to an inability to discriminate between the constituent X and O shapes. The outcomes suggest that young infants failed to group on the basis of form similarity. The same failure to group was observed even when Hs versus Is and squares versus diamonds were used in the place of Xs versus Os.

With the data thus far described failing to turn up support for young infants' use of form similarity, an older age group of infants, 6–7-month-olds, were tested on the same X-O elements → bars task ([Figure 6](#)). This older age group responded by preferring the novel stimulus organization. The combined findings from the two age groups indicate that 6–7-month-olds, but not 3–4-month-olds, can organize visual patterns in accord with form similarity. Given that younger infants are sensitive to a number of other organizational cues, the failure to organize based on form similarity suggests that different Gestalt principles may become functional over different time courses of development. The outcomes are consistent, in particular, with the hypothesized age of onset for Kellman's edge-sensitive process, and also with Spelke's proposal that some Gestalt principles may be learned in a constructivist framework, rather than automatically deployed as conceived by the original Gestaltists. The data are additionally consistent

Figure 6 Familiarization and test stimuli that examined whether infants can organize visual pattern information in accord with shape similarity.

with evidence indicating that adults have independent luminance- and edge-based grouping mechanisms. They are further in accord with the finding that some visual agnostics (i.e., individuals with impaired ability to recognize objects usually associated with brain injury or neurological illness) show intact lightness similarity grouping, but impaired shape configuring ability, and the result that individuals with Williams Syndrome show superior lightness similarity grouping abilities relative to those for form similarity. However, as the next section reveals, young infants' inability to use form information to organize visual images is not absolute.

Development of Form Similarity: Maturation or Experience?

Given the results showing a later development of form similarity, the next question to ask was whether this development was driven by maturation or learning. To address this question, one may reason that if form similarity is under experiential control, then it might be possible to provide younger infants with experience that will allow them to organize visual pattern information in accord with form similarity. Alternatively, if infants' use of form similarity is maturationally determined, then experience would not be expected to bring about form similarity functionality. To this end, one can examine whether variation in the patterns used to depict rows or columns during familiarization enhances infants' performance in the form similarity task. With this manipulation, it is possible that the pattern variation will facilitate performance because the invariant organization of the stimuli will be more easily detected against a changing background. In other words, variation may provide infants with the opportunity to form concepts of 'rows' or 'columns.' To investigate this possibility, the elements → bars generalization version of the form similarity organization task that had previously produced null results (when each of the three different form contrasts was presented individually) was administered, but in this instance, with each of the three form contrasts presented during a single familiarization session (Figure 7). The younger infants now preferred the novel organization of bars. This striking result suggests that 3–4-month-olds are capable of using form similarity to organize elements if they are provided with varied examples with which to abstract the invariant arrangement of the pattern.

Further evidence of the role of learning in infants' use of form similarity was obtained in a study which examined whether an already functional luminance cue system can be

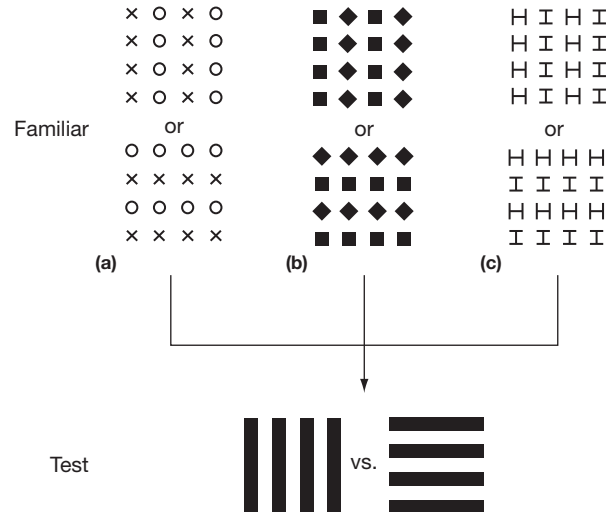

Figure 7 Familiarization and test stimuli used to investigate whether infants can use shape similarity to organize visual patterns if exposed to variable shapes during familiarization. Infants in the single pair condition were familiarized to one of the pairs shown in panels (a)–(c), that is, X-O, square-diamond, or H-I, whereas those in the variable condition were familiarized to all three pairs.

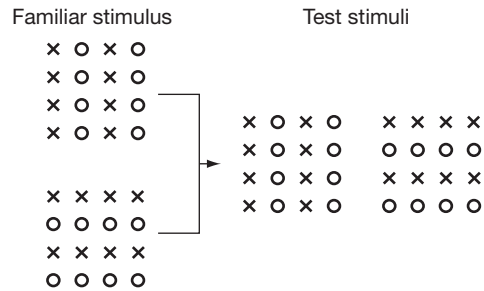

used to scaffold infants' use of form similarity cues. One group of infants was tested on a form-form task in which they were familiarized to columns/rows of Xs and Os and then tested with rows/columns of X and O shapes. Another group, the luminance-form group, was familiarized to columns/rows of dark and light squares and then tested with X and O shapes organized as columns/rows (Figure 8). As expected, the form-form group failed to exhibit evidence of organization, indicating again that 3–4-month-olds ordinarily do not organize using form similarity. However, the luminance-form group did exhibit systematic novelty preference during the test. These results indicate that infants were able to organize using form similarity during the test, provided they were initially able to generate the global gestalts during familiarization using a more readily available system, namely, the luminance similarity system. This work demonstrates that new organizational principles can be learned via bootstrapping onto already functioning organizational principles.

These results are theoretically significant because they demonstrate that the ability to use the form similarity principle does not have to wait until 6–7 months: even younger infants organize using this cue if exposed to variable stimuli or if an already functional organizing principle can scaffold their performance. The evidence is more consistent with the view that learning plays a role in acquiring some aspects of perceptual organization.

Progress on Understanding the Deployment of Lightness and Form Similarity: Automatic Versus Constructivist Grouping

The article has thus far documented a developmental difference in the use of lightness and form similarity and has also raised the possibility that grouping by form similarity may

Shape → Shape

Luminance → Shape

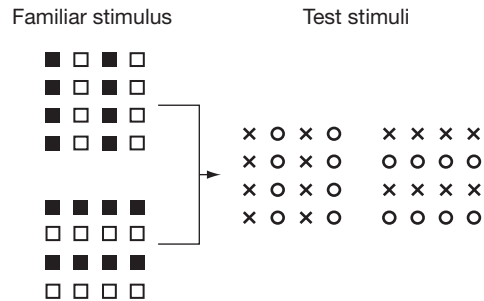

Figure 8 Illustrations of the shape → shape and luminance → shape tasks presented to infants to examine whether infants will learn to use shape cues to organize if presented in the context of organization based on luminance cues.

occur because of learning taking place via the perceptual experience that accrues during the time course of familiarization. These observations motivated an inquiry into the question of how readily the principles of lightness and form similarity may be deployed. The column versus row methodology was used once more, except that in this instance, a condition requiring infants to generalize from elements to bars was compared with a condition requiring infants to generalize from bars to elements. That is, one group of infants was familiarized with columns or rows of elements and preference tested with vertical versus horizontal bars (see Figures 1 and 6), whereas the comparison group tested on the same grouping principle was familiarized with vertical or horizontal bars and preference tested with columns or rows of elements (Figures 9 and 10). It is important to mention that in both the lightness and form similarity studies, the familiar stimulus was presented for six 15-s familiarization trials, whereas the test stimuli were presented for two 10-s test trials. The test trials were deliberately kept to few in number and to a short duration to capture a burst of differential responsiveness toward the novel versus familiar stimulus. If there were more test trials or they were made longer in duration, any initial advantage in responsiveness to the novel stimulus could conceivably begin to subside because that stimulus is now becoming familiar. The rationale behind comparing performance in the elements → bars versus bars → elements versions of the perceptual organization task is that if the Gestalt process that infants use to group by similarity is deployed readily, with the consequence that organization is rapidly apprehended, then one would not expect the nature of the switch from familiarization to test stimuli to affect

Familiar stimulus

Test stimuli

Figure 9 Illustration of the bars → elements version of the lightness similarity perceptual organization task.

Familiar stimulus

Test stimuli

Figure 10 Illustration of the bars → elements version of the shape similarity perceptual organization task.

performance. If, however, Gestalt grouping by similarity occurs less readily, because of learning taking place during the time course of familiarization, then one might expect infants in the bars → elements condition to outperform infants in the bars → bars condition because of the reduced study time available to process the column versus row stimuli in the bars → elements condition.

The results for lightness similarity were that the novel organization was preferred, irrespective of whether infants were familiarized with elements and tested with bars or familiarized with bars and tested with elements. These findings suggest that perceptual organization that occurs via grouping by lightness similarity is readily apprehended. In contrast, in the case of form similarity, the novel organization was preferred only in the elements → bars version of the task. Infants in the bars → elements version of the task did not exhibit a preference between the test stimuli. The results indicate that grouping by form similarity was adversely affected by the switch in familiarization and test stimuli, which in turn implies that grouping via form similarity occurs less readily than grouping by lightness similarity.

The difference in performance on the elements → bars and bars → elements tasks imply that lightness and form similarity grouping processes differ qualitatively. That is, lightness similarity grouping processes may be deployed rapidly because they are hardwired, a suggestion that receives support from a report that even newborns may be capable of organizing visual patterns via lightness similarity. In this view, perceptual organization would be perceived immediately upon presentation

with a column or row pattern of light versus dark elements. By contrast, form similarity grouping processes may be learned from perceptual experience. In this account, perceptual organization would be constructed during the course of the familiarization trials. To these observations, one can add the finding that young infants perform successfully in bars → elements and elements → bars versions of the proximity organization task. These latter findings suggest that perceptual organization that occurs via grouping by proximity is also readily apprehended. Grouping by proximity thus appears to be more similar to grouping by lightness similarity than grouping by form similarity.

Theoretical Progress

The developmental research highlighted in this article reflects an effort to investigate the origins and development of perceptual unit formation during infancy. The data suggest that different organizational principles may become functional over different time courses of development, may be governed by different developmental determinants, that is, maturation versus experience, and that not all principles are readily deployed in the manner originally proposed by Gestalt theorists.

An Orthogenic Perspective

The findings reviewed are consistent with investigations of perceptual grouping in adults that have adopted a microgenetic approach and examined the time course of development of a particular percept. The outcomes of the adult investigations suggest that different grouping principles are differentially powerful or operational at different times in the overall course of processing. In particular, some forms of perceptual organization occur early in the time course of processing and do not require attention, whereas other forms of perceptual organization occur later in the time course of processing and require attention. This work has led to a newly emerging view that perceptual organization is not a monolithic phenomenon, but rather represents a confluence of multiple processes. The findings that lightness similarity and proximity emerge more readily than form similarity during early development (i.e., in younger infants with just a single example pattern and limited presentation time) suggest a correspondence between what is observed ontogenetically in infants and microgenetically in adults. This correspondence is more generally supportive of an orthogenic approach to understanding perceptual organization, one which emphasizes that mechanisms underlying performance become most transparent as they are revealed in the processes of change at different time scales.

Abstract Units

Two of the findings described so far are also noteworthy because they hint that perceptual organizing processes can produce units of processing that have an abstract nature. In the demonstration that proximity is readily apprehended, which was documented by successful performance in the bars → elements version of the proximity grouping task, the generalization from the bars to the familiar organization of elements was

accomplished even though the physical dimensions of the bar stimuli were different from those of the element stimuli. These results suggest that the units that arise as a consequence of grouping have an abstract quality in terms of their transfer. The findings on the flexible nature of proximity grouping are consistent with those reported for grouping by common region by infants where it was shown that elements that grouped in one region were also expected to appear together in a differently shaped region. Both sets of outcomes are further consistent with the finding that infants generalize from elements to bars on the basis of form similarity, but only when provided with multiple form contrasts depicting a column- or row-like organization. All three studies suggest that the emergent features formed from deployment of perceptual organizational principles are conceptual-like in terms of their generalizability.

A Top-Down Contribution

The studies reviewed in the article are consistent with the idea that there may be a multiplicity of cues available for perceptual unit formation by infants. Some of these cues, like those emphasized in this article (e.g., lightness similarity, good continuation, proximity), may be characterized as bottom-up. Other cues, such as knowledge of particular objects and object kinds, reflect experiential information, and may be thought of as top-down.

What are the relative contributions of bottom-up perceptual process and top-down knowledge access in perceptual organization? One current model posits that humans possess a flexible system of perceptual unit formation, one in which the features that come to define objects are extracted during the task of concept learning. The idea is that an individual's history of concept formation (i.e., the concepts possessed by an individual at a specific point in time) will affect his or her subsequent perceptual organization processes.

Investigations have been undertaken to determine whether the proposed interplay between adherence to Gestalt organizational principles and flexible feature creation would be manifested in young infants. The specific question asked was whether features that are specified as coherent by Gestalt principles are 'overlooked' by young infants if alternative means of perceptual organization are 'suggested' by presenting the infants with a category of objects in which the features uniting the objects are 'nonnatural' in the Gestalt sense. In the first experiment, 3- and 4-month-olds were familiarized with a number of complex figures, examples of which are shown in the top portion of [Figure 11](#). Subsequently, during a novelty preference test, the infants were presented with the pacman shape paired with the circle shown in the bottom portion of [Figure 11](#). The infants were found to recognize the circle as familiar as evidenced by their novelty preference for the pacman shape. This finding suggests that the infants had parsed the circle from the complex figures in accord with good continuation.

Follow-up experiments investigated whether an invariant part abstracted during category learning would interfere with perceptual organization achieved by adherence to good continuation. The experiments consisted of two parts. In Part 1, the infants were familiarized with multiple exemplars, each marked by an invariant pacman shape, and were subsequently administered a novelty preference test that paired the pacman

Figure 11 Illustration of the stimuli used to examine whether infants parse the circle shape in accord with the principle of good continuation.

Figure 12 Illustration of the stimuli used to investigate whether exposing infants to novel features (Pac-man shape) causes them to parse images (shown in Figure 11) in novel ways.

shape with the circle shape (Figure 12). The pacman shape was recognized as familiar, as evidenced by a preference for the circle shape. Part 2 of the procedure was then administered and it simply followed the design of Experiment 1 (Figure 11).

The expectation is that if the category learning from Part 1 of the procedure, in particular, the representation of the invariant pacman shape, can interfere with the Gestalt-based perceptual organization that was observed in Experiment 1, then the preference for the pacman shape that was observed in Experiment 1 should no longer be observed. In fact, if the representation of the pacman shape carries over from Part 1 to Part 2 of the procedure, one would expect the opposite result, that is, the infants should continue to prefer the circle. The latter result is what was observed and it suggests that perceptual units formed during category learning can be (1) entered into a perceptual system's working 'featural' vocabulary and (2) available to subsequent object recognition processes. The bias set by the Gestalt principle of good continuation might thus be thought of as soft-wired in the sense that it is subject to interference. More generally, an individual's history of categorization will affect his or her subsequent object parsing.

Future Studies

The research described in this article indicates that the infant's perceptual world is systematically organized based on both general Gestalt rules and on specific personal experiences. However, much remains unknown about how perceptual organization develops. The complexity of the real world implies that Gestalt cues and experiences sometimes work in concert and other times in opposition; how infants at different ages deal with the organizational challenges under such diverse conditions needs to be understood. A comprehensive account of the development of perceptual organization thus has to include the relations between bottom-up rule-based organization and top-down experience-based organization. This will require a systematic analysis of the roles of different kinds of experience on perceptual organization in infancy and an understanding of how these experiences interact with bottom-up processes at different ages. More generally, the separate and interactive roles of experience and maturation have to be studied further in order to understand how the infant perceptual system develops into the adult system.

Glossary

Aphasia Any disorder of speech resulting from brain damage.

Appeasement gestures Behavioral displays (e.g., making yourself smaller) that typically inhibit aggression from others.

Emblems Nonverbal acts which have a direct verbal translation such as nodding the head when meaning 'yes' or shaking the head when meaning 'no'.

Illustrators Movements directly tied to speech, which amplify and elaborate the verbal content of the message.

Manual gesture Communication through the hands and arms.

Microanalysis Study of interpersonal communication through the detailed analysis of video or audio recordings.

Phonemic clause A group of words, averaging five in length, in which there is only one primary (or tonic) stress indicated by changes in pitch, rhythm or loudness. It is terminated by a juncture, where these changes in pitch, rhythm and loudness level off before the beginning of the next phonemic clause.

Regulators Movements that guide and control the flow of conversation, influencing both: who is to speak and how much is said.

Syntax Study of the rules whereby words or other elements of sentence structure are combined to form grammatical sentences

Introduction

The study of gesture can be traced back to classical antiquity. In ancient Rome, both Cicero and Quintilian wrote treatises on rhetoric, which included a number of observations on the use of the hands in oratory. For Quintilian, the term 'gestus' referred not only to actions of the hands and arms, but also to movements of the rest of the body. This use of the term carries through to the modern day: gesture may refer not only to movements of the hands and arms (manual gesture), but also to communication through other parts of the body (the head, trunk, legs and feet). However, the section in which Quintilian deals with manual gesture is by far the lengthiest, and this is also true of contemporary research. It should be noted that gesture as a form of movement is conventionally distinguished from posture, which refers to static positions.

In the seventeenth century, the study of gesture acquired the status of a subject in its own right. Of particular importance were Giovanni Bonifacio's *L'Arte dei Cenni* (published in Vicenza Italy in 1616) and John Bulwer's two volumes: *Chirologia: or the Naturell Language of the Hand*, and *Chironomia: or the Art of Manual Rhetoricke*. Bulwer's two volumes were published in England in 1644. They were the first works written in English to be exclusively concerned with gesture, with what Bulwer called "the naturell language of the Hand, as it had the happiness to escape the curse at the Confusion of Babel." *Chirologia* comprised a descriptive glossary of 64 gestures of the hand and 25 gestures of the fingers. *Chironomia* was a prescriptive guide to the proper usage of an additional 81 gestures during well-delivered discourse, as well as cautions against the improper use of 'manual rhetoricke.'

In the modern era, the scientific study of gesture has only become possible with the development of sophisticated recording apparatus; most contemporary studies of gesture

have used either film or videotape as the main technique of observation. Such recordings allow the researcher the opportunity for repeated viewing, which is of course not possible with 'live' observation. Repeated viewing can be particularly important with complex sequences of movement; these can be replayed time and again, if necessary, in slow motion. In this context, the role of the video recorder has been likened to that of the microscope in the biological sciences. Through the detailed 'micro' analysis of video recordings, behavior can be repeatedly examined and dissected in the finest detail, such that interpersonal communication has become an object of study in its own right.

However, microanalysis did not develop simply as a consequence of innovations in technology. The extensive use of film and video technology in the study of social interaction has only really developed in the past few decades. Its predominance reflects not only a distinctive methodological approach, but also a fundamental change in the way in which we think about interpersonal communication. In particular, it reflects a belief in the value of studying the fine details of social interaction, and a belief in their social significance.

Recent microanalytic studies of gesture have been focussed primarily on its relationship to speech. This contrasts strikingly with the notion of nonverbal communication as 'body language,' regarded by its adherents as a more trustworthy alternative to speech. One particular danger of the body language approach is its neglect of the close interrelatedness between speech and nonverbal behavior. Indeed, it may well be the case that conflicts between nonverbal behavior and speech are the exception rather than the rule. On the other hand, an exclusive focus on the relationship between gesture and speech runs the risk of neglecting the role of gesture in communicating emotions and interpersonal attitudes. For example, in one recent major book on gesture, no attention is paid whatsoever to the

topic of emotion. As far as this book is concerned, the topic does not exist, the word 'emotion' does not even appear in the index.

In this article, both topics are discussed. The first section is focussed on gesture and speech, the second on emotions and interpersonal attitudes; in the final section, the role of gesture in interpersonal communication is discussed.

Gesture and Speech

The Synchronization of Body Movement

Frame-by-frame analysis of film has shown how the body of the speaker moves closely in time with his speech, a phenomenon which is referred to as self synchrony. These observations have not been confined simply to hand gestures; it is movements of all parts of the body that are believed to be closely synchronized with speech.

It has also been claimed that body movements are closely synchronized between conversationalists, sometimes termed interactional synchrony. Not only has it been said that "the body of the speaker dances in time with his speech," but also that "the body of the listener dances in rhythm with that of the speaker." Indeed, it has been claimed that interactional synchrony is a fundamental, universal characteristic of human communication, providing constant feedback from the listener to the speaker concerning the listener's level of attention and interest. These claims were based on detailed frame-by-frame analysis of filmed conversations. They were subsequently criticized by other researchers, who found that body movement coordination between the participants in a group conversation did not significantly exceed that which might have been expected by chance alone. Thus, the concept of interactional synchrony is very much open to dispute.

There is much more evidence for self synchrony, although it is not the case that every bodily movement is related to discourse. In a study of psychotherapy sessions, it was only non-contact hand movements (these do not involve touching the body) which were judged as related to speech; contact hand movements were considered for the most part to be unrelated to speech. In a study of political speeches, a close relationship was also found only between noncontact hand movements and vocal stress. Thus, for the most part, it seems that contact movements serve different functions from noncontact gestures. This view is further supported by a study which found that non-signaling movements (e.g., stroking oneself) were used significantly more by high anxious patients, while low anxious patients made significantly greater use of signaling movements (e.g., pointing). Self-touching movements are often used not for communication but for grooming, so that under conditions of high anxiety they may be used as a means of self-reassurance.
